# Proceedings of the 2017 Federated Conference on Computer Science and Information Systems

September 3–6, 2017. Prague, Czech Republic

Maria Ganzha, Leszek Maciaszek, Marcin Paprzycki (eds.)

# Annals of Computer Science and Information Systems, Volume 11

## Series editors:

Maria Ganzha,

*Systems Research Institute Polish Academy of Sciences and Warsaw University of Technology, Poland*

Leszek Maciaszek,

*Wrocław University of Economy, Poland and Macquarie University, Australia*

Marcin Paprzycki,

*Systems Research Institute Polish Academy of Sciences and Management Academy, Poland*

## Senior Editorial Board:

Wil van der Aalst,

*Department of Mathematics & Computer Science, Technische Universiteit Eindhoven (TU/e), Eindhoven, Netherlands*

Frederik Ahlemann,

*University of Duisburg-Essen, Germany*

Marco Aiello,

*Faculty of Mathematics and Natural Sciences, Distributed Systems, University of Groningen, Groningen, Netherlands*

Mohammed Atiquzzaman,

*School of Computer Science, University of Oklahoma, Norman, USA*

Barrett Bryant,

*Department of Computer Science and Engineering, University of North Texas, Denton, USA*

Ana Fred,

*Department of Electrical and Computer Engineering, Instituto Superior Técnico (IST—Technical University of Lisbon), Lisbon, Portugal*

Janusz Górski,

*Department of Software Engineering, Gdansk University of Technology, Gdansk, Poland*

Mike Hinchey,

*Lero—the Irish Software Engineering Research Centre, University of Limerick, Ireland*

Janusz Kacprzyk,

*Systems Research Institute, Polish Academy of Sciences, Warsaw, Poland*

Irwin King,

*The Chinese University of Hong Kong, Hong Kong*

Juliusz L. Kulikowski,

*Nalecz Institute of Biocybernetics and Biomedical Engineering, Polish Academy of Sciences, Warsaw, Poland*

Michael Luck,

*Department of Informatics, King's College London, London, United Kingdom*

Jan Madey,

*Faculty of Mathematics, Informatics and Mechanics at the University of Warsaw, Poland*

Stan Matwin,

*Dalhousie University, University of Ottawa, Canada and Institute of Computer Science, Polish Academy of Science, Poland*

Michael Segal,

*Ben-Gurion University of the Negev, Israel*

Andrzej Skowron,

*Faculty of Mathematics, Informatics and Mechanics at the University of Warsaw, Poland*

John F. Sowa,

*VivoMind Research, LLC, USA*

**Editorial Associate:**

Katarzyna Wasielewska,

*Systems Research Institute Polish Academy of Sciences, Poland*

Paweł Sitek,

*Kielce University of Technology, Kielce, Poland*

**T<sub>E</sub>Xnical editor:** Aleksander Denisiuk,

*University of Warmia and Mazury in Olsztyn, Poland*

**D**EAR Reader, it is our pleasure to present to you Proceedings of the 2017 Federated Conference on Computer Science and Information Systems (FedCSIS), which took place, for the first time outside of Poland, in Prague, Czech Republic, on September 3-6, 2017.

FedCSIS 2017 was Chaired by prof. Pavel Tvrdik, while prof. Jan Janousek acted as the Chair of the Organizing Committee. This year, FedCSIS was organized by the Polish Information Processing Society (Mazovia Chapter), IEEE Poland Section Computer Society Chapter, Systems Research Institute Polish Academy of Sciences, Warsaw University of Technology, Wrocław University of Economics, and Czech Technical University in Prague.

FedCSIS 2017 was technically co-sponsored by: IEEE Region 8, IEEE Czechoslovakia Section, IEEE Poland Section, IEEE Computer Society, IEEE Computer Society Technical Committee on Intelligent Informatics, IEEE Czechoslovakia Section Computer Society Chapter, IEEE Poland Section Gdańsk Computer Society Chapter Poland, SMC Technical Committee on Computational Collective Intelligence, IEEE Poland Section Systems, Man, and Cybernetics Society Chapter, IEEE Poland Section Control System Society Chapter, IEEE Poland Section Computational Intelligence Society Chapter, ACM Special Interest Group on Applied Computing, Łódź ACM Chapter, International Federation for Information Processing, Committee of Computer Science of the Polish Academy of Sciences, Polish Operational and Systems Research Society, Mazovia Cluster ICT Poland, Polski Klaster Badań i Rozwoju Internetu Rzeczy, and Eastern Cluster ICT Poland. FedCSIS 2017 was sponsored by Intel, Profinit and Abra.

FedCSIS 2017 consisted of the following events (conferences, symposia, workshops, special sessions). These events were grouped into FedCSIS conference areas, of various degree of integration. Specifically, those listed without indication of the year 2017 signify "abstract areas" with no direct paper submissions to them (but with submissions to their enclosed events).

- **AAIA'17 – 12<sup>th</sup> International Symposium Advances in Artificial Intelligence and Applications**
  - AIMA'17 – 7<sup>th</sup> International Workshop on Artificial Intelligence in Medical Applications
  - AIRIM'17 – 2<sup>nd</sup> International Workshop on AI aspects of Reasoning, Information, and Memory
  - ASIR'17 – 7<sup>th</sup> International Workshop on Advances in Semantic Information Retrieval
  - JAWS'17 – 11<sup>th</sup> Joint Agent-oriented Workshops in Synergy
  - LTA'17 – 2<sup>st</sup> International Workshop on Language Technologies and Applications
  - WCO'17 – 10<sup>th</sup> International Workshop on Computational Optimization
- **CSS - Computer Science & Systems**
  - CANA'17 – 10<sup>th</sup> Computer Aspects of Numerical Algorithms
  - C&SS'17 – 4<sup>th</sup> International Conference on Cryptography and Security Systems

- CPORA'17 – 2<sup>nd</sup> Workshop on Constraint Programming and Operation Research Applications
- MMAP'17 – 10<sup>th</sup> International Symposium on Multimedia Applications and Processing
- WAPL'17 – 6<sup>th</sup> Workshop on Advances in Programming Languages
- WSC'17 – 9<sup>th</sup> Workshop on Scalable Computing
- **iNetSApp – International Conference on Innovative Network Systems and Applications**
  - INSERT'17 – 1<sup>st</sup> International Conference on Security, Privacy, and Trust
  - IoT-ECAW'17 – 1<sup>st</sup> Workshop on Internet of Things – Enablers, Challenges and Applications
  - WSN'17 – 6<sup>th</sup> International Conference on Wireless Sensor Networks
- **IT4MBS – Information Technology for Management, Business & Society**
  - AITM'17 – 15<sup>th</sup> Conference on Advanced Information Technologies for Management
  - ISM'17 – 12<sup>th</sup> Conference on Information Systems Management
  - IT4L'17 – 5<sup>th</sup> Workshop on Information Technologies for Logistics
  - KAM'17 – 23<sup>rd</sup> Conference on Knowledge Acquisition and Management
- **SSD&A – Software Systems Development & Applications**
  - IWCPS'17 – 4<sup>th</sup> International Workshop on Cyber-Physical Systems
  - LASD'17 – 1<sup>st</sup> International Conference on Lean and Agile Software Development
  - MIDI'17 – 4<sup>th</sup> Conference on Multimedia, Interaction, Design and Innovation
  - SEW-37 – The 37<sup>th</sup> IEEE Software Engineering Workshop
- **DS-RAIT'17 – 4<sup>th</sup> Doctoral Symposium on Recent Advances in Information Technology**

The 2017 edition of an AAIA'17 Data Mining Challenge, focused on "Helping AI to Play Hearthstone". Its results constitute a separate section in these proceedings. Awards for the winners of the contest were sponsored by: Silver Bullet Solutions and the Mazovia Chapter of the Polish Information Processing Society. Papers resulting from the competition constitute a separate section of these Proceedings.

Each paper, found in this volume, was refereed by at least two referees and the acceptance rate of regular full papers was ~19.3% (96 papers out of 497 general submissions).

The program of FedCSIS required a dedicated effort of many people. Each event constituting FedCSIS had its own Organizing and Program Committee. We would like to express our warmest gratitude to all Committee members for

their hard work in attracting and later refereeing 497 submissions (regular and data mining).

We thank the authors of papers for their great contribution to research and practice in computing and information systems. We thank the invited speakers for sharing their knowledge and wisdom with the participants. Finally, we thank all those responsible for staging the conference in Prague. Organizing a conference of this scope and level could only be achieved by the collaborative effort of a highly capable team taking charge of such matters as conference registration system, finances, the venue, social events, catering, handling all sorts of individual requests from the authors, preparing the conference rooms, etc.

We hope you had an inspiring conference and an unforgettable stay in the beautiful city of Prague. We hope to meet you again for FedCSIS 2018 in Poznań, Poland.

***Co-Chairs of the FedCSIS Conference Series***

TABLE OF CONTENTS

---

---

CONFERENCE KEYNOTE PAPERS

---

<b>Formal Definition of a General Ontology Pattern Language using a Graph Grammar</b>	<b>1</b>
<i>Eduardo Zambon, Giancarlo Guizzardi</i>	
<b>Application of mean-variance mapping optimization for parameter identification in real-time digital simulation</b>	<b>11</b>
<i>Abdulrasaq Gbadamosi, José L. Rueda, Da Wang, Peter Palensky</i>	

---

**12<sup>TH</sup> INTERNATIONAL SYMPOSIUM ADVANCES IN ARTIFICIAL INTELLIGENCE AND APPLICATIONS**

---

<b>Call For Papers</b>	<b>17</b>
<b>Top k Recommendations using Contextual Conditional Preferences Model</b>	<b>19</b>
<i>Aleksandra Karpus, Tommaso di Noia, Krzysztof Goczyła</i>	
<b>On the Use of Nature Inspired Metaheuristic in Computer Game</b>	<b>29</b>
<i>Piotr Andrzej Kowalski, Szymon Łukasik, Małgorzata Charytanowicz, Piotr Kulczycki</i>	
<b>Determining the significance of features with the use of Sobol' method in probabilistic neural network classification tasks</b>	<b>39</b>
<i>Piotr Andrzej Kowalski, Maciej Kusy</i>	
<b>Detection and Dimension of Moving Objects Using Single Camera Applied to the Round Timber Measurement</b>	<b>49</b>
<i>Artem Kruglov, Yuriy Chiryshv, Anastasia Atamanova, Svetlana Zavada</i>	
<b>Bindier Operators in Type-Theory of Algorithms for Algorithmic Binding of Functional Neuro-Receptors</b>	<b>57</b>
<i>Roussanka Loukanova</i>	
<b>Towards Real-time Motion Estimation in High-Definition Video Based on Points of Interest</b>	<b>67</b>
<i>Petr Pulc, Martin Holeňa</i>	
<b>Data Clustering with Grasshopper Optimization Algorithm</b>	<b>71</b>
<i>Szymon Łukasik, Piotr Andrzej Kowalski, Małgorzata Charytanowicz, Piotr Kulczycki</i>	
<b>Co-Evolutionary Algorithm solving Multi-Skill Resource-Constrained Project Scheduling Problem</b>	<b>75</b>
<i>Paweł B. Myszkowski, Maciej Laszczyk, Dawid Kalinowski</i>	
<b>Efficient selection operators in NSGA-II for Solving Bi-Objective Multi-Skill Resource-Constrained Project Scheduling Problem</b>	<b>83</b>
<i>Paweł B. Myszkowski, Maciej Laszczyk, Joanna Lichodij</i>	

<b>Hybrid Multievolutionary System to Solve Function Optimization Problems</b> <i>Krzysztof Pytel</i>	<b>87</b>
<b>Utilizing Multimedia Ontologies in Video Scene Interpretation via Information Fusion and Automated Reasoning</b> <i>Leslie F. Sikos</i>	<b>91</b>
<b>Using Classification for Cost Reduction of Applying Mutation Testing</b> <i>Joanna Strug, Barbara Strug</i>	<b>99</b>
<b>Evolving KERAS Architectures for Sensor Data Analysis</b> <i>Petra Vidnerová, Roman Neruda</i>	<b>109</b>
<b>Measurement of the appropriateness in career selection of the high school students by using data mining algorithms: A case study</b> <i>Ahmet Firat Yelkuvan, Hidayet Takci, Kali Gurkahraman</i>	<b>113</b>

---

## **AAIA DATA MINING CHALLENGE**

---

<b>Call For Papers</b>	<b>119</b>
<b>Helping AI to Play Hearthstone: AAIA'17 Data Mining Challenge</b> <i>Andrzej Janusz, Tomasz Tajmayer, Maciej Świechowski</i>	<b>121</b>
<b>Predicting Unpredictable Building Models Handling Non-IID Data Hearthstone Case Study</b> <i>Dominik Deja</i>	<b>127</b>
<b>Helping AI to Play Hearthstone using Neural Networks</b> <i>Lukasz Grad</i>	<b>131</b>
<b>Evaluation of Hearthstone Game States With Neural Networks and Sparse Autoencoding</b> <i>Jan Jakubik</i>	<b>135</b>
<b>Multi-model approach for predicting the value function in the game of Heathstone: Heroes of Warcraft.</b> <i>Alexander Morgun</i>	<b>139</b>
<b>Use of Domain Knowledge and Feature Engineering in Helping AI to Play Hearthstone</b> <i>Przemysław Przybyszewski, Szymon Dziewiątkowski, Sebastian Jaszczur, Mateusz Śmiech, Marcin Szczuka</i>	<b>143</b>
<b>An ensemble model with hierarchical decomposition and aggregation for highly scalable and robust classification</b> <i>Quang Hieu Vu, Dymitr Ruta, Ling Cen</i>	<b>149</b>

---

## **7<sup>TH</sup> INTERNATIONAL WORKSHOP ON ARTIFICIAL INTELLIGENCE IN MEDICAL APPLICATIONS**

---

<b>Call For Papers</b>	<b>153</b>
<b>Predictive and Descriptive Analysis for Heart Disease Diagnosis</b> <i>František Babič, Jaroslav Olejár, Zuzana Vantová, Ján Paralič</i>	<b>155</b>
<b>Subvocal Speech Recognition via Close-Talk Microphone and Surface Electromyogram Using Deep Learning</b> <i>Mohamed S. Elmahdy, Ahmed Morsy</i>	<b>165</b>
<b>Developing an SVM classifier for extended ES protein structure prediction</b> <i>Piotr Fabian, Katarzyna Stapor</i>	<b>169</b>
<b>Towards a Keyword Extraction in Medical and Healthcare Education</b> <i>Martin Komenda, Matěj Karolyi, Roman Vyškovský, Kateřina Ježová, Jakub Šcavnický</i>	<b>173</b>
<b>Medical biophysics as a combination of the classic educational method and e-learning</b> <i>David Kordek, Martin Kopecek, Petr Voda</i>	<b>177</b>
<b>A Method For Data Classification In Slovak Medical Records</b> <i>Erik Kučera, Oto Haffner, Erich Stark</i>	<b>181</b>
<b>Integration of Virtual Patients in Education of Veterinary Medicine</b> <i>Jaroslav Majerník, Marián Maďar, Jana Mojžišová</i>	<b>185</b>

<b>Semi-real-time analyses of item characteristics for medical school admission tests</b>	<b>189</b>
<i>Patricia Martinková, Lubomír Štěpánek, Adéla Drabinová, Jakub Houdek, Martin Vejražka, Čestmír Štuka</i>	
<b>Moodle Portal in Virtualized Environment - a Performance Analysis</b>	<b>195</b>
<i>Vladimír Mašín, Martin Kopeček, Josef Hanuš</i>	
<b>Feature Selection Methods Applied to Severe Brain Damages Data</b>	<b>199</b>
<i>Wiesław Paja, Krzysztof Pancerz</i>	
<b>Preprocessing compensation techniques for improved classification of imbalanced medical datasets</b>	<b>203</b>
<i>Agnieszka Wosiak, Sylwia Karbowski</i>	
<b>Neuro-Endo-Trainer-Online Assessment System (NET-OAS) for Neuro-Endoscopic Skills Training</b>	<b>213</b>
<i>Vinkle Kumar Srivastav, Britty Baby, Ramandeep Singh, Prem Kalra, Ashish Suri</i>	
<hr/>	
<b>2<sup>ND</sup> INTERNATIONAL WORKSHOP ON AI ASPECTS OF REASONING, INFORMATION, AND MEMORY</b>	
<hr/>	
<b>Call For Papers</b>	<b>221</b>
<b>Formalization of Pell's Equations in the Mizar System</b>	<b>223</b>
<i>Marcin Aciewicz, Karol Pąk</i>	
<b>Progress in the Independent Certification of Mizar Mathematical Library in Isabelle</b>	<b>227</b>
<i>Cezary Kaliszyk, Karol Pąk</i>	
<b>Formalization of the Algebra of Nominative Data in Mizar</b>	<b>237</b>
<i>Artur Kornilowicz, Andrii Kryvolap, Mykola Nikitchenko, Ievgen Ivanov</i>	
<b>Introducing Euclidean Relations to Mizar</b>	<b>245</b>
<i>Adam Naumowicz, Artur Kornilowicz</i>	
<b>Is there a computable upper bound on the heights of rational solutions of a Diophantine equation with a finite number of solutions?</b>	<b>249</b>
<i>Krzysztof Molenda, Agnieszka Peszek, Maciej Sporysz, Apoloniusz Tyska</i>	
<b>Modeling value-based reasoning for autonomous agents</b>	<b>259</b>
<i>Tomasz Zurek, Michail Mokkas</i>	
<hr/>	
<b>7<sup>TH</sup> INTERNATIONAL WORKSHOP ON ADVANCES IN SEMANTIC INFORMATION RETRIEVAL</b>	
<hr/>	
<b>Call For Papers</b>	<b>263</b>
<b>PitchKeywordExtractor: Prosody-based Automatic Keyword Extraction for Speech Content</b>	<b>265</b>
<i>Yurij Lezhenin, Artyom Zhuikov, Natalia Bogach, Elena Boitsova, Evgeny Pyshkin</i>	
<b>Research on Proposals and Trends in the Architectures of Semantic Search Engines: A Systematic Literature Review</b>	<b>271</b>
<i>Jorge Morales, Andrés Melgar</i>	
<b>Just Walk: Rethinking Use Cases in Mobile Audio Travel Guides</b>	<b>281</b>
<i>Evgeny Pyshkin, Pavel Korobenin</i>	
<hr/>	
<b>11<sup>TH</sup> JOINT AGENT-ORIENTED WORKSHOPS IN SYNERGY</b>	
<hr/>	
<b>Call For Papers</b>	<b>289</b>
<b>Preface</b>	<b>291</b>
<b>Failure Analysis for Adaptive Autonomous Agents using Petri Nets</b>	<b>293</b>
<i>Mirgita Frasher, Lan Anh Trinh, Baran Cürüklü, Mikael Ekström</i>	
<b>Development of Simulations for Ambient Assisted Living through Pattern Repositories</b>	<b>299</b>
<i>Rubén Fuentes-Fernández, Jorge Gomez Sanz</i>	

<b>Electricity peak demand classification with artificial neural networks</b>	<b>307</b>
<i>Krzysztof Gajowniczek, Rafik Nafkha, Tomasz Ząbkowski</i>	
<b>Towards an Agent-based Simulation of Building Stock Development for the City of Hamburg</b>	<b>317</b>
<i>Thomas Preisler, Tim Dethlefs, Wolfgang Renz, Ivan Dochev, Hannes Seller</i>	

---

## 2<sup>ND</sup> INTERNATIONAL WORKSHOP ON LANGUAGE TECHNOLOGIES AND APPLICATIONS

---

<b>Call For Papers</b>	<b>327</b>
<b>Document Clustering using a Graph Covering with Pseudostable Sets</b>	<b>329</b>
<i>Jens Dörpinghaus, Sebastian Schaaf, Juliane Fluck, Marc Jacobs</i>	
<b>Event Relation Acquisition Using Dependency Patterns and Confidence-Weighted Co-occurrence Statistics</b>	<b>339</b>
<i>Shohei Higashiyama, Kunihiko Sadamasa, Takashi Onishi, Yotaro Watanabe</i>	
<b>A Comparison of Authorship Attribution Approaches Applied on the Lithuanian Language</b>	<b>347</b>
<i>Jurgita Kapočiūtė-Džikienė, Algimantas Venčkauskas, Robertas Damaševičius</i>	
<b>Extraction of specific data from a sound sample by removing additional distortion</b>	<b>353</b>
<i>Dawid Potap</i>	
<b>Deep Learning methods for Subject Text Classification of Articles</b>	<b>357</b>
<i>Piotr Sembercki, Henryk Maciejewski</i>	
<b>A Hierarchical Approach for Sentiment Analysis and Categorization of Turkish Written Customer Relationship Management Data</b>	<b>361</b>
<i>Mehmet Seyfioğlu, Mustafa Demirezen</i>	
<b>Personality Prediction Based on Twitter Information in Bahasa Indonesia</b>	<b>367</b>
<i>Derwin Suhartono, Veronica Ong, Anneke D. S. Rahmanto, Williem, Aryo E. Nugroho, Esther W. Andangsari, Muhamad N. Suprayogi</i>	
<b>Open Class Authorship Attribution of Lithuanian Internet Comments using One-Class Classifier</b>	<b>373</b>
<i>Algimantas Venčkauskas, Arnas Karpavičius, Robertas Damaševičius, Romas Marcinkevičius, Jurgita Kapočiūtė-Džikienė, Christian Napoli</i>	
<b>Unsupervised tool for quantification of progress in L2 English phraseological</b>	<b>383</b>
<i>Krzysztof Wołk, Agnieszka Wołk, Krzysztof Marasek</i>	
<b>Big Data Language Model of Contemporary Polish</b>	<b>389</b>
<i>Krzysztof Wołk, Agnieszka Wołk, Krzysztof Marasek</i>	

---

## 10<sup>TH</sup> INTERNATIONAL WORKSHOP ON COMPUTATIONAL OPTIMIZATION

---

<b>Call For Papers</b>	<b>397</b>
<b>Optimising SVM to classify imbalanced data using dispersive flies optimisation</b>	<b>399</b>
<i>Haya Alhakbani, Mohammad Majid al-Rifaie</i>	
<b>Correlation clustering: a parallel approach?</b>	<b>403</b>
<i>László Aszalós, Mária Bakó</i>	
<b>An Integer Programming based Ant Colony Optimisation Method for Nurse Rostering</b>	<b>407</b>
<i>Joe Bunton, Andreas Ernst, Mohan Krishnamoorthy</i>	
<b>Ant Colony Optimization Algorithm for Workforce Planning</b>	<b>415</b>
<i>Stefka Fidanova, Gabriel Luque, Olympia Roeva, Marcin Paprzycki, Paweł Gepner</i>	
<b>Comparison of two types of Quantum Oracles based on Grover's Adaptive Search Algorithm for Multiobjective Optimization Problems</b>	<b>421</b>
<i>Gerardo G. Fogel, Benjamín Barán, Marcos Villagra</i>	

<b>Using branching-property preserving Pruefer Code to encode solutions for Particle Swarm Optimization</b>	<b>429</b>
<i>Hanno Hildmann, Dymitr Ruta, Dina Y. Atia, A. F. Isakovic</i>	
<b>Anchored Alignment Distance between Rooted Labeled Unordered Trees</b>	<b>433</b>
<i>Kouichi Hirata, Takuya Yoshino, Yuma Ishizaka</i>	
<b>A Distance-Based Approach for Human Posture Simulations</b>	<b>441</b>
<i>Antonio Mucherino, Douglas S. Gonçalves, Antonin Bernardin, Ludovic Hoyet, Franck Multon</i>	
<b>Solving 0-1 Quadratic Problems with Two-Level Parallelization of the BiqCrunch Solver</b>	<b>445</b>
<i>Camille Coti Etienne Leclercq, Frédéric Roupin, Franck Butelle</i>	
<b>A Fully Fuzzy Linear Programming Model to the Berth Allocation Problem</b>	<b>453</b>
<i>Flabio Gutiérrez Segura, Edwar Luján Segura, Rafael Asmat Uceda, Edmundo Vergara Moreno</i>	
<b>An Electronic Market Model with Mathematical Formulation and Heuristics for Large-Scale Book Trading</b>	<b>459</b>
<i>Ali Haydar Özer</i>	
<b>Distance-2 Collision-Free Broadcast Scheduling in Wireless Networks</b>	<b>469</b>
<i>Valentin Pollet, Vincent Boudet, Jean-Claude König</i>	
<b>Vehicle Oriented Algorithms for the Relocation of Vehicle Sharing Systems</b>	<b>473</b>
<i>Alain Quiliot, Antoine Sarbinowski</i>	
<b>Catching clouds: Simultaneous optimization of the parameters of biological agent plumes using Dirichlet processes to best estimate infection source location</b>	<b>481</b>
<i>James Thompson, Thomas Finnie, Ian Hall, Nina Dobrinkova</i>	
<hr/>	
<b>COMPUTER SCIENCE &amp; SYSTEMS</b>	
<b>Call For Papers</b>	<b>485</b>
<hr/>	
<b>10<sup>TH</sup> WORKSHOP ON COMPUTER ASPECTS OF NUMERICAL ALGORITHMS</b>	
<b>Call For Papers</b>	<b>487</b>
<b>OpenMP Thread Affinity for Matrix Factorization on Multicore Systems</b>	<b>489</b>
<i>Beata Bylina, Jarosław Bylina</i>	
<b>A Framework for Generating and Evaluating Parallelized Code</b>	<b>493</b>
<i>Jarosław Bylina</i>	
<b>Block Subspace Projection Preconditioned Conjugate Gradient Method for Structural Modal Analysis</b>	<b>497</b>
<i>Sergiy Fialko, Viktor Karpilovskyi</i>	
<b>An algorithm for Gaussian Recursive Filters in a Multicore Architecture</b>	<b>507</b>
<i>Ardelio Galletti, Giulio Giunta, Livia Marcellino, Diego Parlato</i>	
<b>On Memory Footprints of Partitioned Sparse Matrices</b>	<b>513</b>
<i>Daniel Langr, Ivan Šimeček</i>	
<b>Optimizing Numerical Code by means of the Transitive Closure of Dependence Graphs</b>	<b>523</b>
<i>Marek Palkowski, Włodzimierz Bielecki</i>	
<b>A Non-Speculative Parallelization of Reverse Cuthill-McKee Algorithm for Sparse Matrices Reordering</b>	<b>527</b>
<i>Thiago Nascimento Rodrigues, Maria Claudia Silva Boeres, Lucia Catabriga</i>	
<b>Least Square Method Robustness of Computations: What is not usually considered and taught</b>	<b>537</b>
<i>Vaclav Skala</i>	

---

## 4<sup>TH</sup> INTERNATIONAL CONFERENCE ON CRYPTOGRAPHY AND SECURITY SYSTEMS

---

<b>Call For Papers</b>	<b>543</b>
<b>Enhancing the Imperceptibility of Image Steganography for Information Hiding</b> <i>Mohamed Fouad Abdelmotagally</i>	<b>545</b>
<b>The impact of malware evolution on the analysis methods and infrastructure</b> <i>Krzysztof Cabaj, Piotr Gawkowski, Konrad Grochowski, Alexis Nowikowski, Piotr Żórawski</i>	<b>549</b>
<b>Quantum color image encryption based on multiple discrete chaotic systems</b> <i>Li Li, Bassem Abd-El-Atty, Ahmed Abd El-Latif, Ahmed Ghoneim</i>	<b>555</b>
<b>TARZAN: An Integrated Platform for Security Analysis</b> <i>Marek Rychlý, Ondrej Ryšavý</i>	<b>561</b>
<b>High-Level Malware Behavioural Patterns: Extractability Evaluation</b> <i>Jana Št'astná, Martin Tomášek</i>	<b>569</b>

---

## 2<sup>ND</sup> WORKSHOP ON CONSTRAINT PROGRAMMING AND OPERATION RESEARCH APPLICATIONS

---

<b>Call For Papers</b>	<b>573</b>
<b>Application of survival function in robust scheduling of production jobs</b> <i>Łukasz Sobaszek, Arkadiusz Gola, Edward Kozłowski</i>	<b>575</b>
<b>A hybrid method for Optimization Scheduling Groups of Jobs</b> <i>Tadeusz Stefański, Jarosław Wikarek</i>	<b>579</b>
<b>Answer Set Programming for Modeling and Reasoning on Modular and Reconfigurable Transportation Systems</b> <i>Walter Terkaj, Marcello Urgo, Daniela Andolfatto</i>	<b>587</b>

---

## 10<sup>TH</sup> INTERNATIONAL SYMPOSIUM ON MULTIMEDIA APPLICATIONS AND PROCESSING

---

<b>Call For Papers</b>	<b>597</b>
<b>Preface</b>	<b>599</b>
<b>Available Bandwidth Estimation in Smart VPN Bonding Technique based on a NARX Neural Network</b> <i>Giacomo Capizzi, Grazia Lo Sciuto, Francesco Beritelli, Francesco Scaglione, Dawid Połap, Kamil Książek, Marcin Wozniak</i>	<b>601</b>
<b>H.265 Inverse Transform FPGA implementation in Impulse C</b> <i>Sławomir Cichoń, Marek Gorgoń</i>	<b>607</b>
<b>New Content Based Image Retrieval database structure using Query by Approximate Shapes</b> <i>Stanisław Deniziak, Tomasz Michno</i>	<b>613</b>
<b>Seniors' experiences with online banking</b> <i>Chrysoula Gatsou, Anastasios Politis, Dimitrios Zevgolis</i>	<b>623</b>
<b>Corneal Endothelium Image Segmentation Using Feedforward Neural Network</b> <i>Anna Fabijańska</i>	<b>629</b>

**Abstract**—In recent years, there has been a growing interest in the use of ontological theories in the philosophical sense (Foundational Ontologies) to analyze and (re)design conceptual modeling languages. This paper is about an ontologically well-founded conceptual modeling language in this tradition, termed *OntoUML*. This language embeds a number of *ontological patterns* that reflect the micro-theories comprising a particular foundational ontology named UFO. We here (re)define *OntoUML* as a formal graph grammar and demonstrate how the models of this language can be constructed by the combined application of ontological patterns following a number of graph transformation rules. As a result, we obtain a version of this language fully defined as a formal *Ontology Pattern Grammar*. In other words, this paper presents a formal definition of *OntoUML* that is both explicit in terms of the ontological patterns that it incorporates and is completely independent of the UML meta-model.

## I. INTRODUCTION

IN RECENT years, there has been a growing interest in the use of ontological theories in the philosophical sense (Foundational Ontologies) and engineering tools derived from these theories to improve the theory and practice of Information Systems Engineering (ISE). In particular, there is a stable tradition on the use of foundational ontologies to analyze and (re) design conceptual modeling languages that play an essential role in ISE. For example, in [1], the authors have conducted an empirical study with 528 practitioners and have shown that the perception of ontological deficiencies in conceptual modeling languages negatively affects the perception of the usability and usefulness of these languages.

This paper is written in the context of a research program involving a particular Foundational Ontology, namely, the Unified Foundational Ontology (UFO) [2] and a particular conceptual modeling language derived from it, namely, *OntoUML* [3]. *OntoUML* was conceived as an ontologically well-founded version of the UML 2.0 fragment of class diagrams. Both UFO and *OntoUML* have gained increasing attention in the context of ontology-driven conceptual modeling. For example, a recent study shows that UFO is the second-most used foundational ontology in conceptual modeling and the one with the fastest adoption rate [4]. Moreover, the study also shows *OntoUML* is among the most used languages in ontology-driven conceptual modeling (together with UML, (E)ER, OWL and BPMN).

In a recent paper [5], we have shown that *OntoUML* comprises a number of *ontology patterns* reflecting corre-

sponding ontological micro-theories put forth by its underlying foundational ontology (UFO) [6]. As discussed in [5], UFO is a system of micro-theories addressing basically all the classic conceptual modeling concepts. For each of the ontological distinctions present in UFO and which are reflected as modeling constructs in *OntoUML*, we have a corresponding axiomatization. This axiomatization makes sure that *OntoUML* constructs can only appear in a model forming clusters of constructs with their ties and associated constraints. In other words, in general purpose languages such as ER, UML or OWL, the actual modeling building blocks of the language are low-granularity modeling primitives such as class, association, attribute, etc. In *OntoUML*, in contrast, the actual modeling primitives are these structures (and their corresponding axiomatization) reflecting the underlying ontological micro-theories. As a consequence, *OntoUML* could be conceived as a *pattern grammar (language)* whose models are constructed via the combined instantiation of the ontological patterns.

In [5], we presented the ontological patterns embedded in *OntoUML*, the connection between these patterns, and their possible combination rules. However, the characterization of *OntoUML* as a full-blown pattern grammar was done there in an informal way. In this paper we remedy this situation by defining and implementing *OntoUML* as an **Ontology Pattern Grammar**. As the main contribution of this paper, we show how *OntoUML* patterns can be formally defined using a graph grammar based on the Single-Pushout Graph Transformation theory. Furthermore, we present a practical implementation of this grammar, using the general-purpose graph transformation tool GROOVE [7][8].

We highlight that the definition and implementation of *OntoUML* as a formal Ontology Pattern Grammar can bring several benefits to the (Ontology-Driven) Conceptual Modeling community, namely: (i) the grammar is defined in a formal, Turing powerful, computational method that circumvents the limitations of the current meta-modeling approaches for defining the abstract syntax of modeling languages; (ii) the language is defined in a way that affords its independence from the UML meta-model and, as consequence, the results presented here can be ported to other conceptual modeling languages (e.g., some ontological distinctions put forth by UFO have been incorporated in the ORM language [9][10]) and employed by the conceptual modeling community at large

beyond UML users; (iii) the language makes explicit its constituting ontology design patterns which, once more, reflect the ontological micro-theories put forth by UFO. In other words, in comparison to the current definition of OntoUML's abstract syntax (in terms of a UML 2.0 meta-model with associated OCL constraints), the implementation of this language in the manner proposed here affords a much higher *ontological transparency* for the language, *i.e.*, the implementation makes much more transparent the ontological commitments embedded in that conceptual modeling language. Finally, we highlight that the implementation of these patterns in a computational tool supports the construction of OntoUML models by employing modeling primitives of a higher-granularity (the ontological patterns). Moreover, since these higher-granularity modeling elements can only be combined to each other in a restricted set of ways, in each modeling step, the design space is reduced. We believe that this strategy reduces the complexity of the modeling process, especially for novice modelers.

The remainder of this paper is organized as follows. Sections II and III present the background of this work. In particular, Section III briefly introduces the basic concepts of graph transformation, including the commonly used Single-Pushout approach, and the definition of a graph grammar and its associated graph language. Section IV presents the syntactical conventions of the GROOVE tool set. Section V presents the definition of OntoUML as an Ontology Pattern (Graph) Grammar and shows its implementation in GROOVE. Finally, by using this implementation, in Section VI we illustrate the use of the proposed grammar to instantiate real OntoUML models. Section VII presents our final considerations.

## II. UFO AND ONTOUML

OntoUML, as all structural conceptual modeling languages (*e.g.*, UML, ER, ORM), is meant to represent type-level structures whose instances are endurants, *i.e.*, they are meant to model **Endurant Universals** and their type-level relations.

Fig. 3 depicts the **Endurant Universals** hierarchy in UFO. A basic formal relation that can hold between (endurant) universals in UFO is the relation of subtyping. If a universal  $B$  is a subtype of a universal  $A$  then we have that: (i) it is necessarily the case that all instances of  $B$  are instances of  $A$ ; and (ii) all properties of universal  $A$  are in a sense *inherited* by universal  $B$ , *i.e.*,  $B$ s are  $A$ s and, therefore, have all properties that are properties defined for universal  $A$ .

Endurant universals are distinguished into **Substantial Universals** and **Moment Universals**. Naturally, these are kinds of universals whose instances are **Substantials** and **Moments** [3], respectively. Substantials are *existentially independent* objects such as John Lennon, the Moon, an organization, a car, a dog. Substantials can have a mereologically complex structure, *i.e.*, they can have parts that are themselves substantials. In case these substantials are *functional complexes*, their parts are functional parts termed components (*e.g.*, a CPU is a functional component of a computer); in case they are *collectives*, they have a uniform structure in which all parts (termed members) are undifferentiated w.r.t. the whole (*e.g.*,

in the sense all trees are considered merely as members of a forest) [3]. Moments, in contrast, are *existentially dependent* individuals such as John's headache (which depends on him) and the marriage between John and Yoko (which depends on both John and Yoko). Being existentially dependent entities, moments can only exist by *inhering in* other endurants [3].

Concerning the substantial universal hierarchy, **Sortal Universals** are the ones that either provide or carry a uniform *principle of identity* for their instances. A principle of identity supports the judgment whether two individuals are the same, *i.e.*, in which circumstances the identity relation holds. In particular, it also informs which changes an individual can undergo without changing its identity. Within the category of **Sortal Universals**, we have the distinction between rigid and anti-rigid universals. A rigid universal is one that classifies its instances necessarily (in the modal sense), *i.e.*, the instances of that universal cannot cease to be so without ceasing to exist. Anti-rigidity, in contrast, characterizes a universal whose instances can move in and out of its extension without altering their identity. For instance, contrast the rigid universal *Person* with the anti-rigid universals *Student* or *Husband*. While the same individual John never ceases to be an instance of *Person*, he can move in and out of the extension of *Student* or *Husband*, depending on whether he enrolls in/finishes college or marries/divorces, respectively. **Kinds** are sortal rigid universals that provide a uniform principle of identity for their instances (*e.g.*, *Person*). **Subkinds** are sortal rigid universals that carry the *principle of identity* supplied by a unique **Kind** (*e.g.*, a kind *Person* can have the subkinds *Man* and *Woman* that carry the principle of identity provided by *Person*). Concerning anti-rigid sortals, we have the distinction between roles and phases. **Phases** are relationally independent universals defined as a partition of a sortal. This partition is derived based on an intrinsic property of that universal (*e.g.*, *Child* is a phase of *Person*, instantiated by instances of persons who are less than 12 years old). **Roles** are relationally dependent (or *externally dependent*) universals, capturing relational properties shared by instances of a given kind, *i.e.*, putting it baldly: entities play roles when related to other entities via the so-called *material relations* (*e.g.*, in the way some plays the role *Husband* when connected via the material relation of "*being married to*" with someone playing the role of *Wife*). Since the principle of identity is provided by a unique **Kind**, each sortal hierarchy has a unique **Kind** at the top [3].

The relational dependence of **Roles** is manifested by the presence of a **Relator** (a particular type of moment that is existentially dependent on multiple individuals) in the model. **Relators** are individuals with the power of connecting entities. For example, an *Enrollment* relator connects a *Student* role with an **Educational Institution**. OntoUML has a construct for modeling relator universals. Every instance of a relator universal is existentially dependent on at least two distinct entities. The formal relation that take place between a relator universal and the object classes it connects is termed *mediation* (a particular type of *existential dependence* relation) [3].

**Non-Sortals** or **Mixins** are universals that aggregate properties that are common to different sortals, *i.e.*, that ultimately classify entities that are of different **Kinds**. Non-sortals do not provide a uniform principle of identity for their instances; instead, they just classify things that share common properties but which obey different principles of identity. *Furniture* is an example of non-sortal (a category) that aggregates properties of *Table*, *Chair* and so on. Other examples include works of art (including paintings, music compositions, statues), insurable items (including works of arts, buildings, cars, body parts, etc.) and social and legal objects (including people, organizations, contracts, legislations, etc.). The meta-properties of rigidity and anti-rigidity can also be applied to distinguish different types of **Non-Sortals (Mixins)**. A **Category** represents a rigid and relationally independent mixin, *i.e.*, a dispersive universal that aggregates essential properties that are common to different rigid sortals [3] (*e.g.*, *Physical Object* aggregates essential properties of *Table*, *Car*, *Glass*, etc). A **RoleMixin** represents an anti-rigid and externally dependent non-sortal, *i.e.*, a dispersive universal that aggregates properties that are common to different **Roles** (*e.g.*, a *Customer* that aggregates properties of *Individual Customer* and *Corporate Customer*) [3].

The leaf ontological distinctions represented in Fig. 3 as well as their corresponding axiomatization (*i.e.*, their corresponding ontological micro-theories) are reflected as modeling constructs in OntoUML [3]. Moreover, as shown in [5], this axiomatization ensures that the OntoUML constructs representing these ontological categories can only appear in a model forming clusters of constructs with their ties and associated constraints. In other words, as previously mentioned, the actual modeling primitives of OntoUML are certain *pattern-based structures* reflecting the ontological micro-theories comprising UFO. Thus, OntoUML is a pattern language whose models are constructed via the combined instantiation of certain foundational patterns. As a pattern grammar, an OntoUML model is a non-empty set of **Endurant Universal Expressions**. These expressions, in turn, as summarized in Table I, are defined in a recursive manner reflecting the taxonomic structure of the UFO ontology of Endurant Universals (Fig. 3) until a level of concrete terminal elements (kinds and concrete ontology patterns) is reached. The OntoUML patterns have already been presented in [5] but at a more informal level. In this paper, we present the OntoUML patterns in a formal manner, using a graph transformation system.

### III. GRAPH TRANSFORMATION

#### A. Basic Concepts

*Graph transformation* (or *graph rewriting*) [11] has been advocated as a flexible formalism, suitable for modeling systems with dynamic configurations or states. This flexibility is achieved by the fact that the underlying data structure, that of graphs, is capable of capturing a broad variety of systems. Some areas where graph transformation is being applied include the visual modeling of systems, the formal specification of model transformations, and the definition of graph languages, to name a few [12][8].

TABLE I  
EXPRESSIONS OF ONTOUML.

Expression	Expression Structure
Endurant Universal Expression	Substantial Universal Expression or Moment Universal Expression
Substantial Universal Expression	Sortal Expression or Mixin Expression
Sortal Expression	Rigid Sortal Expression or Anti-Rigid Sortal Expression
Rigid Sortal Expression	Substance Sortal Expression or SUBKIND PATTERN
Substance Sortal Expression	<<kind>> T or COLLECTIVE PATTERN
Anti-Rigid Sortal Expression	PHASE PATTERN or ROLE PATTERN
Mixin Expression	CATEGORY PATTERN or ROLEMIXIN PATTERN
Moment Universal Expression	MODE PATTERN or RELATOR PATTERN
Relationally Dependent Universal Expression	ROLE PATTERN or ROLEMIXIN PATTERN

Essentially, whenever a system consists of entities with relations between them, this can be naturally captured by a graph in which nodes stand for entities and edges for relations. If, in addition, a main characteristic of such a system is that entities are created or deleted and the relations between them can change, then the transformation of graphs comes into play.

The core concept of graph transformation is the rule-based modification of graphs, where each application of a rule leads to a graph transformation step. A transformation rule specifies both the necessary preconditions for its application and the rule effect (modifications) on a *host graph*. The modified graph produced by a rule application is the result of the transformation.

In this work, we use graph transformations to formally model the construction of ontology patterns. A set of graph transformation rules can be seen as a declarative specification of how the construction of an ontology model can evolve from an initial state, represented by an initial host graph. This combination of a rule set plus an initial graph is called a *graph grammar*, and the (possibly infinite) set of graphs reachable from the initial graph constitute the grammar *language*.

In its basic form, our formal graphs are composed of nodes and directed labeled binary edges. Fig. 1(a) shows a graph representing a single-linked list composed of five cells (nodes labeled C) and a sentinel node (L) to mark the head and tail elements of the list. Labels C and L are actually part of self-loop edges; however, for visual convenience, unary labels are written inside their associated node and the edge is omitted. Node identities are displayed at the top left corner of each node (edge identities are not shown). Edges labeled n indicate

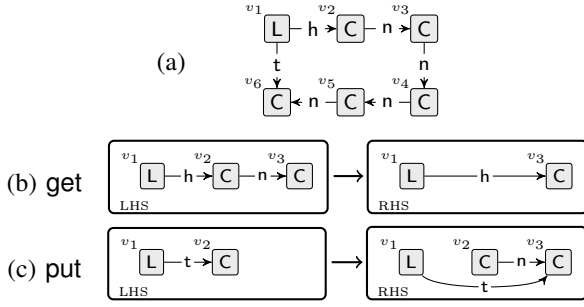

Fig. 1. (a) A graph representing a single-linked list with five elements. (b),(c) Two graph transformation rules.

Fig. 2. Example of a graph transformation, with application of rule *get* to the graph of Fig. 1(a). Match  $m$  is indicated with dashed arrows.

the *next* list element, and labels  $h$  and  $t$ , indicate the list *head* and *tail*, respectively.

Graphs are modified according to transformation (or production) rules, that describe both the conditions for their application and the changes that should be performed to the host graph. In its basic form, a *transformation rule*  $r$  is composed of two graphs, a left-hand side (LHS)  $L$  and a right-hand side (RHS)  $R$ . Fig. 1(b,c) shows rules for removing the head element of a list (*get*) and inserting a new element at the tail of the list (*put*). For rule *get*, we have that the set of deleted nodes is  $\{v_2\}$ , indicating that the head cell is removed by the rule. Additionally, set  $\{\langle v_1, h, v_2 \rangle, \langle v_2, n, v_3 \rangle\}$  corresponds to the set of edges to be removed. Rule *get* does not create new nodes, and set of edges to be created consists solely of  $\{\langle v_1, h, v_3 \rangle\}$ . For the *put* rule given in Fig. 1(c) these sets can be analogously inferred.

Graphs are related by *morphisms*, structure preserving functions over nodes and edges that also respect edge labels. For a rule  $r$  to be *applicable* to a host graph  $G$ , a *match*  $m$  of  $L$  into  $G$  has to exist, where  $m$  must be structure-preserving, i.e.,  $m$  is a morphism from  $L$  to  $G$ . The *application* of  $r$  to  $G$  according to match  $m$  comprises two steps. First, all nodes and edges matched by  $L \setminus R$  are removed from  $G$ . In the second step of rule application, elements of  $R \setminus L$  are added to  $G$ , to obtain the derived graph  $H$ . Fig. 2 depicts the application of rule *get* (Fig. 1(b)) to the host graph of Fig. 1(a), under match  $m$ . The commuting square of morphisms corresponds to a *pushout* in Category Theory, therefore this type of construction for graph transformation is dubbed the Single-Pushout (SPO) approach.

By associating an initial host graph to a set of related rules we obtain a *graph grammar*. A graph grammar defines a *graph language*, the set of all graphs reachable from the initial host graph. If a grammar has at least one rule that is always enabled (i.e., that has an empty LHS), then the grammar language is infinite. However, a finite fragment of a language can still be algorithmically generated. This is the core functionality of the GROOVE tool set, which calls this action *exploration of the grammar state space*. We describe the GROOVE tool in Section IV.

A graph grammar is a Type 0 grammar according to the Chomsky Hierarchy and therefore graph transformations can be seen as an alternative, Turing powerful, computational method [13]. However, despite their theoretical power, graph grammars still require further extensions to be applicable in practice. In this work, we use the concepts of *typed graph grammars* and of *rule schemata*, described in the following two sections.

### B. Node Types and Inheritance

A typed graph transformation with node type inheritance [14] is a formalization of the inheritance concept common to object oriented (OO) systems. The core concept of this formalization requires enriching a graph grammar with a (transitive) inheritance relation over node types. Using the usual graph transformation terminology, the inheritance relation is described by a *type graph* (roughly equivalent to a class diagram, in OO terms) that describes all valid structure of rule and host graph elements.

Roughly speaking, a graph grammar can be typed according to a type graph  $\mathcal{T}$  by the construction of a morphism from any grammar graph (rule or host graphs) into  $\mathcal{T}$ . If no such *typing morphism* can be constructed, then the grammar is considered erroneous. Tools such as GROOVE are properly equipped to handle type graphs and node inheritance, and give error messages if a grammar cannot be typed.

Although we refrain ourselves from presenting the theory of typed graph transformation due to its complexity (an interested reader is referred to [14]), in practice the consequences of using types in a graph grammar are quite straightforward, affecting only the rule matching mechanism. For example, suppose two node types **S** and **T**, with **S** a subtype of **T**. Any occurrence of a **T**-node in the LHS of a rule can be matched by either a **T**- or **S**-node in the host graph. This idea can be generalized to a complete transitive inheritance relation and is properly implemented in the GROOVE tool [8].

Fig. 3 depicts a type graph that describes a UFO-A fragment of Endurant Universals, as presented in [5] and discussed in Section II. The type graph is able to properly capture the complete hierarchy as given in [5], with the exception of annotations such as *disjoint* and *complete*. In addition, the type graph in Fig. 3 can be seen as a formal representation of the recursive relationships between expression structures, as informally presented in Table I of Section II. In Table I, for example, a **Anti-Rigid Sortal Expression** can stand for either a **Phase Pattern** or a **Role Pattern**. This is formalized

Fig. 6. Rules (a) get and (b) put in GROOVE notation.

#### IV. GROOVE

GROOVE [7][8] is a general purpose graph transformation tool set that uses directed labeled graphs. The core functionality of GROOVE is to (partially) compute the language of a graph grammar, by recursively applying all rules from the grammar to the initial host graph, and to all graphs generated by such applications. In the tool terminology, this exploration results in a *state space* consisting of the generated graphs. The main component of the GROOVE tool set is the Simulator, a graphical tool that integrates (among others) the functionalities of rule and host graph editing, and of interactive or automatic state space exploration.

A graph transformation rule is composed of two graphs  $L$  and  $R$ , as defined previously. However, in practice, it is tedious and rather repetitive to describe a rule in terms of its composing graphs. Therefore, in GROOVE, both  $L$  and  $R$  are combined into a single graph, and colors and line strokes are used to visually distinguish them. Fig. 6 shows the get and put rules previously given in Fig. 1(b,c), now in GROOVE notation. The semantics of this notation is summarized as follows:

- The black (continuous thin) components are *reader* elements, which must be present during matching and are preserved by the rule application.
- The blue (dashed thin) components are *eraser* elements, which must be present during matching and are deleted by the rule application.
- The green (continuous fat) components are *creator* elements and are created by the rule application.

#### V. ONTOUML AS A GRAPH GRAMMAR

In this section we describe the main contribution of this paper, namely the **Ontology Pattern Grammar**. In [5], we discussed at length the *static* structure of OntoUML patterns, focusing mainly on the rationale for the usage of a pattern, but without concern with the actual sequencing of pattern constructions that may lead to a complete model. On the other hand, in Section III, we described the major concepts of graph transformation, a formalism aimed at specifying the *dynamic* evolution of graph structures. In this section we merge these two concepts.

Our goal is to use graph transformations to formally capture the dynamic evolution of an OntoUML model from its inception until its final form. To do so, we specify each step in the construction of a Ontology Pattern as the application of a graph transformation rule. This level of granularity in the model construction is justified by the fact that, in OntoUML, the patterns are the actual modeling primitives, as previously stated.

Tables II and III show all graph transformation rules that form the Ontology Pattern Grammar, as implemented in

GROOVE. The initial host graph is empty and thus it is not depicted. Certain patterns admit two or more variants, which are presented consecutively in Tables II and III. Additionally, rules whose names end in  $ki$  are based in rule schemata, with  $i$  indicating the concrete value used in the schema instantiation. In these cases, we indicate in the rule description which nodes are multiple (*i.e.*, have an associated  $k > 0$ ).

With exception of the **Kind Pattern** rule, for any other rule to be applicable, an existing structure must already be present in the model (these are the *reader* and *eraser* elements in the rules). Also, every rule creates an additional graph structure (*creator* elements) with each application. Thus, by sequencing a series of rule applications, the ontology model (which starts empty) grows until reaching its final form, with the GROOVE tool ensuring that only valid (applicable) transformations can be taken at each step. Therefore, the final model created is guaranteed to be structurally and ontologically sound by *construction*.

The first two cells of Table II show the rules for creating a **Category Pattern**, which has two variants. Variant 1 creates a **Category** node for an existing **Mixin** node to inherit from. Variant 2 comes from a schema, where the **RigidSortal** node is multiple, with the rule instance using  $k = 2$ . Thus, in this rule, a category serves as the inheritance point of two rigid sortals. The **Collective Pattern** also comes from a schema, with the **Endurant** node being multiple (the rule instance uses  $k = 1$ ). Thus, in this rule, a new **Collective** node is created as a member of a single existing **endurant**. The **Component**, **Inheritance** and **Membership Pattern** rules are used to respectively create the relations of parthood, inheritance and membership among two existing **endurants**.

The **Kind Pattern** rule is used to create new **Kind** nodes. This is always possible, since a kind has no preconditions to be introduced in the model. Therefore, the **Kind Pattern** rule is always applied first in a new graph (model). The **Mode Pattern** rule follows a schema, with the **Endurant** node the mode depends on being multiple. Here, this multiple node is instantiated with  $k = 1$ . A similar construction occurs in the **Phase Pattern**, with the multiple **Phase** nodes instantiated for  $k = 2$ , indicating that two distinct phases can inherit from an existing **sortal**.

The **Relational Dependence Pattern** has three variants to handle distinct structures of mediation by a **Relator** node. In Variant 1, the mediation is direct, whereas in Variants 2 and 3 the mediation occurs through the membership of a **substantial**. In either case, the goal of these rules is to confirm the existence of a **relator** mediating a **Relationally Dependent Expression** (either a **Role** or **RoleMixin** node). The rules then erase the temporary **RelationalDependencePattern** marker node which was previously created when a **Role** or **RoleMixin Pattern** was introduced.

The **Relator Pattern** has two variants, with Variant 1 handling the creation of a **Relator** node that directly mediates one or more **substantials**. Table III shows instances of the rule schema for  $k = 1, 2, 3$ . Variant 2 behaves similarly but also introduces a reified **MaterialRelation** node to connect

TABLE II  
ONTOLOGY PATTERN GRAMMAR IN GROOVE (PART I)

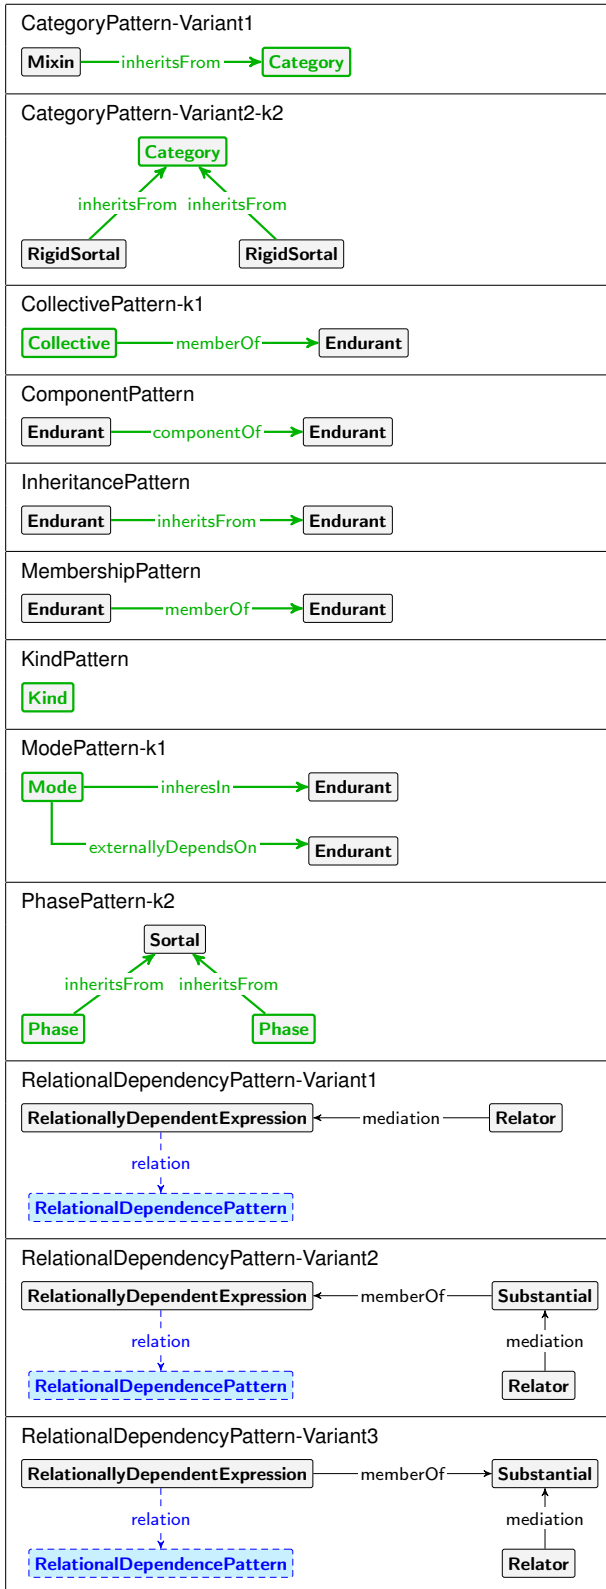

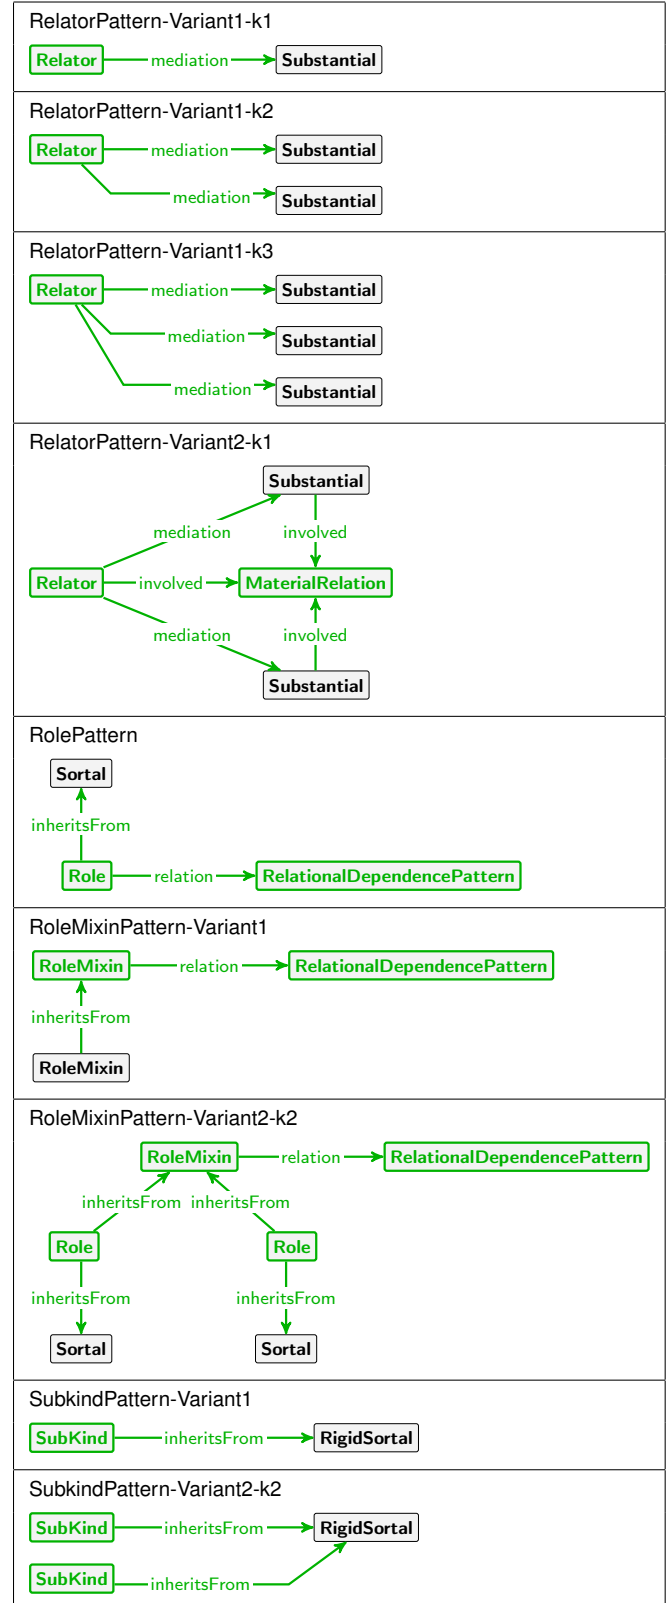

TABLE III  
ONTOLOGY PATTERN GRAMMAR IN GROOVE (PART II)

the involved substantials. This reification is necessary because GROOVE only admits edges connecting nodes (not other edges).

The **Role Pattern** rule creates a **Role** node that inherits from an existing sortal. A role is a **Relationally Dependent Expression** which must be connected to a **Relator Pattern**. Since the relator can only be created after all mediated substantials exist, the rule creates the **RelationalDependencePattern** marker node, to indicate that there is an unresolved dependence in the model. Subsequently, after one or more **Relator Patterns** are created, this marker node is removed by a **Relational Dependence Pattern** rule. A model with one or more **RelationalDependencePattern** nodes is at an intermediate state of construction, and cannot be considered finished until all dependencies are satisfied.

The **Role Mixin Pattern** is similar to the **Role Pattern**, with the distinction that this pattern creates a **RoleMixin** node to aggregate one or more roles. Variant 2 instantiates the rule schema with  $k = 2$ , both for the **Role** and **Sortal** nodes. Variant 1, on the other hand, allows the introduction of a mixin that generalizes an existing one. Finally, the last two cells of Table III show the rules that create the **Subkind Pattern**.

The main functionality of the GROOVE tool is state space exploration (language enumeration) of a graph grammar. Although this functionality can be used with the Ontology Pattern Grammar to (partially) enumerate consistent OntoUML models, this is not the grammar intended use, as the exploration can quickly exhaust computational resources. Conversely, the Ontology Pattern Grammar was designed to be used with the interactive mode of GROOVE, where the user (modeler) decides at each step which rule to apply to introduce a new pattern. This sequencing of rule applications is illustrated in the next section with two examples.

## VI. APPLYING THE ONTOLOGY PATTERN GRAMMAR

In order to illustrate the application of the Ontology Pattern Grammar to produce OntoUML models, we use two existing published models of [5]. The versions of these models produced using the grammar are shown in Figs. 7 and 8, respectively. In the model of Fig. 7, we see on the top-left side the result of an application of a **Kind Pattern** (*Person*) followed by an application of the **Phase Pattern** (*Deceased Person* and *Living Person* specializing the sortal *Person*). In the top-right side of the model, we see an analogous application of the same patterns creating the kind *Organization* and the phases *Extinct Organization* and *Active Organization*. In the center of the model, we see the application of the **RoleMixin Pattern** Variant 2 creating the rolemixin *Customer* and the roles *Personal Customer* and *Corporate Customer* that specialize the sortals *Living Person* and *Active Organization*, respectively. The **Relational Dependence Pattern** node (let us call it RDP-1) created by this **RoleMixing Pattern** Variant 2 serves as a marker to indicate that the rolemixin *Customer* requires a relation with a pattern that is still not present. Continuing with the model construction, the role *Supplier* is introduced via an application of the **Role Pattern**. This role

also requires a **Relational Dependent Pattern** (call it RDP-2). Finally, a relationally dependent expression is introduced with a relator (*Purchase Contract*) and the material relation *purchases from* via the application of the **Relator Pattern** Variant 2. Once the relator *Purchase Contract* is created, both RDP-1 and RDP-2 are satisfied and thus their temporary node markers can be removed with two applications of the **Relational Dependency Pattern** Variant 1. This concludes the model creation, yielding the graph shown in Fig. 7.

In the model of Fig. 8, we can start with the applications of the **Kind Pattern** creating the kinds *Organization*, *Organizational Unit* and *Person*. After that, with the application of the **Component Pattern**, we can make an *Organizational Unit* a component of an *Organization* (both *Organizational Unit* and *Organization* are **Endurant** types). We have then two applications of the **SubKind Pattern** Variant 1 creating the subkinds *Car Rental Branch* and *Car Rental Agency*. Again these two types can be connected by an application of the **Component Pattern**. An application of the **RoleMixin Pattern** Variant 2 creates the rolemixin *Car Rental Provider* as well as the roles *Car Rental Branch Provider* (that specializes the sortal *Car Rental Branch*) and *Car Rental Agency Provider* (that specializes the sortal *Car Rental Agency*). The **Relational Dependency Pattern** instance (let us call it RDP-1) associated to this pattern is left unresolved at this moment. We can then apply the **RoleMixin Pattern** Variant 1 to create the rolemixin *Service Provider* as a supertype of *Car Rental Provider*, leaving a second instance of the **Relational Dependency Pattern** unresolved (let us call it RDP-2). We can apply once more an instance of the **RoleMixin Pattern** Variant 2 creating the rolemixin *Potential Car Renter* and the roles *Potential Person Car Renter* (specializing the sortal *Person*) and *Potential Organization Car Renter* (specializing the sortal *Organization*). Again, we leave an instance of the **Relational Dependency Pattern** unresolved (RDP-3). We can apply again the **RoleMixin Pattern** Variant 1 creating the rolemixin *Target Customer* as a supertype of *Potential Car Renter*, leaving a final instance of a **Relational Dependency Pattern** unresolved (RDP-4). Then, using the **Collective Pattern** we can introduce the *Target Customer Community* as a member of the *endurant Target Customer*. This collective then appears as the supertype of the *Potential Car Renter Community* subkind, created via a **Subkind Pattern** Variant 1. Rule **Membership Pattern** is used next, to introduce the *memberOf* relation between the *Potential Car Renter Community* subkind and the *Potential Car Renter* mixin. Finally, to complete the model we apply the **Relator Pattern** Variant 1 ( $k = 2$ ) twice, to introduce the two relators *Service Offering* and *Car Rental Offering*, which are then connected using the **Inheritance Pattern**. After this step, all relational dependencies are satisfied, and are removed via two applications of the **Relational Dependency Pattern** Variant 1 (handling RDP-1 and RDP-2), and two applications of the **Relational Dependency Pattern** Variant 2 (handling RDP-3 and RDP-4). This concludes the model creation, yielding the graph shown in Fig. 8.

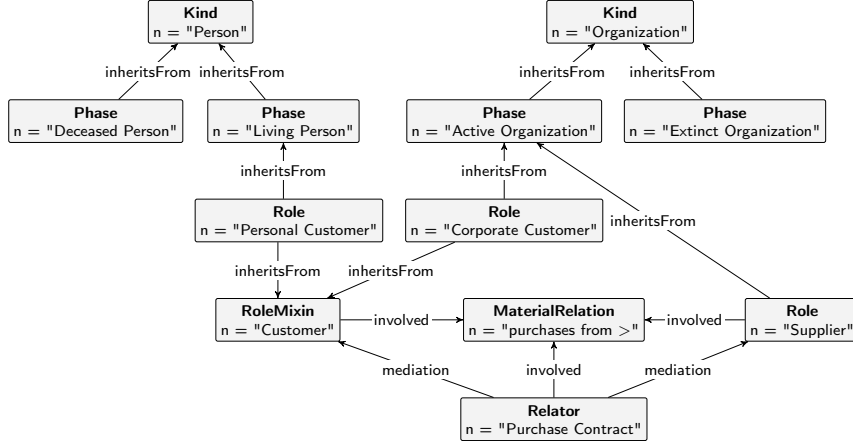

Fig. 7. Model from [5] produced in GROOVE using the proposed Ontology Pattern Grammar.

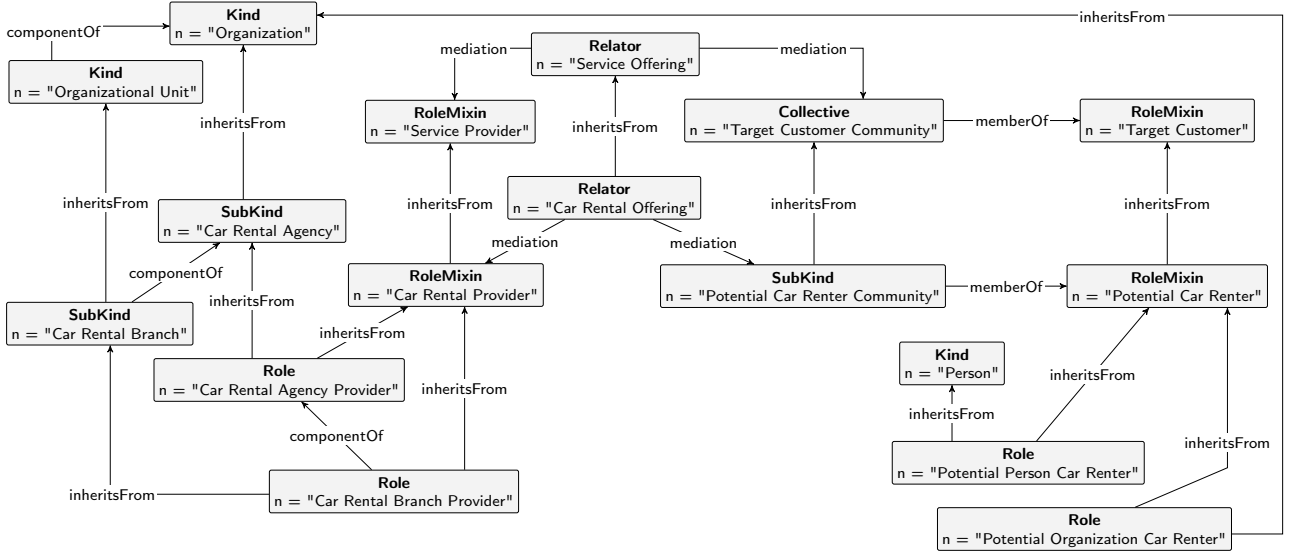

Fig. 8. Model from [5] produced in GROOVE using the proposed Ontology Pattern Grammar.

## VII. CONCLUSION

In this paper, we employ the formalism of a graph grammar to propose an alternative formulation of the OntoUML language, fully defining it as an Ontology Pattern Grammar. Given that (as shown in [4]) OntoUML is among the most used modeling languages for ontology-driven conceptual modeling, we believe that the results presented here amount to a theoretical and practical contribution to the conceptual modeling community.

In an extended version of this paper, we shall elaborate on a version of the OntoUML modeling tool that fully implements a computational support for the modeling strategy proposed here, in which models are completely constructed by the restricted combination of these patterns as higher-granularity modeling primitives (see discussion in [5]). We believe that this strategy dramatically reduces the complexity of the modeling process, especially for novice modelers. This

is, of course, an empirical question, which we intend to address in a series of experiments.

As discussed in [6], the observation of the application of OntoUML over the years conducted by a variety of groups in a variety of domains amounted to a fruitful empirical source of knowledge that triggered the evolution of both UFO and OntoUML. In this process, termed *Systematic Subversions* [6], users of the language systematically created models that were (purposefully) grammatically incorrect but which were needed to express the intended characterization of their underlying conceptualizations that could not be expressed otherwise. These includes the representation of event-related phenomena in structural conceptual models [17], the representation of *powertypes* [18] (types whose instances are types, not individuals), as well as the representation of anti-rigid types (e.g., roles, phases) and non-sortal types (i.e., categories, mixins and role-mixins, whose instances are moments (relators, modes) [19]. As a follow up of this paper, we intend to

propose an updated version of the OntoUML pattern grammar presented here to formally account for new patterns and constraints related to the modeling of these phenomena.

We would like to highlight that the definition and implementation of the language as presented here bring several benefits to this community, namely: (i) the grammar is defined in a formal, Turing powerful, computational method that circumvents the limitations of the current meta-modeling approaches for defining the abstract syntax of modeling languages; (ii) the language is defined in a way that affords its independence from the UML meta-model and, as consequence, the results presented here can be ported to other conceptual modeling languages and employed by the conceptual modeling community at large; and (iii) the language makes explicit its constituting ontology design patterns which, once more, reflect the ontological micro-theories put forth by UFO. In other words, in comparison to the current definition of OntoUML's abstract syntax (in terms of a UML 2.0 meta-model with associated OCL constraints), the implementation of this language in the manner proposed here affords a much higher *ontological transparency* for the language, *i.e.*, the implementation makes much more transparent the ontological commitments embedded in that conceptual modeling language.

In summary, we believe to have proposed in this paper what is (to the extent of our knowledge) the first attempt to produce a general-purpose conceptual modeling language that is ontologically well-founded, explicitly defined as an ontology pattern language, and not tied to a particular legacy meta-model (the UML 2.0 meta-model).

**Abstract**—This paper deals with the process of identifying the parameters of the dynamic equivalent (DE) load model of an active distribution system (ADN) simulated in RTDS using mean-variance mapping optimization (MVMO) algorithm. MVMO is an emerging variant of population-based, evolutionary optimization algorithm whose features include evolution of its solutions through a unique search mechanism within a normalized range of the sample space. Due to the prominent large-scale integration of DG in low and medium voltage networks, it is important to develop equivalent models that are suitable for representing the resulting active distribution network in dynamic studies of large power systems. This would significantly reduce the computational demands and simulation time. Moreover, only a defined portion of a system is usually studied, which means that the external system can be substituted with DE thereby allowing the detailed modelling of the focus area. The IEEE 34-Bus distribution system was modified and used as the reference network where measurement data were gathered for identification of the parameters of its developed DE. An optimization-enabled simulation involving MATLAB, which host the MVMO algorithm and RTDS, which simulates the models was established. The reactions of the detailed network and the DE were compared upon subjecting them to different disturbances in the retained system. The effectiveness of the MVMO algorithm in identifying DE parameters based on its unique mapping function is reflected through the results of the response comparison.

## I. INTRODUCTION

OVER the last couple of years, there has been an increase in the level of renewable energy resources in the electricity grid. Recently, countries such as Germany and Portugal have reportedly supplied most of their energy demands using only renewable energy sources. Consequently, several technical challenges are being faced by utilities with respect to planning and operations of the modern power system. The surge in the capabilities of power electronic devices implies that more large-scale integration of RES such as Wind, PV, Biomass etc. should be expected, especially in MV/LV networks. As a result, there is a paradigm shift in the LV networks from traditionally passive to active networks.

Prior to these technological advancement, power systems planners and operators have utilized results from power system

stability simulation studies to make appropriate decisions on both short and long-term basis. They use simulations to evaluate the performance and limits of power system components in the network upon subjection to several operating conditions which could compromise the stability of the system. Among all power system components, the need to model the electrical characteristics of loads accurately due to their significant influence on the dynamic behaviour of the power system as long been acknowledged and documented [1], [2], [3]. Besides, a working group (WG) C4.605: "Modelling and aggregation of loads in flexible power networks" was established by CIGRE Study Committee in 2009 to address cogent issues related to load modelling. Since then, they have provided critical and updated overview about the current methodologies and approaches used in load modelling [4].

Most notable among the results of an international survey of utilities done by the work group is the lack of aggregated load models for active distribution networks [5]. Admittedly, it was realized that very few recommendations for dynamic equivalencing of ADN and microgrids exist from the industry. Their preliminary reports suggest that supplementary development of equivalent models for ADNs and MGs be investigated. Moreover, the intermittent nature of the DGs in the active distribution network stresses the need for power system planners to develop adequate models that efficiently represent the grid. These models would facilitate reasonable technical and economic decisions to maintain the stability and reliability of their network.

However, it is a herculean task to build detailed models for such large and multifaceted network due to the computational resources required and the long simulation period. For these reasons, only the specific region of interest (internal network) is usually modelled in detail while the rest of the system (external network) is reduced to equivalent models that provide similar responses [6]. Dynamic equivalent (DE) models are simple aggregated representation of large networks, able to provide similar dynamic responses and behaviours as the actual network for stability analysis. Although developing

them can be complex, they significantly reduce the simulation time and computational resources.

There are two main steps required to develop adequate DE models. First is to establish the proper structure of the DE based on the characteristic of the region of the network to be reduced. Many methods have been implemented and well documented in literature such as [7]. However, according to [5], only a few have been deployed for ADNs in real time digital simulations. The DE structure that is used in this research is based on recommendations from [8] as shown in Fig. 1. Secondly, a means of identifying the parameters of the defined model is executed such that its responses correlate with those of the reference detailed system upon subjection to the same disturbances. There have been many studies done on developing such aggregate models in several software like PSSE and DigSilent Powerfactory [9] however, only few have been done on models developed in Real Time Digital Simulators. This research contributes to this important field of load modelling by implementing an optimization-enabled real time digital simulation of ADN.

Fig. 1. Dynamic Equivalent load model structure

After establishing the DE structure, reference signal data from the simulated detailed model are used for the identification of appropriate DE parameters. To do this, several optimization techniques based on metaheuristics such as Genetic Algorithms, (GA) [10], Particle swarm optimization (PSO) [11] and Levenberg-Marquardt algorithm (LMA) [12] have been proposed. However, these techniques have some common limitations such as slow convergence, high computational cost, being trapped in a local optimum or low efficiency, with some having better characteristics than others. These problems are due to the non-linear, non-convex and multi-modal nature of the optimization challenge in attempts to properly identify parameters. Nevertheless, due to impressive results of these heuristic-based techniques, this work uses the mean-variance mapping optimization algorithm (MVMO), with its special mapping function described in [13], to determine the parameters of the DE model on RTDS.

The rest of this paper is structured as follows: Section II presents the project approach while the model used are

discussed in Section III. The MVMO procedure is elaborated in section IV while the test cases and the associated results are presented in Section VI. Finally, derived conclusions and recommendations for further studies are provided in Section VII.

## II. PROPOSED APPROACH

Fig. 2 illustrates the general approach adopted in this research. The reference signals i.e. active and reactive power, were measured at the point of common coupling between the detailed distribution system and the external grid by applying specific disturbances in the external grid. These signals were then stored for subsequent comparison with those measured from the PCC of the DE model. The error between the signals is fed to MVMO algorithm as an objective function. Thereafter, the algorithm supplies new parameters, as a vector  $x$ , to the dynamic equivalent model based on its internal evolutionary mechanism. The optimization process stops when the termination criteria is fulfilled. Then the best obtained parameters are updated to the model thus producing a sufficient dynamic equivalent.

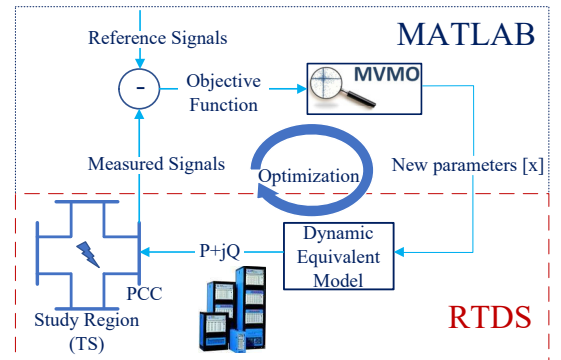

Fig. 2. Research approach

The MVMO optimization algorithm is available as a MATLAB script while the models are built in the RTDS software, RSCAD and simulated in RTDS/Runtime.

## III. DEVELOPED MODELS

The reference detailed model adopted in this research due to the lack of actual field measurement data is the IEEE 34-Bus distribution system, an actual system in Arizona, provided by the IEEE Power Engineering Society [14]. It operates at a voltage level of 24.9KV and includes transformers, voltage regulators, shunt capacitors, overhead distribution lines as well as distributed and spot loads which sum up to 1.769MW/1.04MVAR, thus making it an ideal system for this research. However, the system was modified to become an active DS by including PV generation on 3 buses as described in Fig. 3. The modified system was connected to an external transmission system equivalent grid through a transformer and a 120km transmission line. In addition, induction motors were also added at a few nodes to increase the contribution of dynamic loads in the detailed reference model.

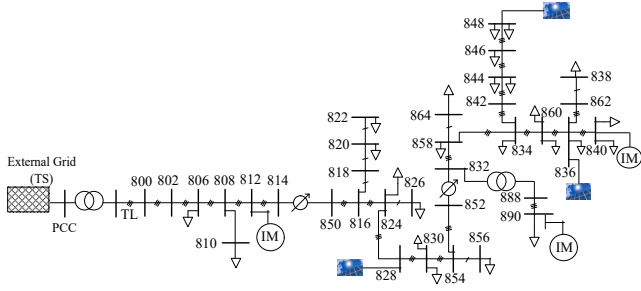

Fig. 3. Modified IEEE 34-Bus reference model

The PV system used for the above modification and also as an aggregate in the DE was modelled using a PV array component in RSCAD component library. The voltage source converter was simulated with small time step in RTDS due to its high switching frequency. The control blocks and the interfacing of the PV array to the grid was implemented as done in [15]. A unique scaling feature is available on the VSC interface transformer which allows the generated power of the PV to be increased without changing any variables. The structure of the DE model was already shown in Fig. 1. The parameters that were chosen for optimization in each block are: the length of the equivalent line, the scale factor and reference voltage ( $V_{sdref}$ ) of the PV model, the ZIP percentages of the load on each phase which totals 18 parameters (6 parameters per phase), and 6 parameters of the IM model. In total, 26 parameters were chosen for optimization. These would determine the accuracy of the DE during the period of disturbance.

#### IV. MVMO-BASED SOLUTION PROCEDURE

Fig. 4 illustrates the overall procedure of the MVMO algorithm as implemented in this research. Firstly, the optimization parameters of the model are initialized with their upper and lower bounds. Then the numerical configuration of the algorithm is done. In this case, its settings are as follows: total number of evaluation is 200, the solution archive size is 4, number of parameters to be randomly varied is 13 and the scaling factor is set to 1. Thereafter, the automated phases of the procedure commence with MVMO generating an initial solution vector by randomly sampling the optimization parameters within the defined  $[min, max]$  bounds.

Since MVMO's evolution mechanism operates in the normalized search space, the generated values are scaled to the  $[0, 1]$  range. This search range restricts the algorithm to the defined boundaries. However, the variables are de-normalized before sending them to the RTDS for dynamic simulations and subsequent objective function evaluation. The OF takes as input, the signals stored from the detailed model and those from the simulation of the DE model. Its output is evaluated for fitness and determines the evolution procedure in the inner loop of the flowchart, shaded in Fig. 4.

The inner loop constitutes the core of the algorithm. The solution archive is continuously updated based on the previous outcomes. The best outcome available in memory is chosen as

the parent solution from which new solutions (i.e. offspring) are generated. The unique mapping function is also applied to strategically produce new values for an optimization variable set. This phase is known as the mutation phase. The entire optimization procedure is concluded upon fulfilling the termination criterion, which is the specified number of evaluations. An elaborate description of the MVMO algorithm is addressed in [13].

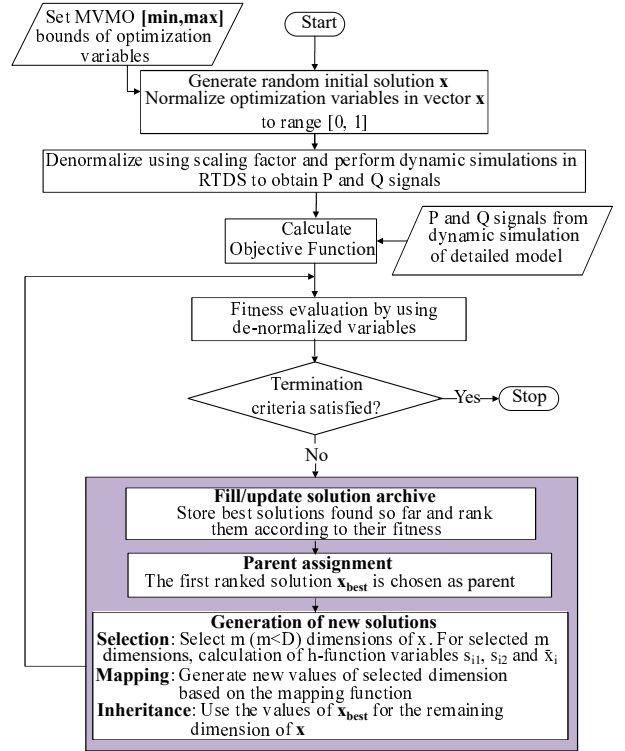

Fig. 4. Flowchart of the approach used for identification of parameters of DE with MVMO

##### A. Optimization Problem Statement

The desired goal of the optimization is to derive optimal values of parameters that effect the closest match between the behaviours of the dynamic equivalent model and the detailed model. To do this, the active and reactive power signals are measured at the boundary bus between the external grid and both models. The comparison is formulated as the objective function given in 1:

Minimize:

$$OF = \sum_{n=1}^p \sqrt{\alpha_n \int_0^{\tau} [(P_n - P_{n_{ref}})^2 + (Q_n - Q_{n_{ref}})^2] dt} \quad (1)$$

Subject to:

$$x_{min} \leq x \leq x_{max} \quad (2)$$

Where  $P_n$  and  $Q_n$  are the active and reactive power signals of the DE, while  $P_{n_{ref}}$ ,  $Q_{n_{ref}}$  are the corresponding signals from the detailed model.  $p$  is the number of disturbances,  $\alpha_n$

is the probability of the  $n$ th disturbance and  $\tau$  is the simulation period. Also,  $x$  is the solution vector that constitutes the set of DE parameters to be optimized while  $x_{min}$  and  $x_{max}$  are the minimum and maximum values defined for each parameter in  $x$ . Equation 1 is based on the Euclidean distance function which calculates the point to point distance between two signal vectors. The algorithm aims to reduce this distance error, thus providing very similar response signals.

### B. Dynamic Simulation

Dynamic simulation of the detailed and equivalent models is implemented in RSCAD Runtime environment. To establish a link between RTDS and MATLAB which host the MVMO, a TCP/IP connection is established as described in Fig. 5. A special Runtime script command called 'ListenOnPort()' is used to open a specific communication port (Runtime becomes a server) for MATLAB to connect as a client. Once the connection is established, the port becomes a bi-directional communication channel. Hence, the P and Q signals derived at the PCC upon applying a fault in the external grid is sent through this port to MVMO on MATLAB. The OF is calculated using equation 1 and new parameters are sent in the other direction from MATLAB to RTDS/Runtime. Sliders are used in the Runtime module to accept the new de-normalized parameters and a push button component is used to initiate the fault occurrence.

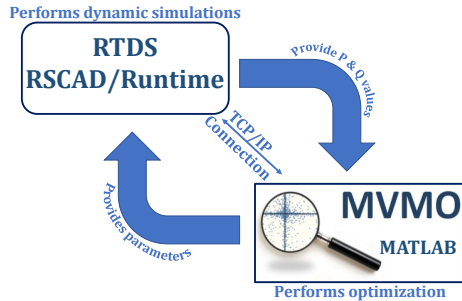

Fig. 5. MATLAB and RSCAD/Runtime Interaction

MATLAB has a `jtcp.m` program which enables it to send and/or receive TCP packets. Some of the basic functions used in MATLAB to communicate with RTDS/Runtime are detailed below:

- `JTCPOBJ = jtcp ( 'REQUEST', Host, Port)` represents a request from MATLAB to RTDS/Runtime to establish a TCP/IP connection on the specified port opened by RTDS/Runtime. The host can be represented by an IP address string (e.g. '192.168.0.10') or by a hostname. Since both applications are on the same host, a loopback address ('127.0.0.1') was used. Port is an integer number between 1025 and 65535 which must be open by the server to enable connection.
- `jtcp ( 'writes', JTCPOBJ, msg)` sends the specified information contained in the 'msg' variable to RTDS/Runtime through the TCP/IP connection.

- `rmsg = jtcp ( 'read', JTCPOBJ)` reads the information that is sent from RTDS/Runtime through the communication port and stores it in a variable 'rmsg'.
- `jtcp ( 'close', JTCPOBJ)` closes the port thereby ending the TCP/IP connection between RTDS/Runtime and MATLAB.

The variable "JTCPOBJ" stores all the necessary information flowing through the communication port which are needed by the remaining functions of the algorithm.

### C. Solution archive

The solution archive is one of the key features of MVMO algorithm. It serves as the knowledge database which guides the algorithm's search direction. Essentially, the  $n$ -best solutions that MVMO has derived at any point in the iteration, with their corresponding fitness value,  $d$  factors and shape, are stored in the archive. The archive size is specified at the beginning of the optimization through the main script.

Furthermore, the archive is gradually filled up in a descending order of fitness as the iteration progresses. When the archive is full, it is only updated if a newly generated solution has better fitness than those already stored in the archive. After each update, the mean and shape variables of every optimization parameter  $x_i$  are calculated using equations 3 and 4 respectively.

$$\bar{x}_i = \frac{1}{n} \sum_{j=1}^n x_i(j) \quad (3)$$

$$s_i = -\ln(v_i) \cdot f_s \quad (4)$$

where the variance  $v_i$  is computed as follows:

$$v_i = \frac{1}{n} \sum_{j=1}^n (x_i(j) - \bar{x}_i)^2 \quad (5)$$

Initially,  $\bar{x}_i$  is the same as the randomly generated value of  $x_i$ , and  $v_i$  is set to 1. The geometric characteristics of the mapping function is highly influenced by the shape variable  $s_i$ , thus, the reason for  $s_i$  being dependent on the user defined scaling factor  $f_s$ . Moreover,  $s_i$  facilitates the control of the mapping function hence the search process.

### D. Evolution of new solutions

The process of generating new offspring solutions distinguishes MVMO from other algorithms. After the parent vector,  $D$  is chosen, a subset  $m$  out of  $D$  optimization variables are selected for mutation through a random, sequential selection scheme. The mutation is facilitated by the mapping function which samples the random selected dimension  $x_i$  within the  $[0, 1]$  limits. The mean and variance of the selected dimension is explored by the function to produce new values. These parameters influence the way the shape of the mapping function varies. As a result, the algorithm's control can switch from a search exploration mode to a search exploitation mode. The mapping function used in this paper based on [13] is as follows:

$$\begin{aligned}
& \text{if } x_r^* < 0.5 & \text{if } x_r^* \geq 0.5 \\
s_1^* &= s_1 / (1 - \bar{x}) & s_2^* &= s_2 / \bar{x} \quad (6) \\
h_m &= \bar{x} - \frac{\bar{x}}{(0.5 \cdot s_1^* + 1)} & h_m &= \frac{(1 - \bar{x})}{(0.5 \cdot s_2^* + 1)} \\
h_f &= \bar{x} \cdot (1 - e^{-x_r^* \cdot s_1^*}) & h_b &= (1 - \bar{x}) / ((1 - x_r^*) \cdot s_2^* + 1) + \bar{x} \\
h_c &= (\bar{x} - h_m) \cdot 2 \cdot x_r^* & h_c &= h_m \cdot 2(1 - x_r^*) \\
x_i^{new} &= h_f + h_c & x_i^{new} &= h_b - h_c
\end{aligned}$$

where  $\bar{x}$  is the mean of the selected variable  $x_i$ ,  $x_i^{new}$  represents the new value of the selected dimension  $x_i$ .  $s_1^*$  and  $s_2^*$  denote the shape factors which vary around measure of entropy as expressed in 5. The entropy measure is a function of the selected variable variance  $v_i$ . The values of  $\bar{x}$  and  $v_i$  are derived from the values available in the solution archive [13].

## V. TEST CASE

A modified version of the IEEE 34-Bus distribution system was used in this research. PV generators and induction motor were connected to different buses to create an active distribution system and account for industrial dynamic loads respectively. The PV generation accounted for 40% of the load while the IM added about 15% additional load. Active (P) and reactive power (Q) signals were measured at the point of common coupling (i.e. HV side of the interfacing transformer) between the external grid and the distribution grid. The measurements were done after three phase faults described in table I were implemented in the external TS grid. Thereafter, these data were stored and used as reference data for validating the parameters of the developed DE load model mentioned in the previous section.

TABLE I  
FAULT CASES

Fault Voltage (pu)	Source Impedance (ohms)	Fault Duration (ms)
0.2	1.0	100
0.4	1.0	100
0.6	1.0	100

Three fault scenarios were considered in this study. The faults were simulated in the external grid by instantaneously varying the level of the source voltage behind a source impedance. The three-phase source model that was used to represent the external grid in RSCAD has a remote fault feature which allows the faults to be initiated while the simulation is running. However, only three-phase faults can be simulated. The percentage drop in the source voltage during faults represents the occurrence of the faults at various places within the transmission system equivalent grid. The

fault duration was set to 100ms through the source model configuration menu. The application of fault during every function evaluation was automated through a MATLAB script which sends instruction to RSCAD/Runtime to push the fault button.

## VI. NUMERICAL RESULTS

The simulations were performed on a personal computer with Intel(R) Core(TM) i7-4510U CPU @ 2.0GHz and 8 GB RAM. As mentioned previously, the algorithm was implemented by interfacing MATLAB which performs the optimization with RTDS/Runtime where the dynamic equivalent model is simulated. A special scripting feature in RTDS/Runtime facilitated the communication between both applications. It takes less than a second for MVMO to generate new parameters. However, due to time delays included in the script to allow the model to stabilize in RTDS, it takes approximately 2 minutes to run one iteration of the optimization scheme.

The termination criterion used for the algorithm is the number of evaluations which was set to 200. A fault is applied in the external grid during each evaluation and the error between the power signals of the detailed and DE model is reduced as the iteration progresses. Fig. 6 shows the convergence of MVMO as it attempts to find the least error. It can be observed that MVMO converges quite fast and obtains a nearly optimal solution after about 100 evaluations which is reached within 3.5 hours.

Fig. 6. Convergence plot of MVMO

The value of the objective function is based on the calculation of the Euclidean distance between the active and reactive power signals generated from the detailed and DE models. Since the timestep used for the dynamic simulation in RTDS is about  $55\mu s$ , the data points for 1 second simulation is 18,182. Therefore, the point to point distance is suitable for determining the difference in the curves. After 200 evaluations, the objective function value was 0.6987 which implies an approximate error reduction of about 95%.

Fig. 7 and 8 show the result of the first and second fault scenarios. The first fault i.e. 0.2pu was applied during the parameter identification process while the second fault 0.4pu was applied to the DE model derived from the first scenario as a way of validating the model. From Fig. 7, it can be seen that the DE model produces an identical response to the detailed model response. Besides, similar responses were also derived when a random fault not used during the optimization procedure was applied as shown in Fig. 8.

Fig. 7. Fault simulation result for 0.2pu retained voltage

Fig. 8. Fault simulation result for 0.4pu retained voltage

## VII. CONCLUSIONS

The application of MVMO for identification of dynamic equivalent parameters in Real time digital simulation was presented in this paper. An optimization-enabled real time digital simulation was implemented by connecting MATLAB to RTDS. PV models were included in the detailed model to properly represent an active distribution network. The suitability of the heuristic-based MVMO algorithm was evident through the close similarity of the DE model reactions to

those of the detailed model. Through its unique search and evolutionary mechanism, adequate parameters of the dynamic equivalent model were generated. Therefore, computational resources and simulation time can be reduced by replacing a detailed distribution system with the DE model. The MVMO exhibits fast convergence which proves its effectiveness in reducing the error between the signals measured on the detailed model and the DE model. To further reduce computation time, future research would explore the possibility of implementing parallel computing with the optimization procedure. The inclusion of other DGs to the reference model shall also be considered in subsequent research.

# 12<sup>th</sup> International Symposium Advances in Artificial Intelligence and Applications

**A** AIA'17 will bring scientists, developers, practitioners, and users to present their latest research, results, and ideas in all areas of Artificial Intelligence. We hope that successful applications presented at AAIA'17 will be of interest to researchers who want to know about both theoretical advances and latest applied developments in AI.

## TOPICS

Papers related to theories, methodologies, and applications in science and technology in this theme are especially solicited. Topics covering industrial applications and academic research are included, but not limited to:

- Decision Support
- Machine Learning
- Fuzzy Sets and Soft Computing
- Rough Sets and Approximate Reasoning
- Data Mining and Knowledge Discovery
- Data Modeling and Feature Engineering
- Data Integration and Information Fusion
- Hybrid and Hierarchical Intelligent Systems
- Neural Networks and Deep Learning
- Bayesian Networks and Bayesian Reasoning
- Case-based Reasoning and Similarity
- Web Mining and Social Networks
- Business Intelligence and Online Analytics
- Robotics and Cyber-Physical Systems
- AI-centered Systems and Large-Scale Applications

We also encourage researchers interested in the following topics to submit papers directly to the corresponding workshops, which are integral parts of AAIA'17:

- AI in Computational Optimization (WCO'17 workshop)
- AI in Language Technologies (LTA'17 workshop)
- AI in Medical Applications (see AIMA'17 workshop)
- AI in Reasoning and Computational Foundations (AIRIM'17 workshop)
- AI in Information Retrieval (ASIR'17 workshop)

All papers accepted to the main track of AAIA'17 and to the above workshops will be treated equally in the conference programme and will be equally considered for the awards listed below.

## PROFESSOR ZDZISLAW PAWLAK BEST PAPER AWARDS

We are proud to continue the tradition started during the AAIA'06 and award two "Professor Zdzisław Pawlak Best Paper Awards" for contributions which are outstanding in their scientific quality. The two award categories are:

- Best Student Paper—papers qualifying for this award must be marked as "Student full paper" to be eligible.
- Best Paper Award.

In addition to a certificate, each award carries a prize of 300 EUR provided by the Mazowsze Chapter of the Polish Information Processing Society.

## ZDZISLAW PAWLAK AWARD COMMITTEE

**Abstract**—Recommender systems are software tools and techniques which aim at suggesting to users items they might be interested in. Context-aware recommender systems are a particular category of recommender systems which exploit contextual information to provide more adequate recommendations. However, recommendation engines still suffer from the cold-start problem, namely where not enough information about users and their ratings is available. In this paper we introduce a method for generating a list of top  $k$  recommendations in a new user cold-start situations. It is based on a user model called Contextual Conditional Preferences and utilizes a *satisfiability* measure proposed in this paper. We analyze accuracy measures as well as serendipity, novelty and diversity of results obtained using three context-aware publicly available datasets in comparison with several contextual and traditional state-of-the-art baselines. We show that our method is applicable in the new user cold-start situations as well as in typical scenarios.

## I. INTRODUCTION

RECOMMENDER systems are software tools and techniques which aim at suggesting to users items they might be interested in. Context-aware recommender systems are a particular category of recommender systems which exploit contextual information to provide more adequate recommendations. For example, a restaurant recommendation for a Saturday evening with your friends should be different from one suggested for a workday lunch with co-workers [1].

We distinguish three forms of context-aware recommendation processes: a *contextual pre-filtering*, a *contextual post-filtering* and a *contextual modeling* [2]. *Pre-filtering* approaches use a current context to select a relevant subset of data on which a recommendation algorithm is applied. *Post-filtering* approaches exploit a contextual information to select only relevant recommendations returned by some algorithm. *Contextual modeling* differs from other techniques as it incorporates a context into a recommendation algorithm.

During last decades many context-aware approaches were proposed. But usually they have considered a situation where a lot of data is available. On the other hand, a recommender systems research still strives for solving the cold-start problem, namely where we have not enough information about users and

their ratings. For example, matrix factorization methods do not work well in the cold start scenarios [3].

Different situations described in the literature are called a cold-start problem. Two of them are well-known and have also another names, respectively: a new item and a new user cold-start problem. Both occur when a recommender system is well-established and a lot of ratings are available. When we introduce a new item into such system, in many recommendation algorithms it will not be recommended to users, because of the lack of its history, i.e. user ratings. The same happens when a new user registers into the recommender system. He will not receive interesting recommendations just because the system does not know his preferences yet [4].

In this paper we introduce a method for generating a list of top  $k$  recommendations in a new user cold-start situations. It is based on a user model called contextual conditional preferences [5] which represents user interests in items in a compact way. We run our experiments on a context-aware datasets publicly available in the Web, i.e. LDOS-CoMoDa dataset [6], Unibz-STS [7] and Restaurant & consumer data [8]. We confirmed that our method is applicable in the new user cold-start situations as well as in typical scenarios.

The main contributions of this paper are:

- a new measure of *satisfiability* to describe how much an item satisfies a contextual conditional preference,
- an algorithm for context-aware reshuffling of items in the recommendations list using contextual conditional preferences.

The advantages of the method are: (I) a possibility to combine it with existing algorithms for a ranking task, and (II) the ability to work well in a typical scenario and a new user cold-start scenario.

The remainder of the paper is constructed as follows. Related work is presented in Section II. Section III briefly introduces contextual conditional preferences and describes our method for generating a list of top  $k$  recommendations. In Section IV the datasets are described. Algorithms and measures used for the evaluation are presented in Section

V. Section VI provides our evaluation approach and obtained results. Conclusions close the paper.

## II. RELATED WORK

The idea of modeling user interests with a preference relation is not new. In [9] a formalism of CP-nets was proposed. CP-nets are intuitive graphical models for representing conditional preferences under the *ceteris paribus* (“all else being equal”) assumption. Preferences presented in this paper always contain “conditional part” which consists of contextual parameters only. Another difference is the lack of the *ceteris paribus* assumption.

In [10] constraint-based recommender systems were described. Since users define their preferences in the form of requirements for a product, they mainly focus on solving the constraints satisfaction problem while recommending new items. Additionally, authors proposed an algorithm that ranks the recommended items according to their degree of a constraint fulfillment. Our approach is slightly similar to this method, because the contextual conditional preferences could be seen as constraints. Furthermore, we also rank and reshuffle items in the primary recommendation list according to a level of a satisfaction of the CCPs. Nevertheless, we focus mostly on the context-awareness and learn the CCPs from a users history.

Contextual preferences were described in [11] as database preferences annotated with a contextual information, where contextual parameters take values from hierarchical domains, allowing different levels of abstraction. While using CCPs, a generalization of contextual variables is not possible.

Context-Aware Recommender Systems is a well-established research area and many recommendation techniques were already proposed. A multi-agent system for making context and intention-aware recommendations of Points of Interest (POI) was presented in [12]. The tasks of collecting an information about POIs and storing a users’ profiles data were divided into two kinds of agents. The user’s Personal Assistant Agent is responsible for receiving queries, storing user data, computing recommendations and updating user preferences according to his feedback. Authors incorporated not only the context but also a user’s goal in visit the POI. Besides a context-awareness, this approach and ours are completely different.

An interesting approach for a context-awareness was proposed in [13]. Authors introduced *micro profiles* which split a user profile into partitions depending on the values of context parameters. They showed that usage of such *micro profiles* gives a significant improvement in the prediction accuracy in the movie domain while considering time as a context variable. CCPs could be seen as a kind of *micro profiling*, because each preference statement consists of user interests and a context in which it is true.

In [14] a new context-aware music recommender system was presented. As a main recommendation technique authors used case-base reasoning (CBR). CBR systems store knowledge in the case base in the form of *cases*. During a recommendation task, the cases are compared to the current

case according to some similarity measure. In the paper, 2-step case-based reasoning was used. Firstly, to determine similar context, and then to find similar users to make predictions. Contextual conditional preferences could be seen as cases, but in fact they are something different. We chose active preferences according to a similarity measure so we could position our work in the CBR research area. However, we do not have iterations or a relevance verification in the recommendation process.

One of the possibilities for contextual pre-filtering are Context-Aware Splitting Approaches (CASA). We could distinguish three kinds of them, i.e. item splitting, user splitting and UI splitting which combines the first two [15]. For the item splitting, we split the item into two items depending on the contextual factor and its value assuming that the user’s ratings are significantly different. Analogously, we could split user into two users based on the contextual condition. The UI splitting uses both kinds of splits, for items and for users. It should be notice that the best contextual factor for splitting users and items could be, and usually is, different, i.e. we do not use the same contextual condition to split users and items. The only two similarities between our post-filtering method and this approach are incorporating contextual information into a recommendation process and dependance from other existing non-contextual algorithms, i.e. both methods cannot be used alone.

A context-aware extension of the SLIM algorithm, contextual SLIM (CSLIM), was introduced in [16]. Authors used a binary vector to denote a contextual situation, i.e. context parameters and their corresponding values. They followed the idea of an aggregation of users’ ratings on other items, and add contextual factors into this aggregation. In the case when no other items were ranked in a certain context, the rating is estimating based on user’s non-contextual ratings on this item. Authors showed that the method outperforms the basic SLIM algorithm as well as context-aware matrix factorization methods. This algorithm differs from our method as it incorporates context in the recommendation phase. Thus, it could be classify as a context modeling method. In contrast, our method is positioned as a post-filtering technique.

An interesting approach was introduced in [17]. Authors presented a context-aware system for events recommendation that addresses the new item cold-start scenario. They identified many contextual signals and models, and used them as features for learning to rank events.

A hybrid matrix factorization model for the cold start problem was presented in [3]. It was shown to work well with the cold and warm start scenarios. Similarly to our work, author used both, user and item information.

## III. GENERATING TOP $k$ RECOMMENDATIONS

The proposed method can be classified as a post-filtering technique. We rely on existing non-contextual algorithms to generate a primary recommendations list which we then reshuffle as described in Section III-C. For this purpose we use

the Contextual Conditional Preferences Model whose details are presented in Section III-A.

#### A. Contextual Conditional Preferences Model

Contextual conditional preferences (CCPs) introduced in [5], [18] are a compact representation of user interests in items in different situations. This model describes relations between a context related to a user's ratings and an item content, and consists of a set of conditional preferences.

We define the Contextual Conditional Preference (CCP) as an expression of the form:

$$(\gamma_1 = c_1) \wedge \dots \wedge (\gamma_n = c_n) \mid (\alpha_1 = a_1) \succ (\alpha_1 = a'_1) \wedge \dots \wedge (\alpha_m = a_m) \succ (\alpha_m = a'_m)$$

with  $\gamma_i$  being contextual variables and  $\alpha_i$  item attributes, and  $c_1, \dots, c_n, a_1, a'_1, \dots, a_m, a'_m$  being concrete values of these parameters.

The above preference is read as *given the context*  $(\gamma_1 = c_1) \wedge \dots \wedge (\gamma_n = c_n)$  *I prefer*  $a_1$  *over*  $a'_1$  *for*  $\alpha_1$  *and*  $a_m$  *over*  $a'_m$  *for*  $\alpha_m$ . An example of the CCP for the Unibz-STS dataset is shown below.

$$\begin{aligned} \text{weather} = \text{sunny} \wedge \text{companion} = \text{with children} \\ \mid \text{category} \in \{\text{walk and trail, park}\} \\ \succ \text{category} \in \{\text{museum}\} \end{aligned}$$

It means that for a given context (i.e. a sunny weather and a companion of the children) a user prefers POIs with categories like “walk and trail” and “park” to those with category “museum”.

We distinguish two types of CCPs: individual and general. An individual CCP (ICCP) represents preferences of a single user, while a general CCP (GCCP) catches a general trend of interests for all users in a certain contextual situation, i.e. we treat ratings from all users like they were made by one person. The GCCPs are very important for this work, since we are unable to learn ICCPs for new users (they do not have any rating history yet).

During our experiments we automatically generated CCPs. Details are described in the next section.

#### B. Contextual Conditional Preferences Extraction

An algorithm of a preferences extraction was originally published in [5].

In order to elicit preference relations we split the dataset into two parts based on the value of the ratings. Depending on a rating scale for a dataset we use a different threshold to divide ratings into positive and negative ones. Then, both datasets are divided into smaller sets containing all of the contextual information and one of the movie features. With such prepared data we computed context-aware individual preferences for each user by running the `Prism` algorithm [19] from the WEKA library<sup>1</sup> (version 3.6.11) to generate rules of the form

$$(\gamma_1 = c_1) \wedge \dots \wedge (\gamma_n = c_n) \mid (\alpha_1 = a_1) \succ (\alpha_1 = a'_1).$$

<sup>1</sup><http://www.cs.waikato.ac.nz/ml/weka/>

Then we compacted preferences with the same “conditional part” into one preference of the form shown below.

$$\begin{aligned} \text{season} = 3 \wedge \text{weather} = 1 \wedge \text{time} = 2 \wedge \text{mood} = 1 \\ \mid \text{genre} \in \{18\} \succ \text{genre} \in \{8, 12, 7\} \\ \wedge \text{director} \in \{5, 8\} \succ \text{director} \in \{3\}. \end{aligned}$$

It means that for a given context (e.g. season is 3 - Autumn) a user prefers a genre with id 18 to those with 8, 12 or 7 and directors from clusters 5 and 8 to those from cluster 3 etc.

If the value of some content parameter was the same on both sides of a preference relation for some certain user's context, then this value was marked as meaningless and not taken into consideration in this context for the user.

The main difference in the computation of general and individual preferences is that in the first case all the ratings from the dataset were treated like they were made by one person. As a consequence, we removed many contradictory values during the merging phase. To better understand the issue, let us consider an example in the movie domain from Tab. I. Besides information about rating for an item, we have also two contextual factors, i.e. *companion* and *day*, and one movie feature, i.e. *genre* in sample user profiles. For all three users we could compute ICCPs. We obtained following individual preferences for Alice:

$$\begin{aligned} \text{companion} = \text{family} \wedge \text{day} = \text{Sunday} \\ \mid \text{genre} \in \{\text{animated}\} \succ \text{genre} \in \{\text{superhero}\}, \\ \text{companion} = \text{friend} \\ \mid \text{genre} \in \{\text{thriller}\} \succ \text{genre} \in \{\text{drama}\}, \\ \text{day} = \text{Saturday} \\ \mid \text{genre} \in \{\text{fantasy}\} \\ \succ \text{genre} \in \{\text{drama, supernatural}\}. \end{aligned}$$

We could observe that Alice's movie preferences vary depending on the company and day. The same applies for Bob and Carol. General preferences (GCCPs) computed for sample profiles are shown below.

$$\begin{aligned} \text{companion} = \text{alone} \\ \mid \text{genre} \in \{\text{fantasy}\} \succ \text{genre} \in \{\text{sciencefiction}\}, \\ \text{companion} = \text{friend} \\ \mid \text{genre} \in \{\text{fantasy}\} \succ \text{genre} \in \{\text{drama}\}, \\ \text{day} = \text{Saturday} \\ \mid \text{genre} \in \{\text{fantasy}\} \succ \text{genre} \in \{\text{drama}\}. \end{aligned}$$

#### C. Reshuffling of recommendations list

An algorithm is presented in Algorithm 1. We describe it and refer to its concrete lines below.

We assume that ICCPs and GCCPs are generated for all non-new users, since new users do not have any rating history.

For a certain user and his current context, first we generate a primary list of top 100 recommendations with some existing non-context-aware algorithm, e.g. *User k Nearest Neighbors* (User kNN) [20] (line 1). Then we have to find the best CCPs that will be further used in the reshuffling process (line 2).

TABLE I  
SAMPLE USER PROFILES OF ALICE, BOB AND CAROL.

User	Item (Movie)	Rating	Companion	Day	Genre
Alice	Donnie Darko	1	friend	Saturday	drama, supernatural
Alice	Girl Interrupted	2	friend	Friday	drama
Alice	How To Hook Up Your Home Theater	4	family	Sunday	animated
Alice	Inception	5	friend	Friday	heist, thriller, science fiction
Alice	The Imaginarium of Doctor Parnassus	5	friend	Saturday	fantasy
Alice	Shrek	5	family	Saturday	animated, fantasy
Alice	Spiderman	1	family	Sunday	superhero
Alice	The Counselor	4	friend	Friday	thriller
Alice	The Lion King	4	family	Sunday	animated, adventure
Bob	An Unexpected Journey	5	alone	Saturday	fantasy, epic, adventure
Bob	City Of Angels	2	girlfriend	Saturday	fantasy, romantic, drama
Bob	Armageddon	2	alone	Friday	thriller, disaster, science fiction
Bob	Inception	1	alone	Tuesday	heist, thriller, science fiction
Bob	Green Mile	5	alone	Saturday	drama, fantasy
Bob	Hunger Games	2	alone	Saturday	science fiction, adventure
Bob	Tourist	4	girlfriend	Friday	thriller, comedy, romantic
Bob	Sleepless In Seattle	4	girlfriend	Friday	drama, comedy, romantic
Bob	The Desolation Of Smaug	5	alone	Tuesday	adventure, epic, fantasy
Carol	At Worlds End	5	friend	Friday	fantasy, swashbuckler
Carol	Dead Mans Chest	5	friend	Friday	fantasy, swashbuckler
Carol	Gangs Of New York	2	friend	Saturday	historical, drama, epic
Carol	The Imaginarium of Doctor Parnassus	5	friend	Saturday	fantasy
Carol	Return Of The King	5	alone	Saturday	epic, fantasy
Carol	The Curse Of The Black Pearl	5	friend	Friday	swashbuckler, fantasy
Carol	The Fellowship Of The Ring	5	alone	Saturday	epic, fantasy
Carol	Two Towers Film	5	alone	Tuesday	epic, fantasy
Carol	Cast Away	2	alone	Saturday	drama, adventure

In this case, the best preferences are those which are the most similar to the considered context. In order to count a contextual similarity between a CCP  $p$  and a current user context  $ctx(u)$  we used the following metric:

$$sim(p, ctx(u)) = \sum_{(\gamma_i, c_i) \in p} overlap(ctx(u), (\gamma_i, c_i)),$$

$$overlap(ctx(u), (\gamma_i, c_i)) = \begin{cases} 1 & (\gamma_i, c_i) \in ctx(u); \\ 0.5 & c_i = -1; \\ 0 & otherwise. \end{cases}$$

The overlap function returns 1 when the pair  $(\gamma_i, c_i)$  is contained in both: the contextual part of  $p$  and in the current user context  $ctx(u)$ . When the pair  $(\gamma_i, c_i)$  is not contained in neither or only in one set of pairs, 0 is returned. When it is uncertain, i.e. when the value  $c_i$  for the dimension  $\gamma_i$  is equal to  $-1$  (the unknown value), 0.5 is returned. Please note that the current user context  $ctx(u)$  is also a set of pairs  $(\gamma'_i, c'_i)$ , i.e. the name of the contextual variable and its value.

For each item in the primary recommendations list and each best CCP we compute *satisfiability* (line 7), namely how much an item  $i$  satisfies a CCP  $p$ :

$$sat(i, p) = \frac{\sum_{\alpha \in a(p)} (sim(v_{\alpha}^m(p), v_{\alpha}(i)) - sim(v_{\alpha}^l(p), v_{\alpha}(i)))}{|a(p)|},$$

where  $sim$  denotes Jaccard similarity,  $\alpha$  is the name of an item feature,  $a(p)$  is the set of item attributes considered in the CCP  $p$ ,  $v_{\alpha}(i)$  is the set of values of an attribute  $\alpha$  for an item  $i$ . Similarly  $v_{\alpha}^m(p)$  and  $v_{\alpha}^l(p)$  denotes the sets of values of an attribute  $\alpha$  for a CCP  $p$  on both sides of the preference relation -  $m$  stands for *more preferred* and  $l$  for *less preferred*.

The *satisfiability* measure represents the difference between item similarities to the both sides of the CCP's preference relation, i.e. the similarity to most preferred part minus the similarity of the less preferred part. In this way we reward items that fit the best to user preferences and penalize items that have features that user does not like, e.g. horror movies. The size of a set of item attributes serves as a normalization factor. Thus, disregarding to the number of item features, the value of *satisfiability* is always between 0 and 1.

The next step is to order the primary recommendations list according to the value of average *satisfiability* of the best CCPs (line 13). The last part is to cut off unneeded items from resulting recommendations list to receive top 5, top 10 or other top  $k$  ranking (line 14).

Let us consider again an example from Tab. I. We assume that some traditional recommendation algorithm returned a following top 10 list for Alice:

*Gangs Of New York, The Curse Of The Black Pearl, Cast Away, An Unexpected Journey, City Of Angels, Armageddon, Green Mile, Hunger Games, Tourist, Sleepless in Seattle.*

We consider a situation when Alice wants to watch a movie with a friend. With our reshuffling method, using two rules (ICCP for Alice profile and GCCP) for this contexts, we obtained the final top 5 recommendations list:

*An Unexpected Journey, Armageddon, Tourist, The Curse Of The Black Pearl, City Of Angels.*

*Fantasy* and *thriller* movies are higher in the final list, while *drama* movies were mostly cut off the list as expected from the user preferences. At this point, we will not evaluate results of this example. A comprehensive evaluation of the algorithm

**Algorithm 1** Generating the list of top  $k$  recommendations with CCPs

---

**Require:**  $alg$  - a name of a baseline algorithm,  
 $k$  - a number of recommendations in the final list,  
 $u$  - a user,  
 $ctx$  - a user context,  
 $ccps$  - a list of all CCPs for user  $u$

**Ensure:**  $topK$  - an ordered list of top  $k$  recommendations

```

list  $\leftarrow$  generateTop100Recommendations( $alg, u$ );
1: best  $\leftarrow$  findBestCCPs( $ccps, u, ctx$ );
   map  $\leftarrow$  empty HashMap;
4: for all item in list do
   sum  $\leftarrow$  0;
6:   for all ccp in best do
   sat  $\leftarrow$  satisfiability(item, ccp);
8:   sum  $\leftarrow$  sum + sat;
   end for
10:  avg  $\leftarrow$  sum/sizeof(best);
   map[item]  $\leftarrow$  avg;
12: end for
   rec  $\leftarrow$  order(map);
14: topK  $\leftarrow$  cutOff(rec, k);

```

---

TABLE II

BASIC STATISTICS OF THREE DATASETS: LDOS-CoMoDa (CoMoDa),  
 UNIBZ-STs (STS) AND RESTAURANT & CONSUMER (R&C).

	CoMoDa	STS	R&C
Number of users	121	325	138
Number of items	1232	249	130
Number of ratings	2296	2534	1161
Max number of ratings per user	275	175	18
Min number of ratings per user	1	1	3
Avg number of ratings per user	18.98	7.80	8.41
Max number of ratings per item	26	282	36
Min number of ratings per item	1	1	3
Avg number of ratings per item	1.86	10.18	8.93

is presented in Section VI.

## IV. DATASETS

We performed our experiments with three datasets, i.e. the LDOS-CoMoDa<sup>2</sup> dataset (LDOS), the Unibz-STs dataset (STS) and the Restaurant & consumer dataset<sup>3</sup> (RC). Basic statistics of the datasets are presented in Tab. II.

The LDOS-CoMoDa [6] contains user interaction with the system, i.e. the rating on a 5-star scale, the basic users' information, the content information about multiple item dimensions and twelve additional contextual information about the situation when the user consumed the item. According to [21] the choice of contextual variables to be used is crucial because of a different amount of information they gain. To eliminate irrelevant variables we computed correlation coefficients between context related attributes. We found only two

of them to be strongly correlated, i.e. *city* and *country*, which was known before the computation. Thus, we could conclude that none of the other contextual factors are correlated.

In [21] six variables in the LDOS-CoMoDa were identified as informative. Since we focus on the cold start problem in this paper, we want to limit the sparsity of the data as much as possible. Therefore, we chose two of six most informative contextual variables, i.e. *dominant emotion* and *end emotion*, to use in our further work presented in this paper. Since we also focus on general trends, we will use *age* parameter which we categorized into 5 groups.

The Unibz-STs [7] dataset was collected by a mobile application that recommends places of interests (POIs) in South Tyrol in Italy. The recommender is called South Tyrol Suggests (STS). The dataset contains ratings on a 5-star scale, an information about a users' personality (e.g. *extraversion*, *emotional stability*), a context of visiting a POI (e.g. *weather*, *season*, *companion*) and a POI's category.

The Restaurant & consumer data [8] consists of three types of information: a restaurant data (e.g. *cuisine*, *smoking*, *dress*), a user information (e.g. *smoker*, *dress preference*, *transport*) and a rating that a user gave to a restaurant. In this dataset ratings are expressed on a 0-2 scale. Contextual parameters such as an information about a user's mood or companion are not available.

## V. ALGORITHMS AND MEASURES

We had to choose some existing recommendation techniques to evaluate our approach since it is designed to work with any of baseline algorithms that generate a list of top  $k$  recommendations. We used six algorithms from the LibRec<sup>4</sup> library [22] that are appropriate for the ranking task, i.e. User kNN, BPR[23], FISM[24], Latent Dirichlet Allocation (LDA)[25], SLIM [26] and WRMF [27], [28] to be used in both scenarios.

To compare our work with other context-aware state-of-the-art algorithms, we chose two methods, i.e. Contextual SLIM (CSLIM) [16] and UI Splitting [15], and used their implementations from the CARSKit<sup>5</sup> library [29]. Since the UI Splitting approach is a pre-filtering technique, it needs to be combined with other existing algorithms. From the methods proposed in the CARSKit library, we chose those that overlap with the algorithms that we already used with our method, i.e. BPR, SLIM and User kNN.

To evaluate our method we use several measures for the ranking task available in the LibRec library, i.e. *mean average precision* (MAP), *mean reciprocal rank* (MRR), *normalized discounted cumulative gain* (nDCG) and the classical information retrieval measures: *precision* and *recall*. The latter two were computed on the top 10 recommendations list. We have also implemented four additional measures. The first one is a *diversity* measure proposed by [30], i.e. Intra-List Diversity

<sup>2</sup>The data is available at <http://212.235.187.145/spletnastran/raziskave/um/comoda/comoda.php>.

<sup>3</sup>The data sets are available at [https://github.com/irecsys/CARSKit/tree/master/context-aware\\_data\\_sets](https://github.com/irecsys/CARSKit/tree/master/context-aware_data_sets).

<sup>4</sup><http://www.librec.net/>

<sup>5</sup><https://github.com/irecsys/CARSKit/>

(ILD) that computes the average distance between each couple of items in the list  $R$ :

$$ILD(R) = \frac{1}{|R|(|R|-1)} \sum_{i,j \in R, i \neq j} (1 - sim(i, j)), \quad (1)$$

where  $i, j$  are items. The  $sim$  function is configurable and application dependent. In our work, we used Jaccard similarity as a similarity measure for all item attributes.

We wanted to compute the serendipity value for obtained recommendations lists. But the problem is that there is no one common serendipity measure. Thus, we decided to implement two measures, i.e. a simple metric presented in [31] and given by a formula (2) that we called *expectedness* and *unserendipity* proposed by Zhang et al. [32] and given by a formula (3).

$$expectedness = \frac{1}{k} \sum_{i=1}^k pop(i), \quad (2)$$

where  $k$  is the size of the recommendations list,  $i$  denotes an item and  $pop(i)$  is a popularity of an item  $i$ .

$$unserendipity = \frac{1}{|H_u|} \sum_{h \in H_u} \frac{1}{k} \sum_{i \in R_{u,k}} sim(i, h), \quad (3)$$

where  $u$  denotes a user,  $h$  is an item from a user history  $H_u$ ,  $k$  is the size of a user  $u$  recommendation list  $R_{u,k}$  and  $i$  denotes an item from a recommendations list  $R_{u,k}$ . The  $sim$  function used by Zhang et al. [32] was a cosine similarity. However, in our work we used the Jaccard similarity as with the previous measures.

Expectedness is a simple measure which sums up the popularity of all items in the recommendations list. The unserendipity measure is more complicated and checks how much items from a recommendations list are similar to those from a user history. Both measures are in opposite to the definition of serendipity. Thus, the lower values of those measures are, the better the serendipity of a recommendations list is.

The last measure is *novelty* [33] which expresses how much items from the list are unknown for a user. It is given by a formula:

$$novelty = \frac{1}{k} \sum_{i \in R_{u,k}} \log_2(pop(i)). \quad (4)$$

Similarly to the formulas presented above,  $u$  denotes a user,  $k$  is the size of a recommendations list  $R_{u,k}$ ,  $i$  denotes an item and  $pop(i)$  is its popularity.

All of the four measures above were computed on the top 10 recommendations list.

In recommender systems, we provide a list of top  $k$  recommendations for each user. However, in the context-aware recommender systems we need to incorporate a context also into an evaluation. Thus, we generate the top  $k$  list for each pairs of a user and his context. The resulting measures values are usually much smaller than the ones in traditional recommender systems, because it is not very common for users to rate multiple items within a same context. This type of evaluation has been used in prior research [15], [16].

## VI. EXPERIMENTS AND RESULTS

We performed two experiments on three datasets described in Section IV. The first, to simulate the new user cold-start situation. The second, to check if our method works also in a typical scenario.

To simulate two different scenarios we prepared two separate splits of each dataset into training and test sets for hold out validation. The following procedures were applied on each datasets.

To be able to check if the method is applicable for a new user cold-start scenario, we randomly chose 20% of users and put all of their ratings in the test set. Remaining ratings were used as a training set. With this construction of the training and test sets, we were unable to generate ICCPs for the test users (we do not have any rating of those users in the training set). Thus, we used GCCPs only. The results obtained with these splits are presented in the Tables III, IV and V, for LDOS-CoMoDa, Unibiz-STS and Restaurant & Customer datasets respectively. Because the *unserendipity* measures a similarity with a user profile and we have only new users in these splits, we omitted it in the tables. In all of the following tables a prefix *ctx-* denotes that the list obtained by the algorithm was reshuffled with our method.

The second splits were to test a typical situation. Thus we randomly chose 20% of each user's ratings and put them in the second test sets, while remaining users ratings were placed in the second training sets. The results obtained with these splits are presented in the Tables VI, VII and VIII, for LDOS-CoMoDa, Unibiz-STS and Restaurant & Customer datasets respectively. A prefix *ctx-* denotes that the list obtained by the algorithm was reshuffled with our method.

It should be notice, that we did not consider the new item problem during the splits. Therefore, all test sets contain some number of items which do not appear in the corresponding training sets.

It has been shown that the most informative contextual variables in the LDOS-CoMoDa dataset are those related to emotions, i.e. *dominant emotion* and *end emotion* [21]. Thus, we decided to use them in all the situations when we could compute both, ICCPs and GCCPs. For the new user scenario, when we are able to generate GCCPs only, we found also *user age* informative. It was not considered in the work [21], since it is fixed for a user for a long time (we have an age categorization), and could not be seen as a user context. Because of the same reasons, it is a bad contextual candidate to compute ICCPs.

The most informative contextual variables in the Unibiz-STS dataset are *weather* and *companion*. In the Restaurant & customer dataset, there are no truly contextual variables. However, we found *smoker*, *drink level*, *dress preference*, *ambience*, *transport*, *personality* and *color* the most useful for the further work.

We tested our method also with other contextual parameters, but the results were similar to those obtained by the traditional

baseline algorithms. It could be seen as a constrain for the proposed method - it is strongly context dependent.

As could be seen in Tables III, IV, V, VI, VII and VIII, the method is also algorithm dependent. It is impossible to identify one algorithm that is better than others in all of the cases for all of the datasets.

For the new user scenario with the LDOS-CoMoDa dataset, our post-filtering method works the best with FISM and LDA algorithms. They improves all of the measures besides *diversity*. The improvements vary for different measures but they are greater than 35 % in comparison with traditional baselines for the first six measures. The reshuffling with other algorithms also gives slightly better results than the traditional baselines in the new user scenario. Surprisingly, baseline context-aware algorithms perform pretty weak according to the accuracy measures. However, they obtained the best values for *expectedness*, *novelty* and *diversity* measures, which is shown in Tab. III.

Interesting is the fact that different algorithms which we combined our method with, are good for a typical scenario in the LDOS-CoMoDa dataset. In this case, the best algorithm to work with our approach is WRMF, which improves all metrics besides *unserendipity* and *diversity*. As seen in Tab. VI, all other algorithms combined with our reshuffling method, improve at least some measures - mostly nDCG and MRR, which means that good recommendations are usually higher in the ranking than without reshuffling, even if the number of good recommendations in the top 10 list is the same or smaller.

For the new user scenario with the Unibiz-STs dataset, the UI Splitting method with BPR algorithm outperforms all other methods according to all of the measures. For the reshuffling method, the best algorithms are SLIM, User kNN and WRMF, which improve all of the accuracy measures and *expectedness* and only slightly decrease *diversity*, which is presented in Tab. IV.

As could be seen in Tables VII and VIII, our reshuffling method performs the best in the typical scenario when combined with BPR and SLIM algorithms for the Unibiz-STs and Restaurant & customer datasets. For the Unibiz-STs dataset, our method with BPR algorithm gives better results for the *novelty* measure than UI Splitting with BPR, which is surprising, since UI Splitting improves *novelty* for almost all of the cases for all of the datasets.

For the new user scenario with the Restaurant & customer dataset, our reshuffling method outperforms all other algorithms according to the accuracy measures when combined with BPR, FISM and LDA algorithms, as shown in Tab. V. Thus, we could conclude that there is no one algorithm which always performs the best with our reshuffling method. It depends on the scenario and the dataset that the experiments are performed on.

From Tables III, IV and V, we could observe that CSLIM and UI Splitting with SLIM and User KNN give exactly the

same results for all of the datasets in the new user cold-start scenario. However, this never occurs for the typical scenario.

CSLIM and UI Splitting almost always give better values of the *expectedness*, *unserendipity*, *novelty* and *diversity* measures. Nevertheless, they received the worst *precision* and *recall* values for all of the cases beside the new user cold-start scenario for the Unibiz-STs dataset, when UI Splitting with BPR performed the best.

The value of *diversity* measure always decreases after reshuffling the primary recommendations list with proposed method. It seems to be the price for improving the accuracy of the recommendation process.

## VII. CONCLUSIONS

In this paper we introduce a method for generating a list of top  $k$  recommendations, which works well also in the new user cold-start situations. The method is based on user interests model called Contextual Conditional Preferences and it also relies on existing non-contextual algorithms for a ranking task, since it could be classified as a post-filtering technique. We performed experiments on three publicly available datasets, i.e. LDOS-CoMoDa, Unibiz-STs and Restaurant & customer, which contain user ratings, contextual information and item features. The experiments confirmed that our method is applicable in the new user cold-start situations as well as in typical scenarios, which is the main advantage of proposed technique. In the first case, when we do not have any test user's rating in the training set, we use only General Contextual Conditional Preferences, while in the second, we use both types: individual and general ones. We identified different algorithms that work the best with the proposed method for different usage scenarios, e.g. BPR and LDA for the new user situation, and WRMF for a typical scenario in the LDOS-CoMoDa dataset. The main constraints of the proposed reshuffling method are the context and the algorithm dependence.

We also compared our reshuffling technique with other context-aware methods, i.e. contextual SLIM and UI Splitting combined with BPR, SLIM and User kNN algorithms. We showed that our method outperforms them according to accuracy measures like *precision* or *recall*, but obtains worse results when considering measures like *novelty* or *diversity*. However, it seems to be the price for improving the accuracy of the recommendation process.

The next step that needs to be taken is a comparison with other cold-start methods. We also plan to automatize the process of a selection of appropriate contextual features, which is crucial to improve our method.

**Abstract**—This paper describes the use of a new swarm-based metaheuristic, namely Krill Herd Algorithm (KHA), in computer gaming. In this work, KHA is employed to find a bots movement strategy in a computer racing game. The complete algorithm is implemented using a Unity Engine in C# language. Herein, the triggering of the metaheuristic optimization task was conducted by the way of a KHA internal parameter investigation. In this approach, the goal of the race (the KHA evaluation function) for both the human and computer player is to finish a lap in the shortest time possible.

## I. INTRODUCTION

**T**He goal of any artificial intelligence algorithm is to create a mechanism that can learn, conclude, and solve problems like a human. In computer games, this creates a form that mimics human behavior, and computer games provide an excellent environment for implementing and even testing artificial intelligence procedures. Developers of computer games are increasingly turning towards creating projects based upon artificial intelligence. Instead of crafting their product through employing predictable algorithms, whose results are identical inside each successive game world, artificial intelligence methods are used to dynamically adapt the behavior of a computer opponent to the player's level of competence.

One of the first games using artificial intelligence tools was released in 1999 by id Software, a first-person shooter game called Quake III Arena. In the production of this, the behavior of the computer player (the so-called bot) was based on an artificial neural network [1]. The bot was able to learn the behavior of its opponents, both the computer generated, and the genuine human player, so as to develop winning strategies.

Swarm intelligence is one of the more important domains of computational intelligence. This group of algorithms is

applied in optimisation tasking. Herein, natural environmental processes and behaviours are the main inspiration [2]. Commonly used metaheuristics are: the Genetic Algorithm [3], the Gravitational Search Algorithm [4], Cuckoo Search [5], Earthworm Optimization Algorithm [6], Harmony Search [7], the Firefly Algorithm [8], Particle Swarm Optimization [9], [10], Ant Colony Optimization [11], the Bat Algorithm [12], the Differential Evolution [13] and the Autonomy-oriented computing methodology [14]. Newer algorithms, have been recently introduced for this tasking. These are: the Krill Herd Algorithm [15], [16], [17], Animal Migration Optimization [18], Wolf Search Algorithm [19], The Dragonfly Algorithm [20], Monarch Butterfly Optimization [21] and the Flower Pollination Algorithm [22]. Such bio-inspired metaheuristic algorithms are able to tackle very hard combinatorial optimisation problems [11] as well as, they can be applied for solving optimization problems in continuous space [23].

In this paper, we decided to test the utilization of the KHA within a computer race game. In this type of game, the user competes with computer generated opponents. Titles of such games currently on the market are: Test Drive or Need for Speed. During the project, interesting concepts were developed for the use of swarm intelligence.

The content of this paper has been divided into two main parts - theoretical and implementation. In the first, (Section II), the problem of utilizing artificial intelligence in the implemented computer game was discussed. Above all, the problem of optimization is delved into, as this issue affects the character and behavior of the computer generated opponent. It is to this that the artificial intelligence tools have been applied. We then thoroughly describe the chosen artificial intelligence

algorithm. In the second part of the article (Section III and Section IV), aspects of both the implementation and, above all, the details related to the adaptation of individual elements as swarm bots, is described. Following this, we present of the results of selected tests of the proposed algorithm. The article ends with a chapter devoted to the summary and towards further plans for the development of this algorithm.

## II. OPTIMISATION BASED ON KRILL HERD ALGORITHM

KHA is an iterative heuristic procedure inspired by the natural phenomena of krill herd behaviour. This method is mainly applied for solving optimization problems in continuous space. Here, the solution of this problem is defined as finding such an argument  $x^\circ$ , included in the space under consideration  $S \subseteq R^N$ , which fulfils the following formula

$$f(x^\circ) = \min_{x \in S} f(x) \quad (1)$$

where  $f(x)$  describes the value of the cost function.

The KHA was proposed by Amir Hossein Gandomi and Amir Hossein Alavi in the article [15], and is based on imitating the behaviour of the individual krill moving together as a herd. Individual krill, and the herd itself, move accordingly to diverse environmental factors. Among these are proximity to neighbours (defined by herd density), dispersion of the animal group, food location and several other biological and environmental phenomena.

In order to solve the optimization problem, we introduced the KHA non-deterministic procedure. Herein, particular elements  $x_i = x_i^1, \dots, x_i^N$  are proposed of an  $N$  dimensional solutions space, in the form of  $P$  individuals. In the  $k$ th iteration, the best solution of the this problem as represented by the  $p$ th members of swarm is given alternatively by these two equations:

$$x^\circ(k) = \arg \min_{p=1, \dots, P} f(x_p(k)) \quad \text{/for minimalization task/} \quad (2)$$

or

$$x^\circ(k) = \arg \max_{p=1, \dots, P} f(x_p(k)). \quad \text{/for maximalization task/} \quad (3)$$

The above best solution corresponds with the minimal or maximal value of cost function  $f^\circ = f(x^\circ)$  given as (2) or (3).

The full KHA procedure as a flow chart description is shown as Figure 1. This procedure begins from an initialization of all its internal parameters, and positions of all  $P$  individuals are generated randomly ❶. In next stage ❷, the cost (or fitness) function values are computed for all initial  $P$  swarm members using (2) or (3). The subsequent step ❸ is of great importance and is characterized by this technique. It consists of formulas describing the movement of particular individuals. Such motion viv-a-vis each individual krill is determined by three main components. They are:

- movement induced by other krill individuals,

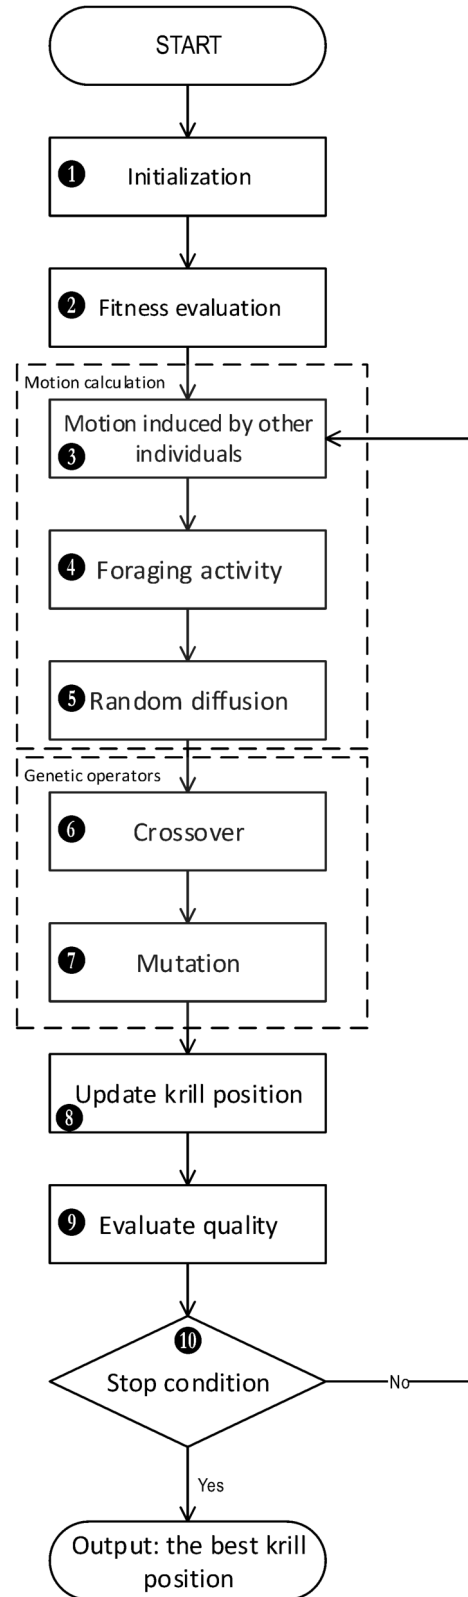

Fig. 1: Flowchart of KHA

- foraging activity,
- random diffusion.

In subsequent iterations, in the KHA technique, a vector of movement for the  $i$ th krill is based on the Lagrangian equation:

$$\frac{dx_i}{dt} = N_i + F_i + D_i, \quad (4)$$

where  $N_i$  is the motion induced by other krill individuals,  $F_i$  denotes the foraging motion and  $D_i$  is the physical diffusion of the krill individuals.

The first element ④ is a reflection of the social inspiration of the individual members of the herd. In the swarm, members are maintained at a high density. Hence, the velocity of each individual is influenced by the movement of others. In consequence, the direction of movement by the  $\alpha_i$  parameter is induced by the presence of other herd individuals. This parameter is determined on the basis of the following parts: local effect and target effect. The individual fractions of motion can be notated as:

$$N_i^{new} = N^{max} \alpha_i + \omega_n N_i^{old}. \quad (5)$$

Here  $N^{max}$  represents the maximum possible speed that can be induced,  $\omega_n$  belongs to the interval  $[0, 1]$ , and is defined as the inertia weight of a particular krill and finally  $N_i^{old}$  is the motion induced in the previous time step. The  $\alpha_i$  parameter is introduced in following way:

$$\alpha_i = \alpha_i^{local} + \alpha_i^{target}, \quad (6)$$

where  $\alpha_i^{local}$  describes the local influence of the neighbours of any particular swarm member, whereas  $\alpha_i^{target}$  is the target direction. The latter is determined by the position and movement of the best individual in a swarm.

The  $\alpha_i^{local}$  parameters are computed according to the formula:

$$\alpha_i^{local} = \sum_{j=1}^{NN} \hat{f}_{ij} \hat{X}_{ij}, \quad (7)$$

where

$$\hat{X}_{ij} = \frac{x_j - x_i}{\|x_j - x_i\| + \epsilon}, \quad (8)$$

and

$$\hat{f}_{ij} = \frac{f_i - f_j}{f_{worst} - f_{best}}. \quad (9)$$

In equation (9),  $f$  in provides the cost value (1) of any investigated krill. Consequently  $f_{worst}$  and  $f_{best}$  represent, respectively, the worst and the best fitness of individuals in swarm. Additionally,  $NN$  describes the identification of the number of reachable krill neighbours, and  $\epsilon$  is a positive number introduced to avoid singularities in the denominator of formula (8).

For determination of distance between particular krills and their neighbours, a parameter designated as being the sensing distance  $d_s$ , is proposed. Its value may be formulated as:

$$d_{s,i} = \frac{1}{5P} \sum_{j=1}^P \|x_i - x_j\|. \quad (10)$$

What is more, each swarm member incorporates its own target vector. This is formulated as follows:

$$\alpha_i^{target} = C^{best} \hat{f}_{i,best} \hat{x}_{i,best}, \quad (11)$$

where

$$C^{best} = 2 \left( rand + \frac{k}{K^{max}} \right). \quad (12)$$

Herein,  $k$ ,  $K^{max}$  designate, respectively, the current iteration number and the maximum number of iterations. Moreover, a  $rand$  is a random value between 0 and 1, whereas  $\hat{f}_{i,best}$  is the best value of fitness function, while  $\hat{x}_{i,best}$  provides the location of the best  $i$ th individual from the previous time steps.

In the equation (4), the symbol  $F_i$  is connected with the food foraging issue. Herein,  $F_i$  is defined in the following way:

$$F_i = V_f \beta_i + \omega_f F_i^{old}, \quad (13)$$

where  $V_f$  is the food foraging speed and  $\omega_f$  describes the inertia of the movement. In equation (13), the food fitness of the  $i$ th krill is designated as follows:

$$\beta_i = \beta_i^{food} + \beta_i^{best}. \quad (14)$$

The aforementioned food aspect is defined by way of its location. Therefore, the centre of food concentration is defined via KHA as a virtual point. This conception by the "centre of mass" approach is interpretable. Hence, the food concentration in each iteration is calculated according to formula:

$$X^{food} = \frac{\sum_{i=1}^P \frac{1}{f_i} x_i}{\sum_{i=1}^P \frac{1}{f_i}}. \quad (15)$$

Here, the food attraction for the  $i$ th swarm member is described via:

$$\beta_i^{food} = C^{food} \hat{f}_{i,food} \hat{X}_{i,food}. \quad (16)$$

The food coefficient in (16) expresses the global attraction of the food centre (15), and may be calculated as:

$$C^{food} = 2 \left( 1 - \frac{k}{K^{max}} \right). \quad (17)$$

The second part of equation (14) is as follows:

$$\beta_i^{best} = \hat{f}_{i,best} \hat{x}_{i,best}. \quad (18)$$

In this equation,  $f_{i,best}$  expresses the best fit achieved by a given  $i$ th individual so far. This is determined by its position  $\hat{x}_{i,best}$ .

The last element of the Lagrangian equation (4) is connected with random physical diffusion ⑤, represented as  $D_i$ . In essence, this component has a fully random character. This part of movement is focused upon the diversity in the swarm;

it allows the individual krill to position itself inside the krill swarm so as to be within a situation of local optimum. This part of equation (4), hence, represents a trade-off between exploration and exploitation. The following equation shows these aspects as a random diffusion:

$$D_i = D^{max} \left(1 - \frac{k}{K^{max}}\right) \delta, \quad (19)$$

where,  $D^{max}$  is the maximum diffusion factor and  $\delta$  expresses the random directional vector.

The motion aspect of krill activity can now be fully described. Herein, all the aforementioned effective parameters are applied. Thus, the position of the  $i$ th individual during the interval  $t$  to  $t + \Delta t$  is determined by the following equation:

$$x_i(t + \Delta t) = x_i(t) + \Delta t \frac{dx_i}{dt}. \quad (20)$$

Here, it should be underlined that parameter  $\Delta t$  is very sensitive to the speed and accuracy of the optimisation task. In this respect, the  $\Delta t$  may be interpreted as being a scale factor of krill movement, and can be obtained by way of the following equation:

$$\Delta t = C_t \sum_{j=1}^N (UB_j - LB_j). \quad (21)$$

In the above equation,  $C_t$  is an empirically found constant number from the interval  $[0, 2]$ . What is more,  $UB_j$  and  $LB_j$  constitute, respectively, the upper and lower bounds of the  $j$ th feature ( $j = 1, \dots, N$ ) of data set  $X = x_1, \dots, x_P$ .

The subsequent step of the heuristic algorithm is an implementation of two genetic or evolutionary operators. In step ⑥, the crossover function is considered. This operator is controlled by the  $Cr$  parameter referred to as the 'crossover probability'. In this approach, this operator is defined randomly, and the crossover is revealed in the change of the  $m$ th coordinate of the  $i$ th individual. This comes about by applying the following formula:

$$x_{i,m} = \begin{cases} x_{r,m} & \text{for } \gamma \leq Cr \\ x_{i,m} & \text{for } \gamma > Cr \end{cases}, \quad (22)$$

where  $Cr = 0.2\hat{K}_{i,best}$ ;  $r \in \{1, 2, \dots, i-1, i+1, \dots, P\}$  and  $\gamma$  is a random number drawn from the interval  $[0, 1]$ , which is generated via uniform distribution. In this solution, the crossover operator is calculated by way of a single individual.

Finally, the mutation operator ⑦ is applied within the last stage of the main loop of the KHA. This changes the  $m$ -th coordinate of the  $i$ -th individual, as shown below by the formula:

$$x_{i,m} = \begin{cases} x_{g_{best},m} + \mu(x_{p,m} - x_{q,m}) & \text{for } \gamma \leq Mu \\ x_{i,m} & \text{for } \gamma > Mu \end{cases}, \quad (23)$$

wherein  $Mu = 0.05/\hat{K}_{i,best}$ ;  $p, q \in \{1, 2, \dots, i-1, i+1, \dots, P\}$  and  $\mu \in [0, 1]$ .

This operation completes all evolutionary procedures. Subsequently, we can now obtain individuals that can be used within the next iteration. In so-doing, in the last step ⑧ of the main loop, the cost function for all the swarm members is calculated. Now, the algorithm's termination condition ⑩ decides whether the next iteration is to be entered into or the optimization algorithm is to be completed. The form of stop condition applied could be that of a time limit, or the reaching of a desired fitness level or a combination of above two.

More information about this metaheuristic algorithm can be found in [15]. Regarding the procedure's internal parameters, the tuning of the KHA is described in papers: [24], [25] and [26], while publications [17] and [16] introduce some modifications into the algorithm. The KHA procedure has been verified for application within optimization problems in the case of discrete input data [27], while a parallel version of this procedure is put forward in [28]. Furthermore, it has been applied in medical tasks [29], for data base domains [30], in mechanism and machine theory [31], in clustering tasks [32], [33], and also in neural learning processes [34]. Extensive use of this algorithm has been collected in the article [35].

### III. IMPLEMENTATION AND OPTIMIZATION OF GAME

The Unity engine [36] is now employed in order to complete the task and to implement the game. This is a tool that allows the creation of games for Windows, Linux, Mac OS, Xbox 360, PlayStation 3, Wii U, iPad, iPhone, Android, Windows Phone 8 and BlackBerry environments. Unity has rapidly gained popularity thanks to its user-friendly interface. It allows for fast development of the game, along with the ability to test existing progress. In optimising Unity for creating cross-platform games, the programmer can use any of three programming languages: C# for the Mono platform, JavaScript, or the Boo-inspired language, Python. All implementations described in this work have been written in C#.

Swarm intelligence is applied in our study application for optimizing the travel time by way of adjusting driving performance. Firstly, the track was divided into sectors that consist of curves of similar characteristics. In doing so, a racing line was formed along which the bots are to move. Figure 2 shows the waypoints which are densely distributed throughout the route.

In completing this task, some parameters are introduced. These are considered as being the same parameters that affect the coordinates of individual krill within the herd. The most important parameter is undoubtedly the maximum speed in the sector. If a bot is currently located in a straightaway or where steering arcs are long, and where the steering input angle is low, a high maximum speed is desirable. In turn, if the bot enters within a twisting and winding section of the track or where the curves are tight and steering input is intense, then the speed must be properly limited, otherwise the car loses its grip, resulting in drift, a wider line of travel and, consequently slower travel times. The second parameter is related to the angle between the car and the next point of the race line. If it is greater than the value for a given sector, then the computer

Fig. 2: Race line with waypoints

player starts to understeer or oversteer and must accelerate or decelerate. This value should be greater for straightforward sectors as it reduces the gliding effect of the car on the track. The third and last parameter of the driving characteristic is the time it takes to make a turn. For winding sectors, the value is less than that for simple sectors, because a faster response is needed. The above parameters are transferred to the algorithms for bots controlling in the game engine.

In presenting the implementation of swarm intelligence, the passage time within a particular sector of the track is optimized by adjusting the driving parameters of a given computer player. Therefore, the algorithm should be run only when all the computer players overcome the sector. Detecting the moment when players finish the passage of a given sector takes place using the so-called 'collider' (Fig. 3). Thus, when the last computer player completes a subsequent sector, the *Run(int)* function is called up for the sector identifier that it is responsible for when executing one iteration of the algorithm.

#### A. Application of KHA to game

For the implementation of the KHA, each computer-based object was coded as a *MKrill* class component representing one individual in the population.

Each object has the following attributes: an identifier in the form of an integer, of times in the current round; sector records which store the performance characteristics of the computer player used in the current lap; the parameters described above (maximum speed in the sector, angle between the car and the next point and time to make a turn); best parameters array; induced vectors, foraging vectors and diffusion vectors as components of KHA; and, finally, lower bounds and upper bounds. All the aforementioned are used to store the lower and upper limits of the respective main driving parameters.

Another important element is the determination of the value of the cost function (1). This is the first step in executing each iteration of the KHA. In this implementation, however, cost

function is not calculated explicitly, because the value of this function is the passage time within the sector for which the algorithm is being executed at the moment.

Now, the individual designated Lagrangian (4) components are calculated (see Section II). Firstly, the determination of the motion induced by other krill individuals is accomplished by applying the formulas (5)-(12). In this part of the algorithm, the displacement vector for each individual in the population is generated. In doing this, in each iteration,  $\alpha^{local}$  and  $\alpha^{target}$  based on equations (7) and (11) are first calculated, and then summed according to equation (6). Thereafter, in each iteration, the appropriate vector (5) is determined, taking into account the following parameters,  $N^{max}$  and  $\omega_n$ .

In the next step of the algorithm, the food foraging movement is ascertained as per notation (13). In this part of the iteration, equations (14)-(18) are applied. This process is similar to that of the  $N_i$  calculation. Due to the optimization of travel time in the presented version of the algorithm, it is not possible to easily determine the value of the cost function for food (the value appearing in equation (16)). Thus, the solution is to assign to its value, the activity adapted by an individual closest to the food.

Finally, with regard to moment computing, a random physical diffusion, notated as  $D_i$ , is performed. In this case, equation (19) is used.

After all the above effective motion parameters are calculated, the change of each  $i$ -th krill position can be ascertained through employing equation (20) and applying notation (21).

Finally, it is worth observing that basic KHA utilizes several other evolutionary operators such as mutation (23) and crossover (22) for swarm member modifications. In the present iteration of the paper, these were not applied.

In summation, it should be noted that utilizing KHA is, in a sense, a way of optimising the computer game activity. The presented implementation of the KHA has its advantages and disadvantages. The disadvantage is the inability to explicitly

Fig. 3: A collider located at the end of the sector

calculate the value of the cost function. This value is the time of sector passage, and it can only be known when the computer player has overcome the sector through applying the parameters specified. Therefore, only the estimation of the effect of food position for the krill movement was applied.

The advantage of this implementation is, undoubtedly, its scalability. When needed, it is easy to take into account additional factors that can influence the nature of the player's computer. Moreover, this implementation is not computationally demanding, because each one iteration takes place when the last competitor crosses the boundary of a given sector. In the case of a track, as used in the game, and assuming that the players are moving close together, this means that one iteration every 1.5 – 2.0 seconds is performed.

#### IV. NUMERICAL SIMULATIONS

While researching the effectiveness of the proposed method, we analysed the impact of KHA internal parameters on quality of solution. Herein, we saw that the quality of the solution can be greatly influenced by the impact of internal parameters [24], [37].

The enclosed figures show the results of the tests that were applied to assess the quality and speed of the solution according to KHA parameters. In this case, the subject quantities were  $C_t$ ,  $\omega_n$ ,  $\omega_f$  and  $N$ .

In the test of the first parameter,  $C_t$ , the remaining parameter values are  $\omega_n = 0.5$ ,  $\omega_f = 0.5$  and  $N = 5$ . The results have been visualized in Figure 4. Here, each line shows the best results (i.e., the shortest time of the lap of the bot-car) for the investigated  $C_t$  value.

From the above tests, it can be inferred that an increase in the value of the variable  $C_t$  resulted in an increase in the difference between the times gained by the individual players in the first phase of the test. This indicates that even the far-fetched points in the solution space are represented. Finally, the best time was reached at  $C_t = 1.5$ . This was 93.27 s.

Fig. 4: Convergence of the optimisation procedure with various  $C_t$  parameters

In the next test, the  $\omega_n$  parameter is modified through the application of a number in the range (0.0; 1.0). This action represents the influence of neighbors in the creating of the movement vector. The obtained results are shown in Figure 5.

In this case, increasing  $\omega_n$ , slowed the computer players in achieving better results. This means that through introducing the calculated influence of the neighbors, a larger value of  $\omega_n$  results in a more accurate search within the krill environment while reducing its pace of approaching the global minimum. The best time passed in the test was for the case of  $\omega_n = 0.2$ . Herein, the time value of 92.30 s was achieved.

In our study, the parameter  $\omega_f$  was modified (Figure 6). This is a number in the range of (0.0; 1.0), and it represents the effect of the phase of the food search on the movement

Fig. 5: Convergence of the optimisation procedure with various  $\omega_n$  parameters

Fig. 6: Convergence of the optimisation procedure with various  $\omega_f$  parameters

vector value. Increasing the value of  $\omega_f$ , therefore, resulted in better player performance. For  $\omega_f = 0.1$ , the best time is 93.69, while for  $\omega_f = 0.9$ , this increased to 95.02. However, it is important to take into account that in this implementation, the approximate value of the cost function of the food is one that was calculated to reduce the efficiency of the entire phase of the food search.

The last test was to change the size of the krill population. In this research, a limited amount of the swarm are employed as bots. The main reason for this is that each krill represents one car on the race route. So a large number of bots in one place holds the implication that their collective movement is

similar to that of a krill herd, and a great number of collisions will take place. The results of racing 3, 5 and 7 bots are shown in Figure 7.

One can observe from Figure 7 that increasing population numbers, increases the speeds in which better lap times are acquired by the computer players. When the population had three individuals, it was only after 10 laps that all players started to regularly achieve lap times less than 100 seconds. In the case of a population of five, this came about on the 7th lap. The main reason for such results is that the parameters for each krill are generated according to a uniform distribution. In other words, increasing the population, increases the probability that one of the individuals will be closer to the global minimum. The second reason is the development of synergies between the herd participants.

In conclusion, the modification of the studied parameters can influence the behaviour of the KHA. Increasing the  $C_t$  parameter speeds up the exploration of the solution space, but at  $C_t > 1.0$ , the incremental value of the movement vector may be too large, which in turn, can lead to better solutions. Increasing the value of variables  $\omega_n$  and  $\omega_f$  clearly slows the pace to gaining better results. Increasing the size of the population, in addition to having impact on the speed of the solution, also affects the quality of the solution, as more agents can better search for better solutions.

## V. SUMMARY

Experimental results indicate that the proposed solution can be used in a professional computer game, but only for one of low and medium difficulty. Thus, the level of computer opponents in this approach could be a challenge only for lesser and intermediate players. In order to streamline the implementation, a number of modifications would have to be made. Among these are the incorporation of target users' game results, as this would help improve the performance of the computer players. In order to eliminate the fluctuations of the final travel times, it would be useful to include the current best path, which would have an impact on the routing of the car. An alternative to improving the algorithm is to reduce the random factor generated through the method of determining a new food distribution, by replacing it with a deterministic algorithm or by manually selecting a developer designated fixed location during the game design. The implementation of the game presented in this paper can be further developed in many different ways. The most interesting directions are to find a better selection of krill algorithm parameters in order to be more efficient; to implement an improved version of the KHA, ie Lévy-flight KHA [37]; or to implement a learning mechanism based on human player experience.

## ACKNOWLEDGMENT

The authors are thankful to Jacek Kurlit and Mateusz Harla (students of CUT) for the helpful implementation of the investigated problem.

**Abstract**—In this article, the problem of determining the significance of data features is considered. For this purpose the algorithm is proposed, which with the use of Sobol method, provides the global sensitivity indices. On the basis of these indices, the aggregated sensitivity coefficients are determined which are used to indicate significant features. Using such an information, the process of features' removal is performed. The results are verified by the probabilistic neural network in the classification of medical data sets by computing model's quality. We show that it is possible to point the least significant features which can be removed from the input space achieving higher classification performance.

## I. INTRODUCTION

**G**LOBAL sensitivity analysis (GSA) embraces a group of algorithms which determine the influence of the input of the model to the model's output. This gives the possibility of estimating how the model output variance is influenced by relative impact of a single input variable and the interactions between them. In GSA, the influence on the output of the model can be assessed by means of regression methods, screening approaches [1], and the variance-based techniques, e.g., Sobol method [2], [3], the Fourier amplitude sensitivity test (FAST) [4], or the extended (EFAST) [5].

In literature, we can find a lot of contributions devoted to applications of GSA to feature selection. For example, in [6], the Sobol method is applied in optimization of shell and tube heat exchangers; the non-influential geometrical parameters which have the least effect on total cost of tube heat exchangers are identified. In turn, in [7], a new GSA based algorithm for the selection of input variables of neural network is proposed. The algorithm ranks the model's inputs according to their importance in the variance of the network output. In reference [8], one can find the use of the standardized

regression coefficients, Morris screening and EFAST methods in assessing the most relevant processes occurring in waste-water treatment systems. The aforementioned methods are applied to a complex integrated membrane bioreactor where various interactions among the input factors are detected. The authors of current work utilize the GSA methods in the domain of neural network structure reduction. In [9], we present how the structure of the probabilistic neural network (PNN) can be optimized by means of Sobol, FAST and EFAST methods.

It is important to note that, in addition to GSA based techniques, many other approaches exist which can be utilized for feature selection. For example, ReliefF algorithm, proposed by Kira and Rendell in [10], computes the weights for data set features. This shows how well the feature values distinguish among patterns which are near to each other, taking into account the output class. On the basis of the weight values, the feature significance can be established. Similarly, Breiman's random forest algorithm [11], within its training process, invokes variable importance procedure. This procedure provides a ranking of the overall relevance of features. On the other hand, the extended version of Naïve Bayes classifier, presented in [12], determines the importance of features in classification process by means of weights of a normalized neural network. The weights are obtained by the backpropagation-like technique applied to the model training. The appropriate connection between the network and the classifier is implemented. The attribute clustering algorithms are also utilized to construct informative subset of available features from high dimensional data. The authors of [13] propose such a solution along with an attribute similarity measure which is useful for identifying groups of features that are likely to be selected for reduction purposes.

In this study, we propose the algorithm for determining the significance of input features. This significance is obtained using Sobol method. For the analysis, the UCI machine learning

The work was supported by Rzeszow University of Technology, Department of Electronics Fundamentals Grant for Statutory Activity (DS 2017).

repository (UCI-MLR) data sets [14] are used. The algorithm is tested in the classification problems conducted using PNN; the correctness of operation is verified by computing the learning and test qualities.

This article is organized as follows. In section II, the Sobol sensitivity analysis fundamentals are provided. Section III, introduces the PNN model highlighting its architecture and training algorithm. In section IV, the algorithm for determining the significance of input features is proposed. Section V presents numerical verification results achieved by the proposed algorithm. In section VI, we shortly summarize our work.

## II. SOBOL SENSITIVITY ANALYSIS

Sobol method is based on decomposition of the model output variance into summands of variances of the input parameters in increasing dimensionality [2], [15]. It establishes the contribution of each input variable and the interactions between them to the overall variance in the output of the model. This is achieved by computing the first-order, second-order, higher-order and the overall sensitivity indices. Below, we show how to determine this contribution of variables according to the Sobol approach.

Let  $\mathbf{x} = (x_1, x_2, \dots, x_N)$  be the set of mutually independent input parameters in which  $x_i \in I^N$  where  $I$  denotes  $[0,1]$  interval and  $I^N$  is the  $N$ -dimensional unit hypercube. The model output, whose sensitivity to the parameters  $x_1, x_2, \dots, x_N$  is to be determined, is an integrable function  $f(\mathbf{x})$  defined in  $I^N$

$$f(\mathbf{x}) = f_0 + \sum_{s=1}^N \sum_{i_1 < i_2 < \dots < i_s} f_{i_1 i_2 \dots i_s}(x_{i_1}, x_{i_2}, \dots, x_{i_s}). \quad (1)$$

It can be seen that the overall number of summands in (1) is  $2^N$ . Equation (1) can be rewritten in the following form

$$f(\mathbf{x}) = f_0 + \sum_{i=1}^N f_i(x_i) + \sum_{i=1}^N \sum_{j=i+1}^N f_{ij}(x_i, x_j) + \dots + f_{12\dots N}(x_1, x_2, \dots, x_N). \quad (2)$$

Formula (1) is called ANOVA-representation of  $f(\mathbf{x})$  if the integral of each summand over each of its own variables is zero

$$\int_0^1 f_{i_1 i_2 \dots i_s}(x_{i_1}, x_{i_2}, \dots, x_{i_s}) dx_k = 0 \quad (3)$$

for  $k = i_1, i_2, \dots, i_s$  where both  $\{i_1, i_2, \dots, i_s\}$  and  $s$  run from 1 to  $N$ .

Some important remarks can now be inferred. First of all, the integration of (1) over  $I^N$  yields

$$\int_0^1 f(\mathbf{x}) d\mathbf{x} = f_0. \quad (4)$$

which allows for computing the term  $f_0$ . Further, after integrating (1) over all variables excluding  $x_i$  one obtains

$$\int_0^1 f(\mathbf{x}) \prod_{k \neq i} dx_k = f_0 + f_i(x_i), \quad (5)$$

which provides

$$f_i(x_i) = \int_0^1 f(\mathbf{x}) \prod_{k \neq i} dx_k - f_0. \quad (6)$$

Similarly, integrating (1) over all variables excluding  $x_i$  and  $x_j$  defines the term  $f_{ij}(x_i, x_j)$  as follows

$$f_{ij}(x_i, x_j) = \int_0^1 f(\mathbf{x}) \prod_{k \neq \{i, j\}} dx_k - f_i(x_i) - f_j(x_j) - f_0. \quad (7)$$

The procedure is performed until last term  $f_{12\dots N}(x_1, x_2, \dots, x_N)$  is determined.

Assuming that  $f(\mathbf{x})$  is square integrable over  $I^N$ , all terms  $f_{i_1 i_2 \dots i_s}$  in (1) are also integrable. Thus

$$\int_0^1 f^2(\mathbf{x}) d\mathbf{x} - f_0^2 = \sum_{s=1}^N \sum_{i_1 < i_2 < \dots < i_s} \int_0^1 f_{i_1 i_2 \dots i_s}^2 dx_{i_1} \dots dx_{i_s}. \quad (8)$$

The left side of (8) is called the total variance of  $f(\mathbf{x})$

$$D = \int_0^1 f^2(\mathbf{x}) d\mathbf{x} - f_0^2 \quad (9)$$

while

$$D_{i_1 \dots i_s} = \int_0^1 f_{i_1 i_2 \dots i_s}^2 dx_{i_1} \dots dx_{i_s} \quad (10)$$

are the partial variances for each term in (1). Using (8)–(10) we receive

$$D = \sum_{s=1}^N \sum_{i_1 < i_2 < \dots < i_s} D_{i_1 \dots i_s}, \quad (11)$$

which means that

$$D = \sum_{i=1}^N D_i + \sum_{i=1}^N \sum_{j=i+1}^N D_{ij} + \dots + D_{12\dots N}. \quad (12)$$

The sensitivity indices are defined as the following ratios

$$S_{i_1 \dots i_s} = \frac{D_{i_1 \dots i_s}}{D}, \quad (13)$$

where

$$S_i = \frac{1}{D} \int_0^1 f_i^2(x_i) dx_i \quad (14)$$

are the first-order sensitivities computed for the variables  $x_i$ ,  $i = 1, \dots, N$ ; the sensitivities  $S_i$  measure how particular  $x_i$  variables affect the output of the model, i.e., the variance of  $f(\mathbf{x})$ . Similarly, the second-order sensitivity

$$S_{ij} = \frac{1}{D} \int_0^1 \int_0^1 f_{ij}^2(x_i, x_j) dx_i dx_j \quad (15)$$

is used to determine the second-order contribution from interaction between  $x_i$  and  $x_j$  to the output variance. The sum of all sensitivity indices for  $x_i$  defined as

$$S_{T_i} = S_i + \sum_{j \neq i} S_{ij} + \dots + S_{12\dots N} \quad (16)$$

measures the overall effect of this parameter on the output of the model. All  $S_{i_1 \dots i_s}$  indices are nonnegative and their sum is equal

$$\sum_{s=1}^N \sum_{i_1 < i_2 < \dots < i_s} S_{i_1 \dots i_s} = 1. \quad (17)$$

A Monte Carlo algorithm is used for an estimation of global sensitivity indices.

### III. PROBABILISTIC NEURAL NETWORK

PNN is a feedforward network initially proposed by Specht in [16], [17]. It is very popular with the scientists in the field of machine learning. PNN is frequently utilized in many applications, e.g.: medical diagnosis and prediction [18], [19], [20], [21], image classification and recognition [22], [23], [24], multiple partial discharge sources classification [25], interval information processing [26], [27], phoneme recognition [28], email security enhancement [29], intrusion detection systems [30] or classification in a time-varying environment [31].

The operation of PNN is based on a Bayes decision rule. In this section, we shortly highlight the structure of the model and its training algorithm.

#### A. Structure of the network

PNN is organized into four layers. The input vector variables  $\mathbf{x} = [x_1, \dots, x_N]$  form the neurons in the first input layer. All given training data, after some activation, are used to create the neurons in the second layer, called the pattern layer. Pattern neurons forward produced output to the next summation layer, where each summation neuron acquires inputs from the pattern neurons representing the same class. In particular, in the summation layer, there exist  $g = 1, \dots, G$  neurons and each  $g$ th neuron sums the signals from the neurons of the  $g$ th class. The last output layer yields the classification outcome on the basis of the highest value obtained from all  $G$  summation neurons.

Different approaches may be utilized to activate pattern neurons of PNN. In this paper, the product kernel involving all input variables is considered

$$K(\mathbf{x}) = \mathcal{K}(x_1) \cdot \mathcal{K}(x_2) \cdot \dots \cdot \mathcal{K}(x_N), \quad (18)$$

where each multiplicand takes the following Cauchy form

$$\mathcal{K}(x_i) = \frac{2}{\pi(x_i^2 + 1)^2}. \quad (19)$$

Such a form of kernel function allows us to define summation neuron output as follows

$$f_g(\mathbf{x}) = \frac{1}{P_g \det(\mathbf{h})} \sum_{p=1}^{P_g} \frac{1}{s_p^N} K \left( \frac{(\mathbf{x} - \mathbf{x}_g^{(p)})^T \mathbf{h}^{-1}}{s_p} \right), \quad (20)$$

where:  $P_g$  stands for the number of cases in the  $g$ th class ( $g = 1, \dots, G$ );  $\mathbf{h} = \text{diag}(h_1, \dots, h_N)$  denotes the vector of smoothing parameters;  $s_p$  is the modification coefficient;  $\mathbf{x}_g^{(p)} = [x_{g,1}^{(p)}, \dots, x_{g,N}^{(p)}]$  is the  $p$ th training vector of the  $g$ th class. The formula (20) is also referred to as the kernel density estimator (KDE) for the  $g$ th class in the context of PNN operation.

Using (18) and (19), the  $g$ th summation layer neuron produces the following signal

$$f_g(\mathbf{x}) = \frac{1}{P_g \det(\mathbf{h})} \sum_{p=1}^{P_g} \frac{1}{s_p^N} \prod_{i=1}^N \frac{2}{\pi \left( \left( \frac{x_i - x_{g,i}^{(p)}}{h_i s_p} \right)^2 + 1 \right)}. \quad (21)$$

The final output layer of PNN determines the class assignment for the sample vector  $\mathbf{x}$  based on the Bayes decision rule [17] for all  $f_g$  KDEs

$$G(\mathbf{x}) = \underset{g=1 \dots G}{\operatorname{argmax}} f_g(\mathbf{x}), \quad (22)$$

where  $G(\mathbf{x})$  provides the predicted class label. The structure of the PNN model is illustrated in Fig. 1.

#### B. Training algorithm

The training algorithm of PNN consists in the appropriate choice of the smoothing parameter  $h_i$  and the computation of the modification coefficients.

For  $N$ -dimensional data sets, when the product kernel is used for KDE estimation, one recommends to compute  $h_i$  by means of the plug-in method [32], [33]. The  $h_i$  parameters are then determined independently for each dimension

$$h = \left[ \frac{R(\mathcal{K})}{U(\mathcal{K})^2} \frac{8\sqrt{\pi}\hat{\sigma}^9}{3P} \right]^{\frac{1}{5}} \quad (23)$$

where  $\hat{\sigma}$  denotes the estimator of the standard deviation and for the Cauchy kernel in (19),  $R(K) = 1$  and  $U(K) = 5/4$ . The calculation of  $\hat{\sigma}$  is solved iteratively using second-order level approximation [34], [33].

As presented in both (20) and (21), KDE for the  $g$ th class depends on the value of the modification coefficient  $s_p$ . For PNN, it is computed separately for each class and is related to the  $p$ th training vector. The modification coefficient is defined as follows [34]

$$s_p = \left( \frac{\hat{f}(\mathbf{x}^{(p)})}{\tilde{s}} \right)^{-c}, \quad (24)$$

where

$$\tilde{s} = \left( \prod_{p=1}^P \hat{f}(\mathbf{x}^{(p)}) \right)^{\frac{1}{P}}, \quad (25)$$

where  $c$  is the non-negative constant used to determine the modification intensity. In literature, one usually assumes  $c = 0.5$  [33].

Fig. 1. The architecture of probabilistic neural network.

#### IV. ALGORITHM FOR DETERMINING SIGNIFICANCE OF FEATURES

This section describes the proposed algorithm for determining the significance of particular features in data set, which in turn, entails the reduction of the PNN's input layer. All components of the this algorithm are set out in Fig. 2 in form of the flowchart. As it can be observed, the flowchart is divided into two parts. The upper part (over the dashed line) concerns a description of PNN topology with all stages of learning process. The bottom part (under the dashed line) shows the application of Sobol method for providing a sensitivity indices what results in establishing the order of data features.

In the first stage of the algorithm, we start from data acquisition ❶. Since the PNN model is utilized, it is assumed (step ❷) that data are distinguished between particular classes. In step ❸, the topology of PNN is created. For this purpose, the number of records, features and classes of the considered data are acquired. Then all training patterns are copied into appropriate neurons (stage ❹) preserving class membership, as it is shown in Fig. 1. This results in obtaining the required structure of PNN ready for training process. Now, as it is presented in subsection III-B, in step ❺, the smoothing parameters  $h_i$  are computed for each of regarded classes separately. As a result  $N$  smoothing parameters are obtained in each class (which gives  $N \cdot G$  in total). In step ❻ of the algorithm, for every  $g$ th class, the modification coefficients  $s_p$ ,  $p = 1, \dots, P_g$ , are determined.

In the second stage of the algorithm, the global sensitivity analysis takes place (❼). The application of Sobol method allows us to obtain required information about influence of individual elements of the input vector on particular KDEs  $f_g(\mathbf{x})$ . Based on the Sobol approach described in Section II, for each input element  $x_i$  and each class estimator  $f_g(\mathbf{x})$ , the first order sensitivity index  $S_{i,g}^{(p)}$  (14) for the  $p$ th training pattern is computed. After determination of  $S_{i,g}^{(p)}$  for all  $P$  training patterns, one can calculate aggregated parameters by applying mean square average sensitivity norm

$$S_{i,g}^{\text{mean}} = \sqrt{\frac{\sum_{p=1}^P \left(S_{i,g}^{(p)}\right)^2}{P}}. \quad (26)$$

Finally, it is required to define the maximum value  $S_i$  in  $i$ th row of the matrix  $\mathbf{S}^{\text{mean}}$  with the elements aggregated according to (26)

$$S_i = \max_{g=1,\dots,G} \{S_{i,g}^{\text{mean}}\}. \quad (27)$$

In the last step ❽, the algorithm returns the sorted vector with  $S_i$  coefficients and the vector which contains the indices corresponding to the sorted coordinates. The first algorithm output item informs us about the aggregated quantitative sensitivity of individual inputs in the PNN's class estimator. These inputs are associated with the features of the considered data set. The second algorithm output item gives us the possibility to indicate the order of features' significance.

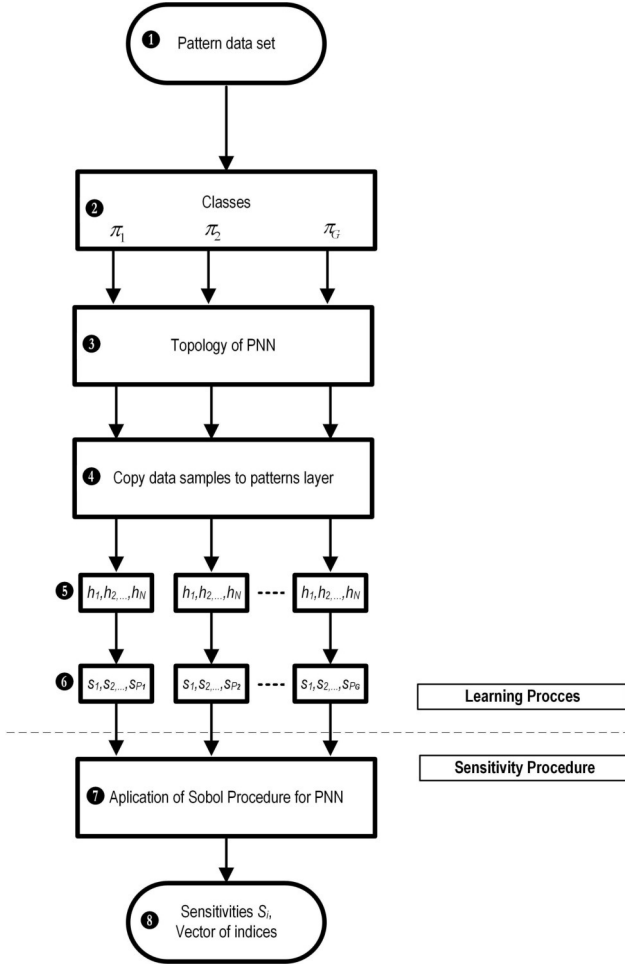

Fig. 2. Flowchart of the proposed algorithm.

The steps 7 and 8 as well as the PNN learning stages 1–6 constitute the complete algorithm for determining the significance of particular features of data set.

In the current paper, we do not focus on providing a priori general criterion to decide what is the right number of features to remove. Such a criterion could, for example, be based on finding explicit difference between two neighboring  $S_i$  elements in the matrix  $\mathbf{S}^{\text{mean}}$ , as shown in [9]. On the other hand, determining a general threshold of feature significance is difficult to establish since it is dependent on classifier applications. However, if we assume the use of PNN in classification tasks, some solution could rely on iterative reduction of the least significant feature along with simultaneous assessment of the network quality.

## V. NUMERICAL RESULTS

In this section, numerical verification results of the proposed algorithm are presented. In the first part, we focus on Sobol sensitivity method applied to determine the significance of input features. The second part considers the evaluation of the introduced algorithm in the classification tasks. To make

our study more representative, three UCI-MLR medical data sets are taken under consideration. Table I characterizes these data sets. In particular, we present: the number of records with class distribution ( $M_i$ ), the number of features ( $N$ ), and the number of classes ( $C$ ). In the last column of the table, the bibliographic reference of each data set is provided.

TABLE I

### A. Significance of data features

This part of paper examines the application of the Sobol method used to determine the significance of the individual features for all data sets presented in Table I. The results of the numerical verification of the algorithm presented in Section IV are shown in three drawings for each data set separately. In particular, for the WBC data set, Fig. 3 contains the sensitivity values  $S_i$  for each data feature, Fig. 4 displays the sorted values of  $S_i$  in descending order while Fig. 5 illustrates the difference between the particular bins presented in Fig. 4, i.e.  $dS_i = S_{i-1} - S_i$  for  $i = 2, 3, \dots, N$ . Figures 6, 7, and 8 depict respectively:  $S_i$ , sorted  $S_i$  and  $dS_i$  for the SH data set. Finally, in Fig. 9, Fig. 10, and Fig. 11, we show  $S_i$ , sorted  $S_i$  and  $dS_i$  for the PD data set, respectively.

Fig. 3. Sensitivity coefficients for the WBC data set.

In the case of the WBC data set (Fig. 3 and Fig. 4), we can see that the 9th feature is the most dominating since its sensitivity is equal  $S_9 = 0.3998$ . Then, two features can be distinguished, i.e.,  $x_6$  and  $x_7$  for which  $S_i \approx 0.2$ . The next distinctive group of features constitute  $x_1$  and  $x_3$  where  $S_i \in (0.05, 0.1)$ . The remaining features, i.e.,  $\{2, 4, 8, 5\}$

Fig. 4. Sorted sensitivity coefficients for the WBC data set.

Fig. 6. Sensitivity coefficients for the SH data set.

Fig. 5. The differences between sorted sensitivity coefficients for the WBC data set.

Fig. 7. Sorted sensitivity coefficients for the SH data set.

comprise the collection of less significant inputs because all their sensitivities are less than 0.025. In Fig. 5, one can clearly notice two distinct values for the first and third bar. This indicates the border between the most important feature  $x_9$ , two elements group of  $x_6, x_7$ , and further features  $x_1$  and  $x_3$ . These visible bars may contribute to discovering the cutoff between significant and negligible features for this data set. This fact will be explained in subsection V-B.

In the case of the SH data set (Fig. 6), it is possible to point out two significant features  $x_6$  and  $x_2$  for which  $S_i$  equals 0.2751 and 0.2434, respectively. The next group of features create the inputs  $x_{13}$  and  $x_3$  with  $S_i \approx 0.1150$ . Then for the features  $\{x_{12}, x_{11}, x_{10}\}$  (what can be observed in Fig. 7), we can remark linear decline of the sensitivity. The remaining features are characterized by a similar value of  $S_i \approx 0.02$ . Only the last feature  $x_1$  is the least significant what results from  $S_1 = 0.0047$ . Analyzing Fig. 8, one can see a noticeable peak at 13th feature and much smaller one at  $x_{12}$ . These observations indicate two potential borders where the input

reduction may occur.

Finally, for the last PD data set considered in this study, which consists of 22 features, one observes that the most important feature index is 10; here  $S_{10} = 0.1602$  (see Fig. 9 and 10). Subsequent group of features is characterized by  $S_i \approx 0.1$  which includes inputs  $\{x_{13}, x_6, x_8, x_{12}\}$ . Analyzing the indices of features from the set  $\{1, 5, 4, 15\}$  we can see a linear decrease in the sensitivity coefficient values. The next two peaks in the figure belong to features 11 and 14 with similar sensitivity (approx. 0.028). The last group of features comprises the ones for which  $S_i < 0.02$ .

#### B. Verification of data features significance in classification task

The results presented in subsection V-A are verified in the classification problems. Firstly, we apply Sobol method globally on the entire data set and determine the order of features' significance. Sorted sensitivity coefficients for the considered WBC, SH and PD data sets are presented in Figures 4, 7 and 10, respectively. Then, the PNN classification

Fig. 8. The differences between sorted sensitivity coefficients for the SH data set.

Fig. 10. Sorted sensitivity coefficients for the PD data set.

Fig. 9. Sensitivity coefficients for the PD data set.

Fig. 11. The differences between sorted sensitivity coefficients for the PD data set.

performance is evaluated using a 10-fold cross validation (CV) procedure. Single classification task is performed by removing the least significant feature. The entire procedure is conducted until a single feature is left. The whole experiment is repeated 30 times. As the result, we provide classification quality computed as the ratio of the number of correctly classified input patterns to the data set cardinality.

For all analyzed data sets, the obtained results are set out in tables and figures. The tables present the following indicators: the current number of features ( $N$ ), the least significant feature index ( $LSF$ ), average learning quality along with standard deviation—denoted as  $q_{cv}^L$  and  $std(q_{cv}^L)$ , and average test quality with standard deviation—denoted as  $q_{cv}^T$  and  $std(q_{cv}^T)$ . In the case of figures, the plotted bars depict  $q_{cv}^L$  (painted gray) and  $q_{cv}^T$  (painted white) determined at particular set of selected features.

Table II and Fig. 12 represent the results for the WBC data set. Analyzing the reduction of individual features, the following is observed. First of all, the inequality  $q_{cv}^L > q_{cv}^T$

holds in the entire range of feature indices. The sensitivity to the reduction in the test set is higher than the one in the learning set. Secondly, by reducing the least significant feature (no. 5) we notice an improvement in the quality of the classification for the test set. However, within the removal of the next least significant features (i.e., 8, 4 and 2), a slight quality decrease is noticed:  $q_{cv}^L$  drops from 0.9987 (for full data set) down to 0.9946 (data set with 6 features) while  $q_{cv}^T$  – from 0.9677 down to 0.9458. Let us proceed further: by removing  $x_3$  and  $x_1$ , we achieve the decrease of the test quality to 0.9311. Now the tendency in quality decrease becomes stronger and stronger since discarding the next two features (7 and 6) results in a sudden  $q_{cv}^T$  decline (0.8912). Finally, leaving only the most significant 9th feature causes a drastic worsening of the test quality (down to 0.7861). The above conclusions strongly refer to the groups of features with similar sensitivity values.

For the SH data set, the results are presented in Table III and in Fig. 13. Here, the effect of simultaneous features' reduction

TABLE II  
SIMULATION RESULTS FOR WBC DATA SET

$N$	$LSF$	$q_{cv}^L$	$std(q_L)$	$q_{cv}^T$	$std(q_T)$
9	5	0.9987	0.0001	0.9677	0.0023
8	8	0.9973	0.0001	0.9697	0.0019
7	4	0.9972	0.0002	0.9589	0.0024
6	2	0.9946	0.0001	0.9458	0.0032
5	3	0.9861	0.0002	0.9421	0.0030
4	1	0.9691	0.0005	0.9311	0.0026
3	7	0.9245	0.0004	0.8918	0.0019
2	6	0.9079	0.0008	0.8912	0.0046
1	9	0.7876	0.0008	0.7861	0.0015

Fig. 12. Simulation results for WBC data set.

and the increase of the classification quality can be discerned. This phenomenon occurs when first two features (i.e., 6 and 2) are deleted from data set. The test quality grows from 0.7781 for original data set up to 0.7819 for the reduced one. The removal of four least significant features leads to 0.0155 decrease of  $q_{cv}^T$  index. The rejection of the subsequent features results in a significant deterioration in the data set representativeness, therefore the obtained outcomes keep on worsening. The smallest value of test quality is obtained for  $N = 2$ . However, for the data set with the single feature ( $N = 1$ ), the value of  $q_{cv}^T$  is over 7% higher than the one determined when  $N = 2$ .

Finally, Table IV and Fig. 14 present the results achieved for the PD data set. As shown, discarding ten least significant features yields a slight fluctuation in classification outcomes, since the overall level of quality varies by about 2% here. The reduction of 11 features makes  $q_{cv}^T$  decrease below 0.84. The removal of seven subsequent features results in  $q_{cv}^T$  changes in the range of 0.87 to 0.83. Discarding 17 least significant features results in a substantial drop in test quality down to a

value of 0.7197. At last, when we get rid of  $N - 1$  features, the worst outcome is provided, i.e.,  $q_{cv} = 0.7015$ .

## VI. SUMMARY

In this work, the complete algorithm for determining the significance of input features in medical data sets was proposed. It was based on the definition of the global sensitivity indices generated according to the Sobol method. The correctness of the algorithm was verified on the UCI-MLR data classification tasks using the PNN model by computing learning and testing qualities. We showed that it was possible to obtain higher classification performance of PNN after removal of the least significant features. According to medical feedback, the proposed algorithm exhibited proper functioning. Based on the numerical verification, the algorithm had advantageous properties in high-dimensional case ( $N = 22$ ) since no increase in data set cardinality was required to achieve satisfactory

**Abstract**—The paper is devoted to the problem of automatic geometry evaluation of the log moving through the conveyor. The video sequence obtained from the single camera is used as the input data. The principal restrictions of the target objects described for the given task, and the requirements to the video recording of the manufacturing process are formulated on the basis of datasets from more than .5M video images. The authors' method for the video sequence segmentation in respect to the log tracking is presented. The algorithm is based on the combination of background subtraction techniques and probabilistic methods. Next part of the paper is devoted to the log geometry estimation methods. The authors' algorithm for the log geometry structure recovery is based on the detection, isolation and approximation of log boundaries. The results of the research are implemented in the development of the conveyor-tracking system for automatic log sorting.

## I. INTRODUCTION

THE recent problem of solid body geometry determination by using machine vision techniques is connected with development of the fast and precise methods for object form and dimension measurements by its two-dimensional images. The peculiarity of the given task is logs volume measurement during their passing through the conveyor. The input data for the measurement algorithm is digitalized video sequence obtained from the camera which is mounted over a conveyor. It should be mentioned that such a problem can be rather successfully solved with 3D scanning by using an expensive laser scanner and particular methods for its output data processing [1]. This paper presents another approach which is least expensive in the view of required technical equipment: data on objects of interest is obtained from one video camera (Fig. 1).

Log geometry determination is a complex task. On the one hand it involves development of the mathematical algorithms for video processing which can sufficiently represent in real time the processes related to the observed objects. This group includes segmentation, detecting and tracking methods. On the other hand it is necessary to investigate the methods for geometry estimation and 3D structure recovery of the object of interest. Implementation of the 3D structure recovery is the principle requirement for the successful

development of the machine vision system for the round timber automatic sorting.

This paper presents a log detection algorithm, which develops the previously suggested approach based on combination of background subtraction and probabilistic methods. The filtering of the false positives at pixel or region of connected pixel levels is presented. The method of log video tracing is considered, thus the method of efficient detection and tracking of several observed logs by predicting of the object position in consecutive frames is developed. Finally, method of an object boundaries search and approximation to restore the geometry of logs is given.

The paper structure is the following. The related works are analyzed and discussed in the Part 2. In the Part 3 an overview of the authors' method for segmentation, detection and isolation of the geometric features of logs is given. The results of experiments and their discussion are given in the Part 4. The Part 5 is the findings of the research performed.

## II. RELATED WORK

First stage of the image sequence processing is the isolation of the moving objects in the scene from the background. The well-known methods performing this operation can be roughly divided into three main groups: background subtraction methods [2,3], probabilistic methods [4-6,12-14] and frame difference methods [11,19]. Each group has its own advantages and disadvantages, so it is necessary to select method or combination of methods obeyed the given task in order to achieve the optimum efficiency of the system. The specifics of the isolation of logs passing through the conveyor are the following:

- Strict restrictions to the algorithm speedup (real time mode);
- Background dynamic changing (due to the moving parts of the conveyor)
- Flat contrast of the scene;
- Probable overlap of the objects of interest which discourages their separation.

The next stage is determination of a direction and velocity of the objects of interest. The problem-solving techniques considered in the research are cross-correlation function,

Fig. 1 Sample images from the video sequence of the logs passing through the conveyor

phase correction and Lukas-Kanade method [10,11,19]. These methods are widely used for movement analysis in real-time surveillance and control systems.

The large amount of methods is developed for the purpose of analyzed scene recovery. They permit estimation of the 3D objects properties by 2D projections with sufficient precise depending on the restrictions for the objects in the scene and recording conditions. All the observed methods can be divided into several groups according to the data source on analyzed scene. This is about features which permit the structure recovery by motion [11,16], texture and silhouettes [26], contours of the objects of interest [15] or data on scene luminosity [19,25]. Structure recovery by motion [18] involves search in the image the key points regions in the form of angles or spots [16,17], determination the correspondence between detected regions, computation of their location and forming the surface of the objects. The approach based on form determination by scene luminosity data is presented in [25]. It means the surface form determination through the calculation of correlation between intensity (luminosity) of the surface element and direction of the normal to the surface by the Lambert's cosine law. Lambertian reflectance method determines the correlation for light source power, surface albedo and distance between surface, sensor and light sources; it can be successfully implemented in tasks where mentioned parameters are priory known or determined by calibration procedure.

Analysis of the video sequence of the given technological process shows that image features suited for making hypothesis about geometry and dimension of the object cannot be implemented in the given task in general as far as they are subjected to the many factors, such as luminosity, form distortion, reflectivity of the objects' surface, etc. For example the surface of a log can be texturized or machined,

which is influence on reflectivity of logs. This restriction does not permit implementation of the motion or scene luminosity methods for object form recovery in the given task. Thus the surface recovery method based on the silhouettes of the object [15,26] was selected for implementation in the given task.

### III. MATERIAL AND METHODS

#### A. Image segmentation and object detection

Literature data and log movement video sequence analyses show that the most appropriate for log segmentation are the background subtraction and statistics-based methods. The former group of methods assumes the extraction of the foreground objects by subtraction of the pattern called background model from the current frame of the video sequence, therefore the subtractive image is formed. The subtractive image of two images can be defined as following:

$$D(i, j) = \begin{cases} true, & |I(i, j) - B(i, j)| > p \\ false, & otherwise \end{cases} \quad (1)$$

where  $p$  – preset threshold,  $D(i, j)$  –subtractive (binary) image,  $I(i, j)$  –video frame,  $B(i, j)$  –background model in each pixel  $(i, j)$  of images.

In order to consider the background alteration it is to be periodically estimated and updated. For this purpose the Gaussian smoothing method which assumes the sequential calculating of frame pixel deviation from pixel value of periodically updated background model. It is expected that each pixel of the background model is described by expectation value and dispersion. The randomized processes can be described by using the Gaussian distribution; however the expectation value and dispersion can be determined

without probability distribution law by averaging the finite number of measurements:

$$\mu = \frac{1}{n} \sum_{t=1}^n I_t(i, j) \quad (2)$$

$$\sigma^2 = \frac{1}{n} \sum_{t=1}^n I_t^2(i, j) - \left( \frac{1}{n} \sum_{t=1}^n I_t(i, j) \right)^2 \quad (3)$$

where  $I_t(i, j)$ —randomized process for pixel  $(i, j)$  at the instant  $t$ .

That is how the background model initialized during first  $n$  frames, so the expectation value and mean square deviation are calculated over  $n$  frames. The belonging of the pixel to the foreground object is confirmed when the difference between mean square deviation of the background pixel and dispersion of the current pixel exceeds the threshold  $p$ :

$$|\mu_t(i, j) - I_t(i, j)| - \sigma_t(i, j) > p \quad (4)$$

The background is updated with the infinite impulse response for the purpose of the scene changes accounting:

$$\mu_{t+1}(i, j) = (1 - \alpha) \mu_t(i, j) + \alpha I_t(i, j) \quad (5)$$

$$\sigma_{t+1}(i, j) = (1 - \alpha) \sigma_t(i, j) + \alpha |I_t(i, j) - \mu_t(i, j)| \quad (6)$$

where  $\alpha$  defines the background model sensitivity to external condition alteration. The problem of the optimal threshold  $p$  and parameter  $\alpha$  selection is considered in Part 4 of this paper.

That way, the segmentation algorithm implements the following procedure for background and foreground separation (Fig. 2):

- preliminary formation of the background model;
- background model updating in real-time mode;
- log isolation at the pixel level.

Next stage is a log detection. It is possible to extract noise from the obtained foreground image by using fast and simple morphology methods such as dilatation and erosion [11]. Then remained connected components are combined into blobs and the minimal bounding rectangle is calculated [21] for each region, by doing so the small regions are excluded from the consideration. After the foreground objects were isolated they should be matched with the objects in the previous frame. At this stage the problem of log tracking

among sequential video frames should be solved. It can be reduced to the assignment problem if the matching of a pair of contiguous frames is formulated as optimization problem with characteristic function which minimum provides the best matching. The assignment problem can be solved by using combinatorial optimization apparatus [22]. In general this problem is stated as following:

Let there be given two sets  $U$  и  $V$  of the same size and a cost function  $C$ . It is necessary to correspond each element of one set to exactly one element of another  $f: U \rightarrow V$  in such a manner that the cost function  $\sum C(u, f(u))$  would be minimum.

In the context of the given task the sum of the Euclidian distances between log images of two contiguous frames is to be minimum. Hence the algorithm output in terms of bipartite graph is a list of edges with minimum weight matching directed from  $U$  to  $V$ . Such parameters as shape similarity and location of blobs as well as dimension and location of their bounding rectangles are implemented as metrics in the given task.

Two common cases are possible during the objects matching:

1. The one-to-one correspondence for the objects in current and previous frames is specified.
2. The full or partial correspondence for the objects in current frame to the objects in previous frame cannot be recognized. This case corresponds with disappearing of the object from video sequence, appearing of the new object, overlapping of two or more objects or splitting object into several blobs.

The separation of the objects by using prediction of the object location from previous frame in the current one is implemented to avoid their overlapping or merging [23].

#### B. Contour extraction and parameters estimation

The main parameters of a log that should be determined are diameter and length. The length of the log is defined as integral sum of its shifts determined for each pair of contiguous frames in video sequence as far as log moves. The magnitude and direction of the shift is determined by matching contiguous frames. The idea of matching is in the determination of the spatial  $g: S \rightarrow T$  and brightness  $f: R \rightarrow R$  transformations which permit transformation of the image  $I_t$  towards image  $I_{t+1}$  in such a way that points belonging to the

Fig. 2 Log segmentation a) background expectation value b) background mean square deviation c) input frame d) background model subtraction result (log silhouette)

Fig. 3 Result of the log boundaries detection

object in one frame are coincident with the points in another one:

$$I_i(x) = f(I_{i+1}(g(x))), xS, g(x)T \quad (7)$$

In the given task the magnitude and direction of the log movement is determined in real-time mode by using group of methods based on the phase correlation [19,20].

For the purpose of log diameter determination the log boundaries detection algorithm by line-to-line image scanning was developed. In assumption that the object is stretched and linear, with vertical orientation, the search of points  $m_R$  and  $m_L$  belonging to the right and left boundaries of the log respectively is applied to each line of log binary image (Fig. 3). As a result two sets  $M_R$  and  $M_L$  containing points of right and left probabilistic boundaries of the log are obtained after processing each line of the current frame. Mahalanobis distance [7] is implemented to determine diameter (distance between points of the right and left boundaries) which is define as following:

$$d(m_R, m_L) = \sqrt{(m_R - m_L)^T S^{-1} (m_R - m_L)} \quad (8)$$

$$S = \begin{vmatrix} \cos^2 \theta & 0 \\ 0 & 1 \end{vmatrix} \quad (9)$$

Matrix  $S$  can be explained as correcting coefficient which considers slope angle  $\theta$  of the log towards vertical projection, if  $S$  is a unity matrix the Mahalanobis distance is equal to Euclidian distance, the log is straight up and down. In order to calculate this coefficient the mathematical tools of inertia moment theory [6,11,19] is implemented.

Obtained sets of the diameters for each frame with a binding to the log movement are stored in the resulted log accumulator  $D$ . The accumulator  $D$  is defined as a set of ordered pairs  $(x,y) \in X \times Y$ , where  $Y$  is a set of diameters and  $X$  is a set of lengths. The diameters' set  $Y$  might contain not only the required points of log boundaries but also the points of other objects, such as conveyor parts, knots or bark, which are distort the log form. In order to exclude these elements three methods for adjustment the noisy data to the log geometry were observed: Random sample consensus (RANSAC) method [9], non-parametric locally weighted scatterplot smoothing LOWESS [8] and polynomial

regression [24]. The results of the method comparison and discussion are presented in Part 3.

### C. Log model reconstruction

The unequivocal reconstruction of the object 3D shape by its contour in 2D image is impossible [19]. However, the reasonable approximation of the objects of interest can be developed in presence of an appropriate model and suited recording conditions. Some assumptions which hold true in practice and simplify the algorithm development should be introduced for this purpose:

1. Log is a generalized cylinder which surface is induced by the movement of cross-section area along the symmetry line; radius of the cross-sectional area can have smooth variations.
2. Internal and external calibration parameters for the camera are given.
3. Camera is downward directed to observe log in such a way that image plane is parallel to the conveyor plane and the distance between the latter and camera is given.

The 3D coordinates of the points which projections in the image are located at the silhouette boundaries are to be determined for the purpose of observed object 3D structure recovery. The photo and video cameras used in technical systems generate image according to the central projection law. This projection of 3D space into plane is not unequivocal as far as all 3D points along the line are reduced into one point of 2D image. The authors' method for log structure determination is based on the assumption that the physical dimensions of the log presented in the image as a silhouette can be determined by using the fact that the rotation body section perpendicular to the symmetry line is a circle. The description of the method is given below.

Fig. 4 illustrates the process of log capturing into image  $P$  at a height  $Z$  over a conveyor plane  $E$ . Points  $a$  and  $b$  are the images of the boundary point  $A$  and  $B$  of the circle cross-section of the conic surface of a log. These points are located at the distances  $ao = r$  and  $bo = r$  from the central point. Intervals  $SA$ ,  $SB$  are tangents to the circle of radius  $R$ . The problem is to find a real radius  $R$  of the object by given value  $r$ .

Fig. 4 Result of the log boundaries detection

The radius  $R$  can be determined as following by using well-known trigonometric expressions:

$$R = \frac{Z}{1 + \sqrt{1 + \frac{f^2}{r^2}}} \quad (10)$$

where focal distance  $f$  is known after calibration performance, distance to the conveyor  $Z$  can be determined at the stage of installation and start-up work.

Thus the 3D structure of a log can be recovered by determination of all the radii forming the generalized cylinder. The log volume in this case can be defined as a sum of the volumes of frustum cone sections along the log length.

$$V = \frac{\pi}{3} \sum_{i=0}^n (R_i^2 + R_i r_i + r_i^2) l_i \quad (11)$$

where  $R_i$  and  $r_i$  – upper and lower radii of the log section,  $l_i$  – section length.

#### IV. RESULTS AND DISCUSSION

Some experiments on real data while changing input parameters of the algorithms and analysis methods were carried out in order to estimate the quality of logs detection and accuracy of their dimensions determination. First experiment was dedicated to the log segmentation quality estimation. The idea of the experiment is in the following. For all images in the sample the standard location of the object of interest is marked out within the accuracy of a pixel (Fig. 5b) and recorded in database. Then the same images (Fig. 5a) are inputted to the detection algorithm at various values of threshold  $p$  and background model sensitivity

Fig. 5 Video sequence segmentation. a) input image b) ground truth c) algorithm output d) algorithm output after noise filtration (morphological filter)

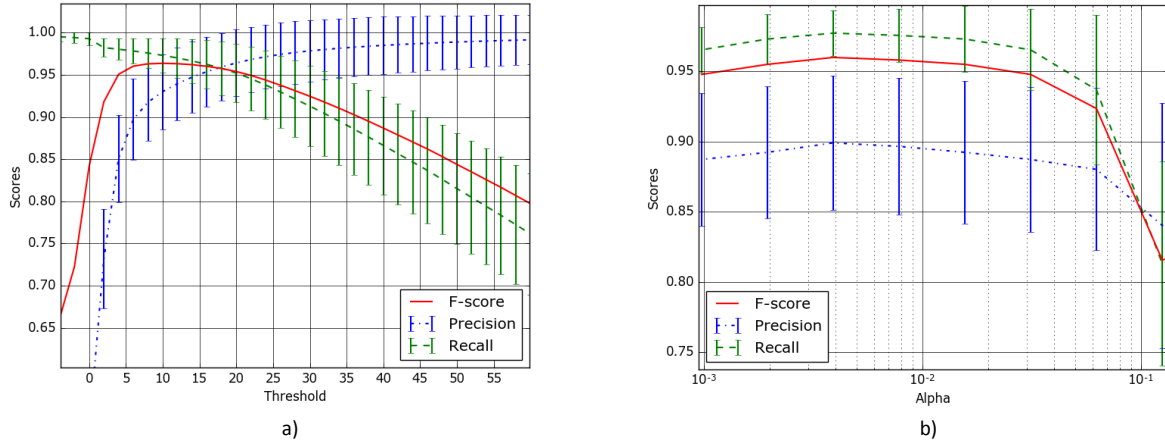

Fig. 6 Detector adjustment. a) binarization threshold p b) background sensitivity parameter  $\alpha$

parameter  $\alpha$ . Resulted binary images (Fig. 5c) are also recorded in database for the purpose of the further comparison with standard images and calculation of the algorithm performance quality.

The F-score index which based on the concept of precision and recall is implemented for algorithm estimation:

$$F_{\beta} = (1 + \beta^2) \frac{\text{Precision} \cdot \text{Recall}}{(\beta^2 + \text{Precision}) + \text{Recall}} \quad (12)$$

where

$$\text{Precision} = \frac{TP}{TP + FP}; \quad \text{Recall} = \frac{TP}{TP + FN} \quad (13)$$

$TP$  – true-positive predicted condition,  $TN$  – true-negative predicted condition,  $FP$  – false-positive predicted condition and  $FN$  – false-negative predicted condition.

Parameter  $\beta$  lies in the range of  $0 < \beta < 1$  if the priority is given to precision, otherwise  $\beta > 1$ . In the given task the priority is given to the recall as far as the accuracy of the log silhouette boundaries detection relies on the minimum rate of the type II error. Thus the  $\beta=2$  was implemented.

The metrics of segmentation algorithm applied to the test video set are illustrated in Fig. 6. The resulted charts demonstrate how the algorithm characteristics vary depending on variations in threshold  $p$  (Fig. 6a) and sensitivity parameter  $\alpha$  (Fig. 6b). The F-scores in both charts have clearly defined global maximum. In this case the algorithm provides permissible compromise between the precision and recall for the log segmentation. For this reason the further investigations implement the detector with threshold  $p=8$  and parameter  $\alpha=0,004$ .

Second experiment was dedicated to the problem of the real log boundaries recovery from noisy input data. This problem can be formulated in terms of regression analysis as following. The set of objects  $X$  and set of possible response  $Y$  are given. The relevant connection  $y^*: X \rightarrow Y$  exists, which true values are known for the test sample only. The transformation  $y: X \rightarrow Y$  which provides minimum mean square error for test sample is to be found:

$$\sum_{i=1}^n (y^*(x_i) - y(x_i))^2 \rightarrow \min y \quad (14)$$

For the task of the log boundaries approximation the set  $Y$  determines the set of diameters and set  $X$  determines the set of lengths. The results of the observed regression methods implementation are shown in Fig. 7.

The noise rate in the input data is high (Fig. 7d, blue column) because of the low contrast of some logs and adverse impact of the conveyor elements and bark. The main disadvantage of the polynomial regression is sensitivity to the spikes in the input data. The sufficient deviation of the approximation function from the real boundary of the log near the minimum and maximum  $x$  values (edge effect) is evidenced by using the polynomial of degree  $k > 1$ . The methods based on locally weighted smoothing and random sample are less sensitivity to the problem of spikes and edge effect. The average results of the regression algorithm implementation are shown in Table 1. The approximation error is calculated according to the formula:

$$MSE = \frac{1}{n} \sum_{i=1}^n (Y_i^* - Y_i)^2 \quad (15)$$

where  $Y_i$  – diameter obtained by the observed algorithm;  $Y_i^*$  – diameter nominal value. Diameter nominal values were founded manually for each test log.

TABLE I.  
MEAN SQUARE ERROR FOR THE REGRESSION METHODS

Method	MSE( $\sigma_{MSE}$ )
Initial data (before smoothing)	1,781(0,153)
LOWESS	0,115 (0,097)
<b>RANSAC</b>	<b>0,045(0,041)</b>
Polynomial (1 degree)	0,271 (0,107)
Polynomial (3 degree)	0,395 (0,139)
Polynomial (5 degree)	0,585 (0,065)
Polynomial (7 degree)	0,726 (0,041)

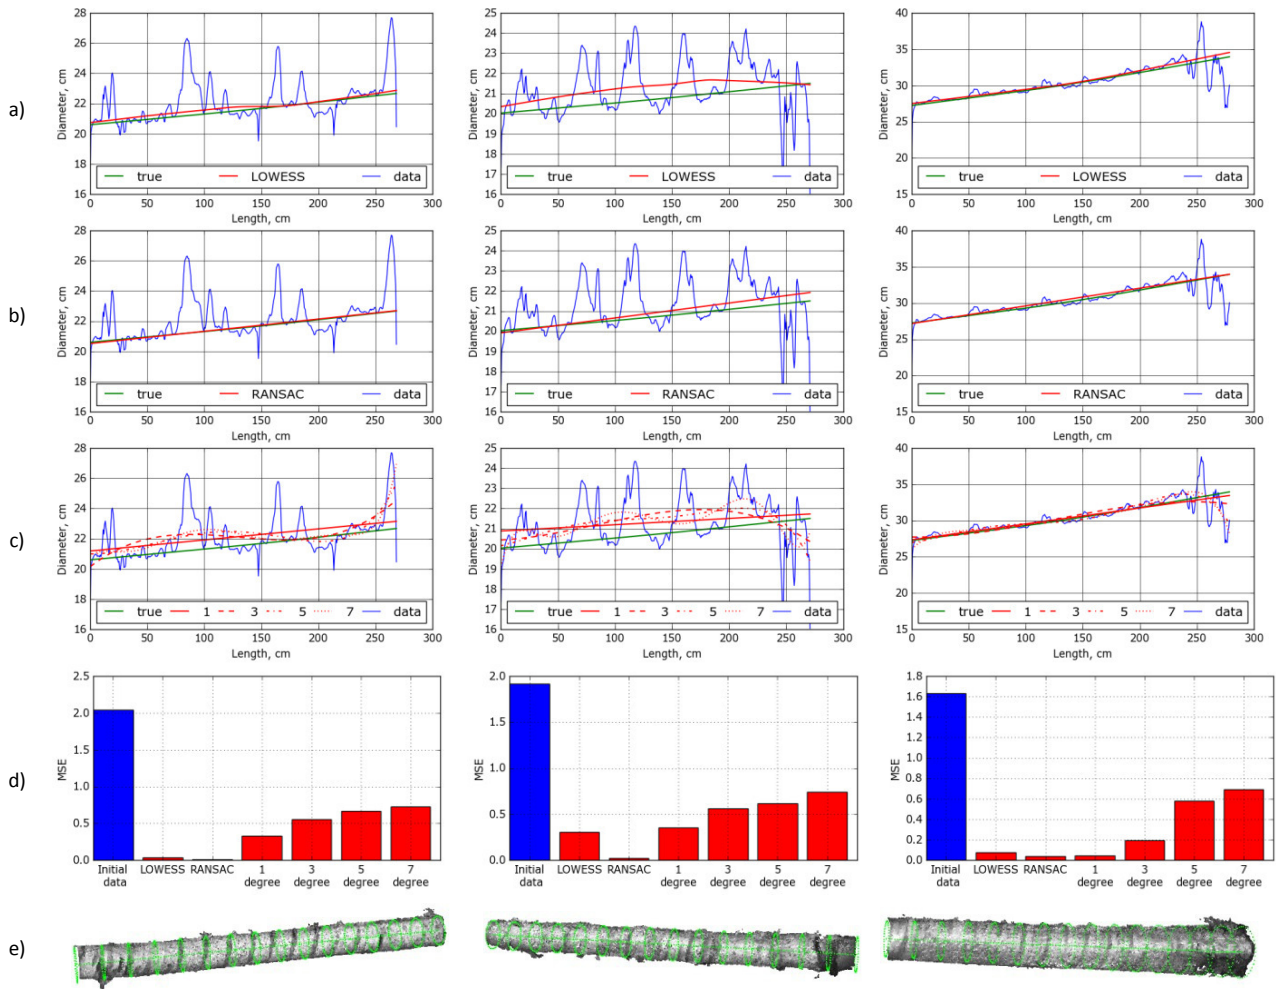

Fig. 7 Result of the regression methods implementation a) LOWESS b) RANSAC c) polynomial regression of the 1,3,5, 7th degree d) error rate comparison e) reconstructed 3D-view of the log

Analysis of the Table 1 allows us to conclude that the RANSAC has the best performance among the observed methods. The RANSAC method is tolerant to noisy input data and provides the relevant connection approximation with minimum mean square error  $0,045 \pm 0,041$ .

The log detection and dimension algorithm introduced within this paper was programmed in C++. It was tested on the PC Intel Core i7, 2800 Mhz, 6Gb DDR RAM, GeForce GTS 450. The operation speed of the algorithm provides processing of the video sequence of 384x288 frame size at 25 frames per second. Thus the algorithm meets the requirement for the implementation in the real-time machine vision system for round timber sorting.

#### V. CONCLUSIONS AND FURTHER WORK

The problem of logs dimensions and form determination during their passing through the conveyor was observed within this paper. The principal feature of this task is that the input data in the form of digitalized video sequence is obtained by using single camera. The results of logs segmentation allow us to conclude that the image can be

separated into background and foreground regions by using quite simple subtraction methods. These methods have successful performance for the cases of the static background. When the global changes of the scene, i.e. movement of the conveyor parts, bark or as a result of the camera vibration, are happened the inappropriate image pixels non-related to any log can be selected even with periodically updated background model. The implementation of the morphological operations partially solves this problem. The result of the segmentation can be recognized as satisfactory as far as algorithm provides quality of the detection at the rate of 96,9% true positive rate with  $2,9 \cdot 10^{-2}$  false positive rate.

The results of the regression and log surface reconstruction experiment show that the RANSAC has the best performance among the observed methods. Moreover the implementation of RANSAC allow eliminating effects of improper segmentation.

The further development of this project is in the adaptation of the system to the two-camera mode for the log surface reconstruction with higher accuracy. This approach also provides an opportunity to estimate not only quantity

(volume, length) but the quality characteristics of logs, such as crook, ovality and buttswell.

# Binding Operators in Type-Theory of Algorithms for Algorithmic Binding of Functional Neuro-Receptors

Roussanka Loukanova  
Stockholm University  
Email: rloukanova@gmail.com

**Abstract**—This paper is on a new approach to mathematics of the notion of algorithm. We extend the higher-order, type-theory of acyclic recursion, i.e., of typed, state-dependent algorithms, which was originally introduced by Moschovakis in [1]. We introduce the concept of recursive  $\lambda$ -binding of argument slots across a sequence of mutually recursive assignments. The primary applications of the extended theory are to computational semantics of formal and natural languages, and to computational neuroscience. We investigate some properties of algorithmic equivalence of functions and relations that bind argument slots of other functions and relations across the recursion operator acting via mutually recursive assignments.

## I. INTRODUCTION

THE IDEAS of the new approach to the mathematical notion of algorithm, by a theory of formal languages of functional recursion, were introduced by Moschovakis [2]. The initial steps for extending the approach in [2] to a typed theory  $L_{ar}^\lambda$  of acyclic algorithms, were introduced by Moschovakis in [1]. The theory  $L_{ar}^\lambda$  and its formal language, also denoted by  $L_{ar}^\lambda$ , use terms formed under an acyclicity condition restricting the theory to acyclic algorithms that always terminate their calculations after finite number of steps. In addition,  $L_{ar}^\lambda$  uses *currying* coding of functions and relations that have multiple arguments, via sequences of unary functions and corresponding terms denoting them. The idea of such coding was initially given by Gottlob Frege. Later, Shönfinkel re-introduced it by mathematical precision. Then, Curry [3] developed the coding into a fully formalised technique, nowadays popularly named as currying. The type theory  $L_r^\lambda$  of algorithms with full recursion, i.e., of algorithms that are not necessarily acyclic, is under development along with  $L_{ar}^\lambda$ .

The type theory  $L_r^\lambda$ , including its sub-theory  $L_{ar}^\lambda$ , extends Gallin  $\lambda$ -calculus and its logic  $TY_2$  (see Gallin [4]), in various aspects. Similarly to traditional  $\lambda$ -calculi,  $L_r^\lambda$  and  $L_{ar}^\lambda$  employ function application and  $\lambda$ -abstraction for construction of complex terms that denote composite functions with components that can involve other functions. E.g., if  $f$  is a constant denoting a unary function, then  $\lambda(x)f(x^3)$  is a term denoting another unary function. The theories  $L_r^\lambda$  and  $L_{ar}^\lambda$  extend traditional  $\lambda$ -calculi, by adding a specialised recursion operator designated by the constant *where*. E.g., the formal terms (1b) and (1c) are constructed by using the constant *where*. The  $L_r^\lambda$  terms (1a)–(1c) denote the same function. The term (1c) represent the algorithm for computing the denotation of these

terms stepwise. At first, the function that is the denotation of the term  $\lambda(x)(x^3)$  is computed, e.g., as a table of argument values and corresponding function values, and saved in the memory slot  $p$ . After that, the denotation of  $\lambda(x)[f(p(x))]$  is computed by using the data saved in the memory slot  $p$ .

$$\lambda(x)f(x^3) \quad (1a)$$

$$\lambda(x)[f(p) \text{ where } \{p := x^3\}] \quad (1b)$$

$$\lambda(x)[f(p(x)) \text{ where } \{p := \lambda(x)(x^3)\}] \quad (1c)$$

In this way,  $L_r^\lambda$  and  $L_{ar}^\lambda$  extend the expressive power of  $\lambda$ -calculus. Actually,  $L_r^\lambda$  is a mathematical theory of the notion of algorithm, which is equivalent to modelling the notion of algorithm, e.g., by Turing machines. The sub-theory  $L_{ar}^\lambda$  models acyclic algorithms, i.e., computations that always end after a finite number of steps. Importantly, this is achieved by the recursion operator *where*, at the object level of  $L_r^\lambda$  for modelling algorithmic computations. The formal theories  $L_r^\lambda$  and  $L_{ar}^\lambda$  have reduction calculi, in various versions. By using the standard reduction calculus of  $L_r^\lambda$  and  $L_{ar}^\lambda$ , the term (1a) can be reduced to (1c) (and even to a more basic term).

The type theory  $L_r^\lambda$  represents crucial semantic distinctions in formal and natural languages. We have demonstrated that  $L_{ar}^\lambda$  has major applications to computational semantics and computational syntax-semantics interfaces of human language. The work in this paper is on development of the mathematics of the notion of algorithms by targeting broad applications to Artificial Intelligence and robotics. In Section II, we give an overview of related work on type-theory of situated algorithms and situated information. Primary applications of  $L_{ar}^\lambda$  have been achieved for computational semantics and computational syntax-semantics interfaces of human language. Development of computational syntax-semantics interfaces, by using  $L_{ar}^\lambda$ , offers significant steps forward to computational representation of context-dependency and ambiguities in human language. In particular, recursion terms with free recursion variables, i.e., memory variables, represent parametric information and parametric algorithms.

This paper is on theoretical development of  $L_r^\lambda$  and  $L_{ar}^\lambda$ . Section IV presents the syntax of an extended version  $L_{raa}^\lambda$  of  $L_{ar}^\lambda$ , which has terms with components for restrictions. In the major Section V, we focus on some properties of generalised binding operators in the type theory of acyclic recursion

$L_{ar}^\lambda$ . We point out that the results presented in Section V, about the binding operators, hold for the language  $L_{raa}^\lambda$ , too. We target applications to computational neuroscience for modelling computational power of neural networks, e.g., as described in Section VI.

## II. RELATED WORK

By providing the technical notion of binding accross recursive assignments, this paper is directly related to and extends the work in Loukanova [5]. For some more explanations, see the beginning of Section IV.

Terms with restrictions, as in Section V, were originally introduced for the first time in Loukanova [6]. That work is on the formalisation of major notions of algorithmic granularity and algorithmic underspecification defined inherently, at the object level of the languages of the typed theory of recursion  $L_r^\lambda$  and  $L_{ar}^\lambda$ . Closely related to the work here, the paper [6] introduces two kinds of constraints on possible specifications of underspecified recursion variables by: (1) general acyclicity constraints, and (2) constraints that arise from specific applications. The theory of acyclic recursion is employed to represent semantic ambiguities in human language, which can not be resolved when only partial knowledge is available, even in specific contexts, with specific speakers and their references. The work in [6] takes the direction of formalisation of the notion of algorithmic underspecification carrying constraints, and fine-granularity specifications via syntax-semantics interfaces. For more details on representation of underspecification in semantics of human language, by using the type theory of acyclic recursion  $L_{ar}^\lambda$ , see Loukanova [7], [8], [9], [5].

The idea of generalised, restricted parameters were originally, for the first time, introduced by Barwise and Perry [10]. An early, more precise mathematical introduction of restricted parameters was given by Loukanova and Cooper [11], and then by Loukanova [12], [13], [14], [15]. Restricted parameters, as semantic objects, in relational semantic domains of mathematical structures, were presented more officially, i.e., mathematically, in Loukanova [16]. The first introduction of formal language of restricted parameters is given by Loukanova [17], which introduces a higher-order, type-theoretical formal language of information content that is partial, parametric, underspecified, dependent on situations, and recursive. The formal system is extended by Loukanova [18]. While the formal syntax of that language is relational and semantically designates relational semantic structures, it is the first, original formalisation of the semantic concept of generalised, restricted parameters and parametric networks. The terms of that formal language represent situation-theoretic objects. The language has specialised terms for constrained computations by mutual recursion. It introduces terms representing nets of parameters that are simultaneously constrained to satisfy restrictions. The restricted terms presented here in Section V are close in their formal structure to corresponding terms in the formal languages in [17], [18]. In this paper, we limit the formal language and theory to functional structures of typed functions, via Curry coding, see Curry [3].

## III. OVERVIEW OF THE TYPE-THEORY OF ACYCLIC RECURSION

Here we give a brief overview of  $L_{ar}^\lambda$  to facilitate the exposition in the rest of the paper. For details, see Moschovakis [1], and Loukanova [5], [19].

### A. Syntax of $L_{ar}^\lambda$

a) The set  $\text{Types}_{L_{ar}^\lambda}$  of  $L_{ar}^\lambda$ : is the smallest set defined recursively by the following rules in Backus-Naur form (BNF):

$$\tau ::= e \mid t \mid s \mid (\tau_1 \rightarrow \tau_2) \quad (2)$$

The type  $e$  is for primitive objects that are entities of the semantic domains, as well as for the terms of  $L_{ar}^\lambda$  denoting such entities. The type  $s$  is for states consisting of context information, e.g., possible worlds (situations), time and space locations, speakers, listeners;  $t$  is the type of the truth values. The type  $(\tau_1 \rightarrow \tau_2)$  is for functions from objects of type  $\tau_1$  to objects of type  $\tau_2$ . The type (3) is for functions on  $n$ -arguments of corresponding types  $\tau_1, \dots, \tau_n$  that take values of type  $\sigma$ , by currying coding.

$$(\tau_1 \rightarrow \dots \rightarrow (\tau_n \rightarrow \sigma)) \quad \sigma, \tau_i \in \text{Types}, \quad n \geq 0 \quad (3)$$

The formal language  $L_{ar}^\lambda$  has typed vocabulary. For each type  $\tau \in \text{Types}$ :

**Constants  $K$ :** denumerable set of typed constants

$$K_\tau = \{c_0^\tau, \dots, c_k^\tau, \dots\} \quad (4a)$$

$$K = \bigcup_\tau K_\tau \quad (4b)$$

**Pure variables  $PV$ :** denumerable set of typed pure variables

$$PV_\tau = \{v_0, v_1, \dots\} \quad (5a)$$

$$PV = \bigcup_\tau PV_\tau \quad (5b)$$

**Recursion (memory) variables  $RV$ :** denumerable set of typed recursion (memory) variables

$$RV_\tau = \{r_0, r_1, \dots\} \quad (6a)$$

$$RV = \bigcup_\tau RV_\tau \quad (6b)$$

**Variables:**

$$\text{Vars}_\tau = PV_\tau \cup RV_\tau \quad (7a)$$

$$\text{Vars} = PV \cup RV \quad (7b)$$

In addition to the terms the typical  $\lambda$ -calculi, the language  $L_{ar}^\lambda$  has new ones formed by using the facility of the recursion, i.e., memory, variables and a new operator for term construction, which we call *recursion operator*, designated by the operator constant *where*, in infix notation.

The recursive rules for generating the set of  $L_{ar}^\lambda$ -terms are given in (8a)–(8e), by using the extended, typed Backus-Naur (TBNF) form, with the assumed types given as superscripts. We also use the typical notation for type assignments:  $A : \tau$ , to express that  $A$  is a term of type  $\tau$ .

**Definition 1.** The set  $\text{Terms}_{\text{L}_{\text{ar}}^\lambda}$  of the terms of  $\text{L}_{\text{ar}}^\lambda$  consists of the expressions generated by the following rules, in Typed Backus-Naur Form (TBNF):

$$A ::= c^\tau : \tau \quad (8a)$$

$$| x^\tau : \tau \quad (8b)$$

$$| B^{(\sigma \rightarrow \tau)}(C^\sigma) : \tau \quad (8c)$$

$$| \lambda(v^\sigma)(B^\tau) : (\sigma \rightarrow \tau) \quad (8d)$$

$$| A_0^\sigma \text{ where } \{p_1^{\sigma_1} := A_1^{\sigma_1}, \dots, p_n^{\sigma_n} := A_n^{\sigma_n}\} : \sigma \quad (8e)$$

where  $A_1 : \sigma_1, \dots, A_n : \sigma_n$  are in  $\text{Terms}$ ;  $p_1 : \sigma_1, \dots, p_n : \sigma_n$  ( $n \geq 0$ ), are pairwise different recursion variables of the types of the assigned terms, such that the sequence of assignments  $\{p_1^{\sigma_1} := A_1^{\sigma_1}, \dots, p_n^{\sigma_n} := A_n^{\sigma_n}\}$  satisfies the following Acyclicity Constraint (AC):

**Acyclicity Constraint (AC):** the sequence of assignments  $\{p_1 := A_1, \dots, p_n := A_n\}$  is acyclic iff there is a function  $\text{rank} : \{p_1, \dots, p_n\} \rightarrow \mathbb{N}$  such that, for all  $p_i, p_j \in \{p_1, \dots, p_n\}$ ,

$$\text{if } p_j \text{ occurs freely in } A_i \text{ then } \text{rank}(p_j) < \text{rank}(p_i) \quad (9)$$

$\text{Types}_\tau$  is the set of the terms of type  $\tau$ , For each  $\tau \in \text{TYPE}$ .

We call the terms of the form (10) *recursion terms*, or alternatively *where-terms*:

$$[A_0 \text{ where } \{p_1 := A_1, \dots, p_n := A_n\}] \quad (10)$$

We say that a term  $A$  is *explicit* if the constant *where* does not occur in it.

**Notation 1.** We shall use the abbreviation (11a) for *stated-dependent types sigma*, and (11b) for *state-dependent truth values*:

$$\tilde{\sigma} \equiv s \rightarrow \sigma \quad (11a)$$

$$\tilde{t} \equiv s \rightarrow t \quad (11b)$$

We may use the following abbreviations and similar variants:

**Notation 2.**

$$\vec{p} := \vec{A} \equiv p_1 := A_1, \dots, p_n := A_n \quad (n \geq 0) \quad (12a)$$

**Notation 3.**

$$H(\vec{x}) \equiv H(x_1) \dots (x_n) \quad (13)$$

$$\lambda(\vec{v}_j) \equiv \lambda(v_{j,1}, \dots, v_{j,l_j}) \equiv \lambda(v_{j,1}) \dots \lambda(v_{j,l_j}) \quad (14)$$

We use the typical notation  $\mathbb{N}$  of the set of the natural numbers.

**Definition 2** (Immediate terms). The set of the immediate terms, which we denote by  $\text{ImT}$ , is defined as follows:

**Definition 3** (Immediate Terms). The set  $\text{ImT}$  of immediate terms is defined as follows:

$$\text{ImT}^\tau ::= X \mid \quad (15a)$$

$$Y(v_1) \dots (v_m) \quad (15b)$$

$$\text{ImT}^{(\sigma_1 \rightarrow \dots (\sigma_n \rightarrow \tau))} ::= \lambda(u_1) \dots \lambda(u_n) Y(v_1) \dots (v_m) \quad (15c)$$

where  $n \geq 0, m \geq 0$ ;  $u_i \in \text{PV}_{\sigma_i}$ , for  $i = 1, \dots, n$ ;  $v_j \in \text{PV}_{\tau_j}$ , for  $j = 1, \dots, m$ ;  $X \in \text{PV}_\tau$ ,  $Y \in \text{RV}_{(\tau_1 \rightarrow \dots (\tau_m \rightarrow \tau))}$ .

**Definition 4** (Proper terms). A term  $A$  is proper if it is not immediate, e.g, the set  $\text{PrT}$  of the proper terms of  $\text{L}_{\text{ar}}^\lambda$  consists of all terms that are not in  $\text{ImT}$ :

$$\text{PrT} = (\text{Terms} - \text{ImT}) \quad (16)$$

## B. Reduction Calculus

### a) Reduction Rules:

**Congruence:** If  $A \equiv_c B$ , then  $A \Rightarrow B$  (con)

**Transitivity:** If  $A \Rightarrow B$  and  $B \Rightarrow C$ , then  $A \Rightarrow C$  (t)

**Compositionality:**

If  $A \Rightarrow A'$  and  $B \Rightarrow B'$ , then  $A(B) \Rightarrow A'(B')$  (c-ap)

If  $A \Rightarrow B$ , then  $\lambda(u)(A) \Rightarrow \lambda(u)(B)$  (c- $\lambda$ )

If  $A_i \Rightarrow B_i$ , for  $i = 0, \dots, n$ , then

$A_0 \text{ where } \{p_1 := A_1, \dots, p_n := A_n\} \Rightarrow B_0 \text{ where } \{p_1 := B_1, \dots, p_n := B_n\}$  (c-r)

**Head rule:**

$$(A_0 \text{ where } \{\vec{p} := \vec{A}\}) \text{ where } \{\vec{q} := \vec{B}\} \Rightarrow A_0 \text{ where } \{\vec{p} := \vec{A}, \vec{q} := \vec{B}\} \quad (h)$$

given that no  $p_i$  occurs freely in any  $B_j$ , for  $i = 1, \dots, n$ ,  $j = 1, \dots, m$ .

**Bekiř-Scott rule:**

$$A_0 \text{ where } \{p := (B_0 \text{ where } \{\vec{q} := \vec{B}\}), \vec{p} := \vec{A}\} \Rightarrow A_0 \text{ where } \{p := B_0, \vec{q} := \vec{B}, \vec{p} := \vec{A}\} \quad (B-S)$$

given that no  $q_i$  occurs freely in any  $A_j$ , for  $i = 1, \dots, n$ ,  $j = 1, \dots, m$

**Recursion-application rule:**

$$(A_0 \text{ where } \{\vec{p} := \vec{A}\})(B) \Rightarrow A_0(B) \text{ where } \{\vec{p} := \vec{A}\} \quad (rap)$$

given that no  $p_i$  occurs freely in  $B$  for  $i = 1, \dots, n$

**Application rule:**

$$A(B) \Rightarrow A(p) \text{ where } \{p := B\} \quad (ap)$$

given that  $B$  is a proper term and  $p$  is a fresh recursion variable

**$\lambda$ -rule:**

$$\lambda(u)(A_0 \text{ where } \{p_1 := A_1, \dots, p_n := A_n\}) \Rightarrow \lambda(u)A'_0 \text{ where } \{p'_1 := \lambda(u)A'_1, \dots, p'_n := \lambda(u)A'_n\} \quad (\lambda)$$

where for all  $i = 1, \dots, n$ ,  $p'_i$  is a fresh recursion variable and  $A'_i$  is the result of the replacement of the free occurrences of  $p_1, \dots, p_n$  in  $A_i$  with  $p'_1(u), \dots, p'_n(u)$ , respectively, i.e.:

$$A'_i \equiv A_i \{p_1 := p'_1(u), \dots, p_n := p'_n(u)\} \quad \text{for all } i \in \{1, \dots, n\} \quad (20)$$

**Definition 5** (Reduction Relation). *The reduction relation in  $L_{ar}^\lambda$  is the smallest relation, denoted by  $\Rightarrow$ , between terms that is closed under the reduction rules.*

**Definition 6** (Term Irreducibility). *We say that a term  $A \in \text{Terms}$  is irreducible if and only if*

$$\text{for all } B \in \text{Terms, if } A \Rightarrow B, \text{ then } A \equiv_c B \quad (21)$$

Here we shall present some of the major results that are essential for algorithmic semantics and which have direct relevance to this paper.

**Theorem 1** (Canonical Form Theorem: existence and uniqueness of the canonical forms). *(See Moschovakis [1], § 3.1.) For each term  $A$ , there is a unique, up to congruence, irreducible term  $C$ , denoted by  $\text{cf}(A)$  and called the canonical form of  $A$ , such that:*

- 1)  $\text{cf}(A) \equiv A_0$  where  $\{p_1 := A_1, \dots, p_n := A_n\}$ , for some explicit, irreducible terms  $A_1, \dots, A_n$  ( $n \geq 0$ )
- 2)  $A \Rightarrow \text{cf}(A)$
- 3) if  $A \Rightarrow B$  and  $B$  is irreducible, then  $B \equiv_c \text{cf}(A)$ , i.e.,  $\text{cf}(A)$  is the unique, up to congruence, irreducible term to which  $A$  can be reduced.

**Theorem 2** (Referential Synonymy Theorem). *(For the original theorem, see Moschovakis [1]) Two terms  $A$  and  $B$  are algorithmically synonymous, i.e., algorithmically equivalent,  $A \approx B$ , if and only if there are explicit, irreducible terms of corresponding types:  $A_0 : \sigma_0, \dots, A_n : \sigma_n$ , and  $B_0 : \sigma_0, \dots, B_n : \sigma_n$  ( $n \geq 0$ ), such that:*

$$A^{\sigma_0} \Rightarrow_{cf} A_0^{\sigma_0} \text{ where } \{p_1 := A_1^{\sigma_1}, \dots, p_n := A_n^{\sigma_n}\} \quad (22a)$$

$$B^{\sigma_0} \Rightarrow_{cf} B_0^{\sigma_0} \text{ where } \{p_1 := B_1^{\sigma_1}, \dots, p_n := B_n^{\sigma_n}\} \quad (22b)$$

and for all  $i = 0, \dots, n$ ,

$$\text{den}(A_i)(g) = \text{den}(B_i)(g), \quad \text{for all } g \in G \quad (23)$$

Thus,  $A$  and  $B$  are algorithmically synonymous,  $A \approx B$ , if and only if

- 1) either  $A$  and  $B$  are proper terms that have the same denotations computed by the same algorithm
- 2) or  $A$  and  $B$  are immediate and have the same denotations

When  $A \approx B$ , we also say that  $A$  and  $B$  are referentially synonymous, in case we refer to the algorithms they designate.

**Theorem 3** (Compositionality Theorem for algorithmic synonymy). *For all  $A \in \text{Terms}_\sigma$ ,  $B, C \in \text{Terms}_\tau$ ,  $x \in \text{PV}_\tau$ , such that the substitutions  $A\{x \equiv B\}$ , and  $A\{x \equiv C\}$  are free, i.e., do not cause variable collisions:*

$$B \approx C \implies A\{x \equiv B\} \approx A\{x \equiv C\} \quad (24)$$

*Proof.* See Moschovakis [1], § 3.22.  $\square$

**Corollary 1.** *For all explicit, irreducible terms  $A : \sigma$  and  $B : \sigma$ ,*

$$A \approx B \quad \text{iff} \quad \text{den}(A)(g) = \text{den}(B)(g), \quad (25) \\ \text{for all } g \in G$$

$$\frac{A \approx B}{A \approx B} \quad (27)$$

$$\frac{A \approx A \quad \frac{B \approx A}{A \approx B} \quad \frac{A \approx B \quad B \approx C}{A \approx C}}{A \approx B} \quad (28)$$

$$\frac{A_1 \approx B_1 \quad A_2 \approx B_2}{A_1(A_2) \approx B_1(B_2)} \quad \frac{A \approx B}{\lambda(u)A \approx \lambda(u)B} \quad (29)$$

$$\frac{A_0 \approx B_0 \quad A_1 \approx B_1 \quad \dots \quad A_n \approx B_n}{A_0 \text{ where } \{\vec{p} := \vec{A}\} \approx B_0 \text{ where } \{\vec{q} := \vec{B}\}} \quad (30)$$

$$\frac{\models C = D}{C \approx D} (*) \quad \frac{}{(\lambda(u)C)(v) \approx C\{u \equiv v\}} (C \text{ e.i.}) \quad (31)$$

where:

“e.i.” abbreviates “explicit, irreducible”;

(\*):  $C, D$  are both e.i. terms;

$\models C = D \iff$  for all  $g \in G$ ,  $\text{den}(C)(g) = \text{den}(D)(g)$ .

$u, v \in \text{PV}$  and the substitution  $C\{u \equiv v\}$  is free.

TABLE I  
THE CALCULUS OF ALGORITHMIC SYNONYMY

**Corollary 2.** *For every explicit, irreducible term  $A : (\sigma \rightarrow \tau)$  and  $x \in \text{PV}_\sigma$ ,  $x : \sigma$ , such that  $x$  does not occur in  $A$ :*

$$\lambda(x)(A(x)) \approx A \quad (26)$$

#### IV. SEQUENTIAL BINDERS

Loukanova [5] renders sentences of human language, which contain several quantifiers with multiple scope interpretations, into underspecified  $L_{ar}^\lambda$  terms. These terms contain quantifier expressions  $Q_i$ , e.g., for  $i = 1, 2, 3$ , that can have multiple scope distributions over a joint core relation  $h$ , depending on context. The common characteristics of such terms is that regardless of the specified scope distribution of the quantifier subterms  $Q_i$ , each  $Q_i$  binds a fixed argument slot of  $h$ , i.e.,  $i$ -th argument of  $h$ .

Recursion terms in canonical forms provide a very sophisticated and elegant representation of scope distributions. They display the common factors across multiple scope distributions corresponding to a given sentence  $A$  with several quantifiers. By factoring out the differences, the canonical forms of the  $L_{ar}^\lambda$  terms representing different scopes give a common *underspecified* term that represents the set of all scope distributions for  $A$ . Such a term has free recursion variables that can be instantiated to specific scope distributions. The technique is based on formal linking of each of the quantifiers  $Q_i$  with the corresponding  $i$ -th argument slot of  $h$  that it binds, across  $\lambda$ -abstractions, recursion assignments, and reduction steps.

The details of the formalisation of linking the quantifiers to the respective argument slots that they bind across recursive assignments are left open in [5].

The rest of this paper elaborates the formalisation of binding concepts for a broad class of terms that bind argument slots. The class of these terms include terms denoting quantifiers and other binding relations and functions.

For sake of rigour and clarity, in Theorem 4, we provide detailed assumptions, the formal types (33a)–(33h), and extra

subterms in (32a)–(32e) and (34b)–(34i). These details are important for the proof. They can be ignored for understanding the essence of the theorem. Similarly, we provide such details in other theorems and results presented in this paper.

**Theorem 4** (Reduction of Strong Binders 4). *Let  $T_{m+1}$  be the term (32a)-(32e):*

$$T_{m+1} \equiv Q_{i_m} \left[ \lambda x_{i_m} Q_{i_{(m-1)}} \left[ \lambda x_{i_{(m-1)}} Q_{i_{(m-2)}} \left[ \right. \right. \right. \quad (32a)$$

$$\lambda x_{i(m-2)} Q_{i(m-3)} [\lambda x_{i(m-3)} Q_{i(m-4)} [$$
 (32b)

• • •

$$\lambda x_{i(j+1)} Q_{ij} [\lambda x_{ij} Q_{i(j-1)} [\lambda x_{i(j-1)} Q_{i(j-2)} [$$
 (32c)

• • •

$$\lambda x_{i_3} Q_{i_2} [ \quad (32d)$$

[illegible]

where we assume that:

- $m, n \in \mathbb{N}$ ,  $m, n \geq 1$
- $x_1, \dots, x_n \in PV$  are pure variables of types  $\sigma_i$ , i.e.,  $(x_i : \sigma_i)$ , for  $\sigma_i \in \text{Types}$ ,  $i = 1, \dots, n$
- $x_{i_1}, \dots, x_{i_m} \in PV$  are pure variables of types  $\sigma_{i_j}$ , i.e.,  $(x_{i_j} : \sigma_{i_j})$ , for  $\sigma_{i_j} \in \text{Types}$ ,  $i_j \in \mathbb{N}$ ,  $j = 1, \dots, m$
- $Q_{i_1}, \dots, Q_{i_m}, H$  are terms of the corresponding types in (33a)–(33h):

$$H : (\sigma_1 \rightarrow \cdots \rightarrow (\sigma_{n-1} \rightarrow (\sigma_n \rightarrow \sigma))) \quad (33a)$$

$$Q_{i_1} : ((\sigma_{i_1} \rightarrow \sigma) \rightarrow \tau_{i_1}) \quad (33b)$$

$$Q_{i_2} : ((\sigma_{i_2} \rightarrow \tau_{i_1}) \rightarrow \tau_{i_2}) \quad (33c)$$

...

$$Q_{i_{j-1}} : ((\sigma_{i_{j-1}} \rightarrow \tau_{i_{j-2}}) \rightarrow \tau_{i_{j-1}}) \quad (33d)$$

$$Q_{i_j} : ((\sigma_{i_j} \rightarrow \tau_{i_{j-1}}) \rightarrow \tau_{i_j}) \quad (33e)$$

$$Q_{i_{j+1}} : ((\sigma_{i_{j+1}} \rightarrow \tau_{i_j}) \rightarrow \tau_{i_{j+1}}) \quad (33f)$$

...

$$Q_{i_{m-1}} : ((\sigma_{i_{m-1}} \rightarrow \tau_{i_{m-2}}) \rightarrow \tau_{i_{m-1}}) \quad (33g)$$

$$Q_{i_m} : ((\sigma_{i_m} \rightarrow \tau_{i_{m-1}}) \rightarrow \tau_{i_m}) \quad (33h)$$

(The types are such that  $T_{m+1}$  in (32a)-(32e) is a well-formed term.)

*In addition, assume the following:*

- (1)  $H$  is a proper, i.e., not immediate, term
- (2)  $m \leq n$
- (3)  $x_1, \dots, x_n \in PV$  are pairwise different, pure variables
- (4)  $x_{i_1}, \dots, x_{i_m} \in PV$  are pairwise different, pure variables
- (5)  $\{x_{i_1}, \dots, x_{i_m}\} \subseteq \{x_1, \dots, x_n\}$ , i.e.,  
 $\{i_1, \dots, i_m\} \subseteq \{1, \dots, n\}$

Then, the term  $T_{m+1}$  in (32a)-(32e) can be reduced to the term  $R_{m+1}$  in (34b)-(34i):

$$T_{m+1} \Rightarrow R_{m+1} \equiv \quad (34a)$$

$$Q_{i_m}[R_{i_m}^0] \text{ where } \{ \quad (34b)$$

$$R_{i_m}^0 := \lambda(x_{i_m}) Q_{i_{(m-1)}} [R_{i_{(m-1)}}^1(x_{i_m})], \quad (34c)$$

$$R_{i(m-1)}^1 := \lambda(x_{i_m})\lambda(x_{i(m-1)})Q_{i(m-2)}[R_{i(m-2)}^2(x_{i_m})(x_{i(m-1)})], \quad (34d)$$

$$R_{i(m-2)}^2 := \lambda(x_{i_m})\lambda(x_{i(m-1)})\lambda(x_{i(m-2)})Q_{i(m-3)}[R_{i(m-3)}^3(x_{i_m})(x_{i(m-1)})(x_{i(m-2)})], \quad (34e)$$

$$R_{i_{(j+1)}}^{m-(j+1)} := \lambda(x_{i_m}) \dots \lambda(x_{i_{(j+1)}}) Q_{ij} [ \dots R_{i_j}^{m-j}(x_{i_m}) \dots (x_{i_{(j+1)}}) ], \quad (34f)$$

$$R_{i_j}^{m-j} := \lambda(x_{i_m}) \dots \lambda(x_{i_{(j+1)}}) \lambda(x_{i_j}) Q_{i_{(j-1)}} [R_{i_{(j-1)}}^{m-(j-1)}(x_{i_m}) \dots (x_{i_j})], \quad (34g)$$

$$| \text{ for } j = m, \dots, 2,$$

$$R_{i_2}^{(m-2)} := \lambda(x_{i_m}) \dots \lambda(x_{i_2}) Q_{i_1} [ \begin{matrix} \dots \\ R_{i_1}^{(m-1)}(x_{i_m}) \dots (x_{i_2}) \end{matrix} ], \quad (34h)$$

$$R_{i_1}^{(m-1)} := \lambda(x_{i_m}) \dots \lambda(x_{i_2}) \lambda(x_{i_1}) H(\vec{x}) \} \quad (34i)$$

for some fresh recursion variables  $R_k^l \in RV$  of the types (35a)–(35f):

$$R_{i_1}^{(m-1)} : (\sigma_{i_m} \rightarrow \cdots \rightarrow (\sigma_{i_2} \rightarrow (\sigma_{i_1} \rightarrow \sigma))) \dots \quad (35a)$$

$$R_{i_2}^{(m-2)} : (\sigma_{i_m} \rightarrow \cdots \rightarrow (\sigma_{i_2} \rightarrow \tau_{i_1}) \dots) \quad (35b)$$

...

$$R_{i_j}^{m-j} : (\sigma_{i_m} \rightarrow \dots \rightarrow (\sigma_{i_{j+1}} \rightarrow (\sigma_{i_j} \rightarrow \tau_{i_{j-1}})) \dots) \quad (35c)$$

$$R_{i_{(j+1)}}^{m-(j+1)} : (\sigma_{i_m} \rightarrow \cdots \rightarrow (\sigma_{i_{j+1}} \rightarrow \tau_{i_j}) \cdots) \quad (35d)$$

...

$$R_{i_{(m-1)}}^1 : (\sigma_{i_m} \rightarrow (\sigma_{i_{m-1}} \rightarrow \tau_{i_{m-2}})) \quad (35e)$$

$$R_{i_m}^0 : (\sigma_{i_m} \rightarrow \tau_{i_{m-1}}) \quad (35f)$$

*Proof.* The proof is by induction on the number of the terms  $Q_{i_1}, \dots, Q_{i_m}$ . It uses the reduction rules of  $L_{ar}^\lambda$  (and  $L_r^\lambda$ ) and verifies the types.

The superscripts of the variables  $R_{ij}^{m-j}$  are counters of the number of the applications of the  $\lambda$ -rule ( $\lambda$ ). For sake of space, we do not include the proof here.  $\square$

**Note 1.** The types of the terms  $Q_{i_1}, \dots, Q_{i_m}, H$  do not need to be such that  $Q_{i_1}, \dots, Q_{i_m}$  can denote quantifiers over arguments of a range denoted by  $H$ , which are in the focus of the work in Loukanova [5]. In this paper, we investigate the broader class of terms  $Q_{i_1}, \dots, Q_{i_m}, H$ , such that  $Q_{i_1}, \dots, Q_{i_m}$  can bind argument slots of the term  $H$ .

**Note 2.** The requirements (4)–(5) in Theorem 4 guarantee that there is binding of existing argument slots of  $H$ . I.e., the bindings in the term  $T_{m+1}$  in (32a)–(32e) are strong, not vacuous. Therefore, the chained bindings by  $R_{m+1}$  in (34b)–(34i) are strong too. The term  $H$  may still denote a function that does not depend essentially on some of its arguments, including such that are bound by some  $Q_{i_j}$ . The requirements (4)–(5) in Theorem 4 can be removed in a general term  $T_{m+1}$  of the same form (32a)–(32e), while the reduction to the term  $R_{m+1}$  in (34b)–(34i) holds.

**Theorem 5.** The term  $R_{m+1}$  in (34b)–(34i) is algorithmically synonymous (equivalent) with the term  $R'_{m+1}$  in (36b)–(36i).

$$R_{m+1} \approx R'_{m+1} \equiv \quad (36a)$$

$$Q_{i_m}[\lambda(x_{i_m})R_{i_m}^0(x_{i_m})] \text{ where } \{ \quad (36b)$$

$$R_{i_m}^0 := \lambda(x_{i_m})Q_{i_{(m-1)}}[ \quad (36c)$$

$$\lambda(x_{i_{(m-1)}})R_{i_{(m-1)}}^1(x_{i_m})(x_{i_{(m-1)}})],$$

$$R_{i_{(m-1)}}^1 := \lambda(x_{i_m})\lambda(x_{i_{(m-1)}})Q_{i_{(m-2)}}[ \quad (36d)$$

$$\lambda(x_{i_{(m-2)}})R_{i_{(m-2)}}^2(x_{i_m})(x_{i_{(m-1)}})$$

$$(x_{i_{(m-2)}})],$$

$$R_{i_{(m-2)}}^2 := \lambda(x_{i_m})\lambda(x_{i_{(m-1)}})\lambda(x_{i_{(m-2)}})Q_{i_{(m-3)}}[ \quad (36e)$$

$$\lambda(x_{i_{(m-3)}})R_{i_{(m-3)}}^3(x_{i_m})(x_{i_{(m-1)}})$$

$$(x_{i_{(m-2)}})(x_{i_{(m-3)}})],$$

...

$$R_{i_{(j+1)}}^{m-(j+1)} := \lambda(x_{i_m}) \dots \lambda(x_{i_{(j+1)}})Q_{i_j}[ \quad (36f)$$

$$\lambda(x_{i_j})R_{i_j}^{m-j}(x_{i_m}) \dots (x_{i_{(j+1)}})(x_{i_j})],$$

$$R_{i_j}^{m-j} := \lambda(x_{i_m}) \dots \lambda(x_{i_{(j+1)}})\lambda(x_{i_j})Q_{i_{(j-1)}}[ \quad (36g)$$

$$\lambda(x_{i_{(j-1)}})R_{i_{(j-1)}}^{m-(j-1)}(x_{i_m}) \dots$$

$$(x_{i_j})(x_{i_{(j-1)}})],$$

| for  $j = m, \dots, 2,$

...

$$R_{i_2}^{(m-2)} := \lambda(x_{i_m}) \dots \lambda(x_{i_2})Q_{i_1}[\lambda(x_{i_1}) \quad (36h)$$

$$R_{i_1}^{(m-1)}(x_{i_m}) \dots (x_{i_2})(x_{i_1})],$$

$$R_{i_1}^{(m-1)} := \lambda(x_{i_m}) \dots \lambda(x_{i_1})H(\vec{x}) \} \quad (36i)$$

*Proof.* For every  $i_j \in \{i_1, \dots, i_m\}$ , from (35c), we have that  $R_{i_j}^{m-j} \in \text{RV}$ :

$$R_{i_j}^{m-j}(x_{i_m}) \dots (x_{i_{(j+1)}}) : (\sigma_{i_j} \rightarrow \tau_{i_{j-1}}) \quad (37a)$$

$$\therefore R_{i_j}^{m-j}(x_{i_m}) \dots (x_{i_{(j+1)}})(x_{i_j}) : \tau_{i_{j-1}} \quad (37b)$$

$$\therefore \lambda(x_{i_j})R_{i_j}^{m-j}(x_{i_m}) \dots (x_{i_{(j+1)}})(x_{i_j}) : (\sigma_{i_j} \rightarrow \tau_{i_{j-1}}) \quad (37c)$$

Since  $R_{i_j} \in \text{RV}$ , the terms  $R_{i_j}^{m-j}(x_{i_m}) \dots (x_{i_{(j+1)}})(x_{i_j})$  and  $\lambda(x_{i_j})R_{i_j}^{m-j}(x_{i_m}) \dots (x_{i_{(j+1)}})(x_{i_j})$  are immediate, and thus explicite, irreducible. Furthermore, for all  $g \in G$ :

$$\text{den}(R_{i_j}^{m-j}(x_{i_m}) \dots (x_{i_{(j+1)}}))(g) \quad (38)$$

$$= \text{den}(\lambda(x_{i_j})R_{i_j}^{m-j}(x_{i_m}) \dots (x_{i_{(j+1)}})(x_{i_j}))(g)$$

By Corollary 2, it follows that:

$$R_{i_j}^{m-j}(x_{i_m}) \dots (x_{i_{(j+1)}}) \approx \quad (39)$$

$$\lambda(x_{i_j})R_{i_j}^{m-j}(x_{i_m}) \dots (x_{i_{(j+1)}})(x_{i_j})$$

for every  $i_j \in \{i_1, \dots, i_m\}$

From (39), by using the rules for algorithmic synonymy in Table I, it follows that

$$R_{m+1} \approx R'_{m+1} \quad (40)$$

Thus, the terms  $R_{m+1}$  and  $R'_{m+1}$  are algorithmically equivalent.  $\square$

**Definition 7** (Recursive Distance). Let  $T$  be the a term of the form:

$$T \equiv A_0 \text{ where } \{ p_n := A_n, \dots, \quad (41a)$$

$$p_{i+1} := A_{i+1}, p_i := A_i, \dots, \quad (41b)$$

$$p_1 := A_1, \} \quad (41c)$$

The recursive distance  $\text{Rdist}(p_n, H, A_1) = \text{Rdist}(p_n, H, p_1) = \text{Rdist}(A_n, H, A_1) = \text{Rdist}(A_n, H, p_1)$  of  $A_n$  (or its  $p_n$ ), from a subterm  $H$  of a term  $A_1$  (or its recursion memory  $p_1$ ), in a recursion term  $T$  of the form (41a)–(41c) (modulo congruence with respect to the order of the assignments), is defined by induction:

$$\text{Rdist}(p_i, H, A_i) = \text{Rdist}(A_i, H, A_i) \quad (42a)$$

$$= \text{Rdist}(p_i, H, p_i) = 0,$$

if  $H$  occurs in  $A_i$

$$\text{Rdist}(p_{i+1}, H, A_1) = \text{Rdist}(A_{i+1}, H, A_1) \quad (42b)$$

$$= \text{Rdist}(p_{i+1}, H, p_1) = \text{Rdist}(A_{i+1}, H, p_1)$$

$$= \min\{ \text{Rdist}(p_i, H, p_1) \mid p_i \text{ occurs in } A_{i+1} \} + 1,$$

Note:  $\text{Rdist}(p_n, H, A_1)$  is a partial function.

**Theorem 6** (Binding Across Recursion 6). Let  $R_{m+1}$  be a term of the form (43b)–(43h). as in Theorem 5.

$$R_{m+1} \equiv \quad (43a)$$

$$Q_{i_m}[\lambda(x_{i_m})R_{i_m}^0(x_{i_m})] \text{ where } \{ \quad (43b)$$

$$R_{i_m}^0 := \lambda(x_{i_m})Q_{i_{(m-1)}}[ \quad (43c)$$

$$\lambda(x_{i_{(m-1)}})R_{i_{(m-1)}}^1(x_{i_m})(x_{i_{(m-1)}})],$$

$$R_{i_{(m-1)}}^1 := \lambda(x_{i_m})\lambda(x_{i_{(m-1)}})Q_{i_{(m-2)}}[ \quad (43d)$$

$$\lambda(x_{i_{(m-2)}})R_{i_{(m-2)}}^2(x_{i_m})(x_{i_{(m-1)}})$$

$$(x_{i_{(m-2)}})],$$

...

$$R_{i_{(j+1)}}^{m-(j+1)} := \lambda(x_{i_m}) \dots \lambda(x_{i_{(j+1)}})Q_{i_j}[ \quad (43e)$$

$$\lambda(x_{i_j})R_{i_j}^{m-j}(x_{i_m}) \dots (x_{i_{(j+1)}})(x_{i_j})],$$

$$R_{i_j}^{m-j} := \lambda(x_{i_m}) \dots \lambda(x_{i_{(j+1)}})\lambda(x_{i_j})Q_{i_{(j-1)}}[ \quad (43f)$$

$$\lambda(x_{i_{(j-1)}})R_{i_{(j-1)}}^{m-(j-1)}(x_{i_m}) \dots$$

$$(x_{i_j})(x_{i_{(j-1)}})],$$

| for  $j = m, \dots, 2,$

...

$$R_{i_2}^{(m-2)} := \lambda(x_{i_m}) \dots \lambda(x_{i_2})Q_{i_1}[\lambda(x_{i_1}) \quad (43g)$$

$$R_{i_1}^{(m-1)}(x_{i_m}) \dots (x_{i_2})(x_{i_1})],$$

$$R_{i_1}^{(m-1)} := \lambda(x_{i_m}) \dots \lambda(x_{i_1})H(x_1) \dots (x_n), \quad (43h)$$

$$\vec{p} := \vec{A} \} \quad (43i)$$

Then, for every  $i_j \in \{i_1, \dots, i_m\}$ , (1) the term  $Q_{i_j}$  binds the  $i_j$ -th argument slot of  $H$ , and (2)  $R_{i_j}^{m-j}$  is  $\lambda$ -abstraction  $\lambda(x_{i_m}) \dots \lambda(x_{(i_j+1)}) \lambda(x_{i_j})$  over the  $i_m$ -th,  $\dots$ ,  $i_j$ -th argument slots of  $H$  in this specific order.

*Proof.* The proof is by induction on  $j = 1, \dots, m$ , i.e., on the recursive distance of  $R_{i_j}^{m-j}$  from  $H$  in  $R_{i_1}^{m-1}$ .  $\square$

**Theorem 7** (Binding Across Recursion 7). *Let  $R_{m+1}$  be a term of the form (44b)–(44h), as in Theorem 4:*

$$R_{m+1} \equiv \quad (44a)$$

$$Q_{i_m}[R_{i_m}^0] \text{ where } \{ \quad (44b)$$

$$R_{i_m}^0 := \lambda(x_{i_m}) Q_{i_{(m-1)}} [R_{i_{(m-1)}}^1(x_{i_m})], \quad (44c)$$

$$R_{i(m-1)}^1 := \lambda(x_{i_m})\lambda(x_{i(m-1)})Q_{i(m-2)}[R_{i(m-2)}^2(x_{i_m})(x_{i(m-1)})], \quad (44d)$$

$$\begin{aligned}
& \dots \\
R_{i_{(j+1)}}^{m-(j+1)} &:= \lambda(x_{i_m}) \dots \lambda(x_{i_{(j+1)}}) Q_{i_j} [ \\
& R_{i_j}^{m-j}(x_{i_m}) \dots (x_{i_{(j+1)}})],
\end{aligned} \tag{44e}$$

$$R_{i_j}^{m-j} := \lambda(x_{i_m}) \dots \lambda(x_{i_{(j+1)}}) \lambda(x_{i_j}) Q_{i_{(j-1)}} [R_{i_{(j-1)}}^{m-(j-1)}(x_{i_m}) \dots (x_{i_j})], \quad (44f)$$

$$| \text{ for } j = m, \dots, 2,$$

$$R_{i_2}^{(m-2)} := \lambda(x_{i_m}) \dots \lambda(x_{i_2}) Q_{i_1} [R_{i_1}^{(m-1)}(x_{i_m}) \dots (x_{i_2})], \quad (44g)$$

$$R_{i_1}^{(m-1)} := \lambda(x_{i_m}) \dots \lambda(x_{i_2}) \lambda(x_{i_1}) H(\vec{x}) \quad (44h)$$

$$\vec{p} := \vec{A} \} \quad (44i)$$

Then, for every  $i_j \in \{i_1, \dots, i_m\}$ , (1)  $Q_{i_j}$  binds the  $i_j$ -th argument slot of  $H$ , and (2)  $R_{i_j}^{m-j}$  is  $\lambda$ -abstraction  $\lambda(x_{i_m}) \dots \lambda(x_{i_{j+1}}) \lambda(x_{i_j})$  over the  $i_m$ -th,  $\dots$ ,  $i_j$ -th argument slots of  $H$  in this specific order.

*Proof.* The proof is by induction on  $j = 1, \dots, m$ , i.e., on the recursive distance of  $R_{i_j}^{m-j}$  from  $H$  in  $R_{i_1}^{m-1}$ .  $\square$

Now, we show that Theorem 4 holds by weakening the requirement (3).

**Theorem 8** (Reduction of Strong Binders 8). *Let  $T_{m+1}$  be the term (45a)-(45e):*

$$T_{m+1} \equiv Q_{i_m} \left[ \lambda x_{i_m} Q_{i_{(m-1)}} \left[ \lambda x_{i_{(m-1)}} Q_{i_{(m-2)}} \left[ \right. \right. \right. \quad (45a)$$

$$\lambda x_{i(m-2)} Q_{i(m-3)} [\lambda x_{i(m-3)} Q_{i(m-4)} [$$
 (45b)

$$\dots \lambda x_{i_{(j+1)}} Q_{i_j} [\lambda x_{i_j} Q_{i_{(j-1)}} [\lambda x_{i_{(j-1)}} Q_{i_{(j-2)}} [ \quad (45c)$$

$$\dots \quad \lambda x_{i_3} Q_{i_2} [ \quad (45d)$$

$$\lambda x_{i_2} Q_{i_1} [\lambda x_{i_1} H(v_1) \dots (v_k)]]]]]]]]]] \quad (45e)$$

where we assume that:

- $m, n \in \mathbb{N}$ ,  $m, n \geq 1$
- $x_{i_1}, \dots, x_{i_m} \in PV$  are pure variables of types  $(x_{i_j} : \sigma_{i_j})$ , for  $\sigma_{i_j} \in \text{Types}$ ,  $i_j \in \mathbb{N}$ ,  $j = 1, \dots, m$
- $Q_{i_1}, \dots, Q_{i_m}, H$  are terms of the corresponding types in (33a)–(33h):

*In addition, assume the following:*

- (1)  $H$  is a proper, i.e., not immediate, term
- (2)  $m \leq n$
- (3)  $v_1, \dots, v_k \in PV$  are pure variables, not necessarily pairwise different.
- (4)  $x_{i_1}, \dots, x_{i_m} \in PV$  are pairwise different, pure variables
- (5)  $\{x_{i_1}, \dots, x_{i_m}\} \subseteq \{v_1, \dots, v_k\}$ , i.e.,  
 $\{i_1, \dots, i_m\} \subseteq \{1, \dots, n\}$

Then, the term  $T_{m+1}$  in (45a)-(45e) can be reduced to the term  $R_{m+1}$  in (46a)-(46i)

$$T_{m+1} \Rightarrow R_{m+1} \equiv \quad (46a)$$

$$Q_{i_m}[R_{i_m}^0] \text{ where } \{ \quad (46b)$$

$$R_{i_m}^0 := \lambda(x_{i_m})Q_{i_{(m-1)}}[R_{i_{(m-1)}}^1(x_{i_m})], \quad (46c)$$

$$R_{i(m-1)}^1 := \lambda(x_{i_m})\lambda(x_{i(m-1)})Q_{i(m-2)}[R_{i(m-2)}^2(x_{i_m})(x_{i(m-1)})], \quad (46d)$$

$$R_{i(m-2)}^2 := \lambda(x_{i_m})\lambda(x_{i(m-1)})\lambda(x_{i(m-2)})Q_{i(m-3)}[R_{i(m-3)}^3(x_{i_m})(x_{i(m-1)})(x_{i(m-2)})], \quad (46e)$$

$$R_{i_{(j+1)}}^{m-(j+1)} := \lambda(x_{i_m}) \dots \lambda(x_{i_{(j+1)}}) Q_{i_j} [R_{i_j}^{m-j}(x_{i_m}) \dots (x_{i_{(j+1)}})], \quad (46f)$$

$$R_{i_j}^{m-j} := \lambda(x_{i_m}) \dots \lambda(x_{i_{(j+1)}}) \lambda(x_{i_j}) Q_{i_{(j-1)}} [R_{i_{(j-1)}}^{m-(j-1)}(x_{i_m}) \dots (x_{i_j})], \quad (46g)$$

$$| \text{ for } j = m, \dots, 1,$$

$$R_{i_2}^{(m-2)} := \lambda(x_{i_m}) \dots \lambda(x_{i_2}) Q_{i_1} [ \dots R_{i_1}^{(m-1)}(x_{i_m}) \dots (x_{i_2}) ], \quad (46h)$$

$$R_{i_1}^{(m-1)} := \lambda(x_{i_m}) \dots \lambda(x_{i_2}) \lambda(x_{i_1}) H(\vec{v}) \} \quad (46i)$$

for some fresh recursion variables  $R_k^l \in RV$  of the types (35a)–(35f).

*Proof.* The proof is similar to that of Theorem 4.

Similarly, Theorem 5 holds by weakening the requirement (3), but we do not present it here for sake of space.

**Theorem 9** (Reduction of Strong Binders 9). *Let  $T_{m+1}$  be the term<sup>1</sup> (47a)-(47e):*

$$T_{m+1} \equiv Q_{i_m} \left[ \lambda x_{i_m} Q_{i_{(m-1)}} \left[ \lambda x_{i_{(m-1)}} Q_{i_{(m-2)}} \left[ \right. \right. \right. \quad (47a)$$

<sup>1</sup>The difference from Theorem 8 is that now  $H$  is immediate, i.e., not proper

given that:  $c$  is a constant;  $x$  is a variable of ether kind;  $A_1 : \sigma_1, \dots, A_n : \sigma_n, C_1 : \tau_1, \dots, C_m : \tau_m \in \text{Terms}_{L_{\text{raa}}^\lambda}$ ;  $p_i : \sigma_i, i = 1, \dots, n$  ( $n \geq 0$ ) in (49e) are pairwise different recursion variables of respective types, such that the sequence of assignments  $\{p_1^{\sigma_1} := A_1^{\sigma_1}, \dots, p_n^{\sigma_n} := A_n^{\sigma_n}\}$  satisfies the Acyclicity Constraint (AC); and each  $\tau_i$  is either the type  $\mathbf{t}$  of truth values, or the type  $\tilde{\mathbf{t}}$  of state dependent truth values (see (11b)).

By extending the reduction calculus of  $L_{\text{ar}}^\lambda$  with a rule for reducing terms with restrictions of the form (49f), the results in Section III and Section IV hold for the extended language  $L_{\text{raa}}^\lambda$  of restricted algorithms. These properties are not in the subject of this paper because they require extensive mathematical work. They will be in a forthcoming paper devoted to them.

The rules (49a)–(49f) applied recursively provide very expressive formal terms that represent algorithmic computations that end after finite number of computational steps, because of the Acyclicity Constraint (AC).

In particular, combination of the rules (49e) and (49f), gives terms of recursion and restrictors of the forms (50a)–(50b) and (51a)–(51b):

$$([A_0^{\sigma_0} \text{ where } \{p_1^{\sigma_1} := A_1^{\sigma_1}, \dots, p_n^{\sigma_n} := A_n^{\sigma_n}\}]) \quad (50a)$$

$$\text{such that } \{C_1^{\tau_1}, \dots, C_m^{\tau_m}\} \quad (50b)$$

$$([A_0^{\sigma_0} \text{ such that } \{C_1^{\tau_1}, \dots, C_m^{\tau_m}\}]) \quad (51a)$$

$$\text{where } \{p_1^{\sigma_1} := A_1^{\sigma_1}, \dots, p_n^{\sigma_n} := A_n^{\sigma_n}\} \quad (51b)$$

## VI. MODELLING ALGORITHMIC NEURAL NETWORKS

### A. Procedural and Declarative Neural Networks

We present the use of the recursion terms with constraints for modelling neural networks.

Neural systems (in peripheral and central nervous systems) of living organisms, even as simple as *Drosophila melanogaster*, have innate faculty of both procedural and declarative memory, see, e.g., Kandel et al. [20] and Squire and Kandel [21].

a) *Neural Networks of Procedural Memory*: Here, we propose to model procedural memory by terms having recursive assignments of the form (49e), while employing the entire range of term forms (49a)–(49f).

The systems of assignments in terms of the form (49e) represent mutually recursive computations of the denotations of the terms  $A_i^{\sigma_i}$ , which are saved in the corresponding memory cells  $p_i$ . Procedural memory is modelled via the assignments  $p_i^{\sigma_i} := A_i^{\sigma_i}$ . The system of mutually recursive assignments (52b) models the following fundamental phenomena of functional, procedural neural networks:

- 1) The collection (52a) is a recursively linked network of memory cells  $p_i : \sigma_i$  of corresponding types
- 2) The system (52b) has algorithmic, i.e., procedural, nature of a network of memory cells  $p_i$ :

Under completion of the computation of the data  $A_i^{\sigma_i}$ , i.e., of the denotation of  $A_i^{\sigma_i}$ , it is saved in the designated memory cell, i.e., in the neuron  $p_i$ .

- 3) The rank function, in according to the Acyclicity Constraint (AC), by (9), guarantees that the network (52b) has memorised the corresponding data pieces, after completing the algorithmic computations

$$p_1 : \sigma_1, \dots, p_n : \sigma_n \quad (52a)$$

$$\{p_1^{\sigma_1} := A_1^{\sigma_1}, \dots, p_n^{\sigma_n} := A_n^{\sigma_n}\} \quad (52b)$$

b) *Declarative Information*: Declarative information is modelled by terms of the form  $A : \tau$ , where  $\tau$  is either the type  $\mathbf{t}$  of truth values, or the type  $\tilde{\mathbf{t}}$  of state dependent truth values (see (11b)).

c) *Neural Networks of Declarative Memory*: Here, we model declarative memory by the specialised networks, or sub-networks, of systems of assignments of the form (53a):

$$t_1^{\sigma_1} := P_1^{\sigma_1}, \dots, t_k^{\sigma_k} := P_k^{\sigma_k} \quad (53a)$$

$$\text{for } P_i : \tau_i, \text{ where} \quad (53b)$$

$$\tau_i \text{ is either the type } \mathbf{t} \text{ of truth values, or} \quad (53c)$$

$$\text{the type } \tilde{\mathbf{t}} \text{ of state dependent truth values} \quad (53d)$$

Declarative memory is innately integrated into networks of procedural memory. That is, neural networks of declarative memory (53a) are typically integrated as recursive subsystems of more general procedural assignments (52b):

$$\{t_1 : \tau_1, \dots, t_n : \tau_n\} \subseteq \{p_1 : \sigma_1, \dots, p_n : \sigma_n\} \quad (54)$$

### B. Algorithmic Binding of Functional Neuro-Receptors

A term  $T_{m+1}$  of the form (55a)–(55f) represents a neural network. The head term (55a)–(55e) is a neural sub-network of sequentially bound neural cells (55c), which are sequentially linked by binding functionality. Each subterm  $\lambda x_{i_j} Q_{i_{(j-1)}}$  models a neural cell. Its neural body  $Q_{i_{j-1}} : ((\sigma_{i_{j-1}} \rightarrow \tau_{i_{j-2}}) \rightarrow \tau_{i_{j-1}})$  has a receptor represented by its argument slot of the corresponding type  $(\sigma_{i_{j-1}} \rightarrow \tau_{i_{j-2}})$ .

The  $\lambda$ -abstraction  $\lambda x_{i_j}$  in  $\lambda x_{i_j} Q_{i_{(j-1)}}$  represents the axon of the neural cell  $\lambda x_{i_j} Q_{i_{(j-1)}}$ . Similarly, the  $\lambda$ -abstraction  $\lambda x_{i_{(j-1)}}$ , in  $\lambda x_{i_{(j-1)}} Q_{i_{(j-2)}}$ , represents the axon of  $\lambda x_{i_{(j-1)}} Q_{i_{(j-2)}}$ . In the subsequently bound (linked) neural cells, represented by the subterm of the form (55c),  $Q_{i_{(j-1)}}$  binds the axon  $x_{i_{(j-1)}}$  of  $\lambda x_{i_{(j-1)}} Q_{i_{(j-2)}}$ , for each  $j = 3, \dots, (m-3)$ .

$$T_{m+1} \equiv Q_{i_m} \left[ \lambda x_{i_m} Q_{i_{(m-1)}} \left[ \lambda x_{i_{(m-1)}} Q_{i_{(m-2)}} \left[ \right. \right. \right. \quad (55a)$$

$$\left. \left. \left. \lambda x_{i_{(m-2)}} Q_{i_{(m-3)}} \left[ \lambda x_{i_{(m-3)}} Q_{i_{(m-4)}} \left[ \right. \right. \right. \right. \right. \quad (55b)$$

...

$$\left. \left. \left. \lambda x_{i_{(j+1)}} Q_{i_j} \left[ \lambda x_{i_j} Q_{i_{(j-1)}} \left[ \lambda x_{i_{(j-1)}} Q_{i_{(j-2)}} \left[ \right. \right. \right. \right. \right. \quad (55c)$$

...

$$\left. \left. \left. \lambda x_{i_3} Q_{i_2} \left[ \right. \right. \right. \quad (55d)$$

$$\left. \left. \left. \lambda x_{i_2} Q_{i_1} \left[ \lambda x_{i_1} H(x_1) \dots (x_n) \right] \right] \right] \right] \quad (55e)$$

$$\text{where } \{ \vec{p} := \vec{A} \} \quad (55f)$$

The term  $T_{m+1}$  of the form (55a)–(55f) represents a neural network in its ‘encapsulated’ form, where the algorithmic steps of binding axons by the corresponding receptors are ‘hidden’ below encapsulating membranes.

In the canonical form  $\text{cf}(T_{m+1})$ , the head term of  $T_{m+1}$  representing the head neural sub-network, i.e., (55a)–(55e), is reduced to a subterm  $R_{m+1}$  that have the structural form of  $R_{m+1}$  in (34b)–(34i). The term  $R_{m+1}$  represents the innate, inner algorithmic structure of the same neural sub-network of  $T_{m+1}$ , inside its encapsulating membrane. On the other hand, the neural network  $R_{m+1}$  is algorithmically synonymous (equivalent) with the term  $R'_{m+1}$  in (36b)–(36i), while they are structurally different.

## VII. FORTHCOMING AND FUTURE WORK

The recursion assignments in Section IV include  $\lambda$ -terms binding argument slots of the “innermost” subterm, sequentially by recursion within the scope of the recursion operator where. We have started the exposition by reducing the term (32a)–(32e). That resulted the specific variables for the  $\lambda$ -abstracts. However, these terms are congruent to terms by renaming variables bound by the  $\lambda$ -operator. There are more interesting results related to linking of the bindings related to these  $\lambda$ -terms and renaming variables abstracted away with  $\lambda$ -operator. Such properties of the binding operators  $Q_{ij}$  introduced in this paper are in our forthcoming work.

Other forthcoming work is to relate the results in this paper with the reduction calculus in Loukanova [19] and rendering expressions of natural language, e.g., similar to the underspecified quantification presented in Loukanova [5], as well as with other extensions of  $L_{\text{ar}}^\lambda$ .

Questions whether the approach presented in Ślęzak et al. [22] is comparable with the type theory of Moschovakis algorithms extended in this paper, and if yes, how, remains open work. Studying the shared ideas and differences in these approaches may provide mutual enrichments and developments.

**Abstract**—Currently used motion estimation is usually based on a computation of optical flow from individual images or short sequences. As these methods do not require an extraction of the visual description in points of interest, correspondence can be deduced only by the position of such points.

In this paper, we propose an alternative motion estimation method solely using a binary visual descriptor. By tuning the internal parameters, we achieve either a detection of longer time series or a higher number of shorter series in a shorter time. As our method uses the visual descriptors, their values can be directly used in more complex visual detection tasks.

## I. INTRODUCTION

MOTION ESTIMATION can be considered one of the basic tasks in video signal processing. The detection of object position changes is fundamental for areas such as robotics and video surveillance. Generalisation to the tracking of interest point positions is then used in many fields of image processing, including image stitching (to acquire panorama [1] or super-resolution [2]), tracking of facial features (for emotion detection [3]) or image stabilisation [4].

Many other methods can utilise a tracking algorithm to reduce the complex payload computation. Processing (based e.g. on Deep Convolutional Neural Networks [5]) could be limited to only several “best” frames. The extracted features would be then extrapolated to the rest of the video segment if needed [6]. Therefore, the motion estimation approach could present a lightweight counterpart to an expensive processing of all frames in new Video to Text (VTT) tasks.

An important motivation for our interest in motion estimation is the *search for suitable meta-features in multimedia*, as the extracted motion can be used either directly as a meta-feature or as a basis for obtaining other meta-features.

In the next section, we present state of the art in video motion estimation, including the traditionally used Kanade-Lucas-Tomasi (KLT) algorithm, and its drawbacks. In II-B we also briefly discuss other feature point selection and description algorithms. Moreover, in II-C we provide a summary of our previous experiments. Section III discusses a proposal of Oriented FAST and Rotated BRIEF (ORB) feature descriptor use for interest point registration between two consecutive frames. Section IV introduces the use of registered key points for the deduction of continuous motion time series. Section V

provides the preliminary results and compares our approach with the KLT feature tracker. We will discuss possible extensions of the herein presented method in Section VI.

## II. STATE OF THE ART

A naïve motion estimation algorithm could be, in theory, constructed by the selection of a patch from one video frame and its convolution with the next frame. An area of the frame containing similar intensities would give a strong response. However, with transformations other than translation, such a method would be prone to many errors. Therefore, more sophisticated motion estimation algorithms are commonly used.

### A. Kanade-Lucas-Tomasi

One of the widely adopted approaches to point tracking is the Lucas-Kanade algorithm [7] combined with feature point selection of Shi-Tomasi [8]. This point tracking algorithm exploits the assumption that motion in video sequences with sufficient frame rate can be estimated by a smooth optical flow function. Therefore, the new position of a feature point is expected to be in a relatively small proximity.

For computation of the new feature point position, a corresponding spatial intensity gradient of a window around a given point of interest (typically  $31 \times 31$  pixels) is to be found. The iteratively discovered displacement of the intensity gradients is then considered as the optical flow vector and translated to motion vectors of the nearby points of interest. To ensure scale invariance and faster detection in a larger neighbourhood, the Lucas-Kanade algorithm uses a pyramidal approach, where the optical flow is computed on the coarsest level of the pyramid and then refined on the lower levels, ultimately in the full resolution. Backwards tracking is used to assess the error of the point tracking. Feature points with a bidirectional error of more than 3 pixels are usually considered as lost.

As Shi and Tomasi stated in [8], the point tracking algorithm will yield insufficient results if unsuitable feature points are selected in the first frame. However, “good features to track” should be based only on the ability to track them, not an a priori quality. This definition is rather unfortunate, as we cannot use a multi-pass approach in the real-time environment.

Requirements on the feature points stated by Shi and Tomasi are however widely accepted.

The Kanade-Lucas-Tomasi (KLT) is a powerful and fast keypoint tracker. However, it has several drawbacks:

- (i) Lost feature points are not reconnected if they reappear.
- (ii) New feature points should be added in place of lost ones.
- (iii) The feature points are described only in the first frame.

The point replacement, mentioned in (ii), should favour an ability to track new objects as soon as possible. Detection of new features, however, slows down the motion estimation. Omitting the feature point regeneration, on the other hand, degrades the quality of tracked points throughout time.

If opposed to (iii), the description of feature points is available in all frames, it can be passed directly to more complex image processing methods.

### B. Feature Points and Visual Descriptors

The Harris-Stephens Combined Corner and Edge Detector [9] uses linked edges from the Canny detector [10]. The corner candidates are then filtered by the Harris response function which is still widely used for an assessment of corner quality.

The above mentioned Shi-Tomasi detector [8] directly computes the minimal eigenvalue. If it is close to zero, the considered point is not added to the set of corners.

Some corner detectors compare the intensity of the proposed corners to the intensities of points in a circular mask. If the area with similar intensities is small enough, SUSAN [11] detects a corner. FAST [12] makes this method faster by selecting the pixels for comparison in a pre-trained order.

Other feature point detectors search for scale-space extrema in the Laplacian of Gaussians [13] (or a box filter [14]) on each octave. This introduces the possibility of a multi-scale feature that is considered more stable regarding detection repeatability under various deformations. Modifications of FAST (Oriented FAST [15] and AGAST [16]) also use the scale pyramid to provide the scale information.

For the use in image registration and other tasks, detected points are passed to a visual descriptor. To enable scale and rotation invariance of the description, dominant direction and scale are used from the interest point detection. Therefore, the descriptor is usually connected with a particular point detector.

SIFT [13] and SURF [14] are based on a histogram of neighbouring gradient orientation (or wavelet response, respectively). The local texture information is scale and rotation invariant due to information passed from its detector.

ORB [15] and BRISK [17] (Binary robust invariant scalable keypoints), both binary feature descriptors, use the pixel intensity differences to the detected corner. Order of pixels in the descriptor is based on the gradient orientation (and scale in BRISK).

In the following sections, we will consider only the use of ORB, for several reasons: According to both [18] and our experiments [19], ORB provides the same or even better results on approximately registered features than SIFT and SURF. The computation time of both corner detection and description is however significantly reduced. The principles

of our motion estimator can be, however, used in combination with any point detector and appropriate descriptor, only with a slight compromise on the speed of feature detection.

### C. Our Previous Research

In our previous work [19], we have shown that interest point registration across consecutive frames is a feasible solution for motion estimation. The resulting motion vectors were grouped by hierarchical clustering to propose objects on the scene. Then we utilised an extended min-cut algorithm to acquire subpixel precise segmentation boundaries.

The main caveat of this approach was, however, the speed of feature registration. Each feature descriptor was matched in a high-dimensional space (especially for SIFT and SURF). The Approximate Nearest Neighbors [20] approach was in some cases even slower than a brute-force search. Also, spatially distant feature points were commonly misregistered. However, this can be (under assumptions of smooth optical flow, discussed in [21]) eliminated by considering only the neighbourhood of the key point in the next frame. We elaborate on this idea further in this paper. Mainly with a requirement to speed up the process of key point registration. Our approach is discussed in the next section.

Another issue is that we use hierarchical clustering on a relatively large number of not very distinct motion vectors (represented by position, length and direction). To provide more information for future clustering, we propose in Section IV to gather time series of key point position history.

## III. VIDEO SEQUENCE POINT OF INTEREST REGISTRATION

Key point registration describes a process through which the points with similar visual neighbourhood are mapped onto each other. Instead of actual pixels, feature descriptors are used to both speed up the method of matching and to introduce invariance to common deformations.

The search for a matching descriptor is then usually carried out with the nearest neighbour operator. A point of interest is represented as a vector in feature space, and an appropriate measure is used to find its distance to other points. To eliminate a majority of unpromising comparisons, vectors are usually indexed in a k-d tree [22] or a PCP tree [23]. FLANN [20] is a widely used framework for approximate nearest neighbour search in a k-means tree structure.

A video sequence consisting of a single shot with sufficient framerate presents only minor changes between consecutive frames. Points of interest are therefore spatially almost registered, and detected motion is to some extent smooth. Hence, it is beneficial to index the key points by their location as well. Only the adjacent key points are then checked for descriptor correspondence. Because such index is only two-dimensional, k-d tree indexing is chosen as the approach with the fastest query time and the smallest overhead [20].

Our approach uses a k-d tree for indexing of the interest points by their position. Only points closer than a given radius (by default 2%) and with the Hamming distance of its descriptor smaller than 64, as proposed in [15], are considered

as candidates. The point with the lowest Hamming distance is considered a match and excluded from the k-d tree.

For k-d tree indexing and search, we used a header-only implementation `nanoflann` [24], which allowed us to control the indexing of points fully. The time required for the construction of the index is negligible –  $\mathcal{O}(n \log n)$ , where  $n$  is the number of points indexed. The radius search is, however, significantly improved. Instead of comparing distances to all points and sorting in  $\mathcal{O}(n + n \log n)$ , the search in the k-d tree takes only  $\mathcal{O}(n^{\frac{1}{2}} + m)$ , where  $m$  is the number of results. We can also estimate the feature position from the previous frame, as we discuss in the next section.

#### IV. DEDUCTION OF OPTICAL FLOW

After processing the first two frames and with an assumption of smooth motion, the approximate position of the key point in the next frame can be estimated. Such an assumption enables us to provide a more likely query point for the radius search as well as a possibility to reduce the radius to increase the speed of registration.

To this end, we keep a list of active tracked features with current position and ORB description, position delta, radius and history of positions. Each successive frame is then registered by the algorithm presented in the previous section and matched features are updated accordingly. Unmatched features increase the radius and can, therefore, recover for some time. When radius exceeds a threshold, the feature becomes lost. The rest of the newly detected points of interest is appended to the set of active points with default uncertainty value and zero position delta, as no history is presumably available.

As a result, we obtain a list of features with their description and history of positions. This information can be used during the processing of multimedia content for online recognition and detection scenarios, or offline for multimedia content classification and deeper analysis.

#### V. MOTION ESTIMATION RESULTS AND PERFORMANCE

Figure 1 presents a comparison of the original Kanade-Lucas-Tomasi algorithm with our proposed method based on matching ORB descriptors. The test sequences were captured just for this experiment by Lumix FZ80, as it provides a 4K video recording. The camera moves downwards during the shot and continuously tilts upwards. The background is therefore visually moving downwards, and the tap with the marble fountain moves up throughout the considered sequence.

Figure 1(a) presents a result of feature detection on the first frame and tracking by the Lucas-Kanade algorithm with recommended settings, yet without filtering. As can be seen, the fountain presents many points that are considered as convenient for tracking, whereas the Shi-Tomasi detector proposes no key point in the background, even though visually good (but unsharp) edges are available on the bench and lamppost. From the visual perspective, several severe misdetections accumulate during the processing.

The result of our method, presented in Figure 1(b) shows features tracked in this frame with rather short history lines.

(a) Kanade-Lucas-Tomasi on all frames without cross checking and feature renewal

(b) Active motion vectors detected by ORB matching with history, proposed by our algorithm

Fig. 1: Visual comparison of motion estimation. For full resolution, please refer to <http://github.com/petrpulc/orb-flow/tree/master/img>

We assume that this is mainly caused by the overly precise matching of the point descriptors, which is however crucial for the stability of the registration algorithm. When all gathered timelines are overlaid, the combined history length is comparable. Our proposed algorithm is, however, capable of considering new points of interest as soon as they appear without a need to wait for lost features. Due to that, several good features are detected on the bench, providing at least some information about the background movement.

Our other goal was to make the motion estimation possible in a higher resolution video in real time. According to the results presented in Table I(b), we are currently able to detect motion on circa 350 newly detected interest points for each frame in 1440p resolution. Higher parallelism (e.g. in the feature point matching stage) would lead to higher utilisation of available resources and possibly even better results.

The processing time of Kanade-Lucas-Tomasi (see Table I(a)), is dependent almost only on the resolution, which indicates a slow detection of key points. If the detection is not carried out on every frame, the time required for processing is appropriately reduced. However, the problem of connecting segmented motion time series emerges.

In our implementation, the motion detection speed can be increased by decreasing the lost point threshold. This, however, results in detection of many shorter sequences that would need to be reconnected in further processing.

TABLE I: Comparison of elapsed time [ms] required to process a single frame

Darker green represents processing above 30 fps, lighter green above 25fps.

In Table II, we present the number of detected sequences with an arbitrary history length in a sequence of 120 frames. With increasing resolution of the frame, the key point detector is less likely to select the same point and the more likely the feature becomes lost. Also, such features may be based on noise or not very robust image areas.

## VI. CONCLUSION

In comparison to the baseline in real-time feature tracking, Kanade-Lucas-Tomasi algorithm, our approach is able to provide a sufficient number of tracked points of interest even on a FullHD or higher resolution without utilising GPU. The time sequences gathered from our motion estimation are, however, relatively short and may require additional processing.

Our future research will be, therefore, aimed mainly at improving the matching capabilities of our algorithm, resulting in longer time sequences. These sequences will be then more suitable for clustering of the gathered time sequences for the purpose of faster object segmentation and ultimately object detection and description.

## ACKNOWLEDGEMENTS

This reported research was supported by the Czech Science Foundation (GAČR), grant № 17-01251. The work of Petr Pulc was also partially supported by the Grant Agency of the Czech Technical University in Prague, grant № SGS17/210/OHK3/3T/18.

**Abstract**—Dividing a dataset into disjoint groups of homogeneous structure, known as data clustering, constitutes an important problem of data analysis. It can be solved with broad range of methods employing statistical approaches or heuristic procedures. The latter often include mechanisms known from nature as they are known to serve as useful components of effective optimizers. The paper investigates the possibility of using novel nature-inspired technique – Grasshopper Optimization Algorithm (GOA) – to generate accurate data clusterings. As a quality measure of produced solutions internal clustering validation measure of Calinski-Harabasz index is being employed. This paper provides description of proposed algorithm along with its experimental evaluation for a set of benchmark instances. Over a course of our study it was established that clustering based on GOA is characterized by high accuracy – when compared with standard K-means procedure.

## I. INTRODUCTION

RECENT years brought significant advances in the field of nature-inspired optimization. Several new algorithms have been proposed – aimed at tackling both continuous, combinatorial and multiobjective optimization problems. To illustrate this fact: Evolutionary Computation Bestiary website lists over 120 optimization techniques, with almost 30 of them being developed during last three years (that is between 2015 and 2017) [1]. The emergence of diverse techniques mimicking natural phenomena brought attention – due to their efficiency – but also criticism arguing that relying on metaphors is potentially leading the area of metaheuristics away from scientific rigor [2]. Most of studied algorithms however offer high performance on known set of benchmark instances – which makes investigating their performance in real-world optimization tasks worthwhile.

Grasshopper Optimization Algorithm (GOA) is an optimization technique introduced by Saremi, Mirjalili and Lewis in 2017 [3]. It includes both social interaction between ordinary agents (grasshoppers) and the attraction of the best individ-

ual. Initial experiments performed by authors demonstrated promising exploration abilities of the GOA – and they will be further examined in the course of our study.

The goal of this contribution is to evaluate clustering method which uses GOA as the optimization strategy – aimed at minimizing the value of Calinski-Harabasz index [4] – one of internal clustering validity measures.

Cluster analysis constitutes a data mining problem of identifying homogeneous groups in data. Clustering can be perceived as combinatorial optimization problem – which is known to be NP-hard [5]. It is the reason why diverse heuristic approaches have been already used to tackle it [6], [7]. As a point of reference classic K-means [8] algorithm can be named. It is founded on minimizing the within-cluster sum of squares (WCSS) and its main drawback is a convergence to a local minimum of WCSS value – without a guarantee of obtaining the global one. That is why more up-to-date approaches are based on using metaheuristic techniques to solve clustering problem in the alternative way. Previous work in this area involve the use of – for instance – Flower Pollination Algorithm [9] and Krill Herd Algorithm [10]. The importance of clustering manifests itself through a variety of disciplines where its instances appear, e.g. in agriculture [11], automatic control [12], marketing [13] or text mining [14].

The paper is organized as follows. First, in the next Section, the general description of data clustering is given along with its formulation within the field of optimization. It is followed by the brief introduction to the Grasshopper Optimization Algorithm which is the most important component of the technique described in this paper. Section 3 explains the details of the clustering approach and subsequent part of the paper covers the results of numerical experiments along with comparative analysis. Finally general remarks regarding algorithms's features and planned further studies are under consideration.

## II. METHODOLOGICAL BACKGROUND

### A. Data Clustering and Its Formulation in the Optimization Domain

Let us to denote  $Y$  as a data matrix of  $M \times N$  dimensionality. Its  $N$  columns represent features describing objects. They in turn correspond to matrix rows, referred to as dataset elements or cases. The goal of clustering is to assign dataset elements  $y_1, \dots, y_M$  to clusters  $CL_1, CL_2, \dots, CL_C$ .

Clustering remains an unsupervised learning procedure, frequently with known number of clusters  $C$  being the only information available. Cluster validation constitutes a task of assessing if obtained solution reflects the structure of the data and natural groups which can be identified within its records [15]. So called external validation consists of using correct cluster labels and comparing them directly with the results of clustering whereas internal validation uses only partitioned data. Calinski-Harabasz index is representative technique of the latter. It can be written as:

$$I_{CH} = \frac{N - C}{C - 1} \frac{\sum_{i=1}^C d(u_i, U)}{\sum_{i=1}^C \sum_{x_j \in CL_i} d(x_j, u_i)} \quad (1)$$

whereas  $u_i \in R^N$  for non-empty cluster  $CL_i$  corresponds to cluster center defined by:

$$u_i = \frac{1}{M_i} \sum_{y_j \in CL_i} y_j, \quad i = 1, \dots, C \quad (2)$$

with  $M_i$  being cardinality of cluster  $i$  and – likewise –  $U$  corresponds to the center of gravity of the dataset:

$$U = \frac{1}{M} \sum_{j=1}^M y_j. \quad (3)$$

Clustering solutions which describe the dataset structure will result in high value of  $I_{CH}$  index. The choice of this index was motivated by our successful experiments on other heuristic algorithms using  $I_{CH}$  value [10] as a key component. Also recent studies on clustering indices demonstrate its sound potential to validate clustering solutions [16].

### B. Grasshopper Optimization Algorithm

GOA represents a population-based metaheuristic which is aimed at solving continuous optimization problems, that is finding argument (solution)  $x^*$  which minimizes cost function  $f: S \rightarrow R$ . It can be formally written as:

$$x^* = \arg \min_{x \in S} f(x), \quad (4)$$

with  $S \subset R^D$ . Population based heuristic algorithms solve (4) using a swarm of  $P$  individual agents, in iteration  $k$  of the algorithm represented by a set  $\{x_p\}_{p=1}^P$ , with  $x_p = [x_{p1}, x_{p2}, \dots, x_{pD}]$ . The important concept for the construction of this class of procedures is also a measure of closeness between two swarm members  $p_1$  and  $p_2$ , denoted here by Euclidean distance  $dist(x_{p1}, x_{p2})$ . The best solution found by the swarm within  $k$ -iterations is stored as  $x^*(k)$ . It is

also assumed here that search space  $S$  is bounded and this type of constraints is represented by the values of the lower  $LB_1, LB_2, \dots, LB_D$  and upper bound  $UB_1, UB_2, \dots, UB_D$ . Effectively it means that:

$$LB_d \leq x_{pd}(k) \leq UB_d \quad (5)$$

for all  $k = 1, 2, \dots, p = 1, 2, \dots, P$  and  $d = 1, 2, \dots, D$ .

Grasshopper Optimization Algorithm claims to be inspired by the social behavior of grasshoppers – insects of *Orthoptera* order (suborder *Caelifera*) [3]. Each member of the swarm constitutes a single insect located in search space  $S$  and moving within its bounds. The algorithm is reported to implement two components of grasshoppers movement strategies. First it is the interaction of grasshoppers which demonstrates itself through slow movements (while in larvae stage) and dynamic motion (while in insect form). The second corresponds to the tendency to move towards the source of food. What is more deceleration of grasshoppers approaching food and eventually consuming is also taken into account.

The movement of individual  $p$  in iteration  $k$  (index  $k$  was omitted for the sake of readability) can be written using the following equation:

$$x_{pd} = c \left( \sum_{q=1, q \neq p}^P c \frac{UB_d - LB_d}{2} s(|x_{qd} - x_{pd}|) \frac{x_{qd} - x_{pd}}{dist(x_q, x_p)} \right) + x_d^* \quad (6)$$

with  $d = 1, 2, \dots, D$ . Parameter  $c$  is decreased according to the formula:

$$c = c_{max} - k \frac{c_{max} - c_{min}}{K} \quad (7)$$

with maximum and minimum values –  $c_{max}, c_{min}$  respectively – and  $K$  representing maximum number of iterations serving as algorithm's termination criterion. First occurrence of  $c$  in (6) reduces the movements of grasshoppers around the target – balancing between exploration and exploitation of the swarm around the target. It is analogous to the inertia weight present in the Particle Swarm Optimization Algorithm. Component  $c \frac{UB_d - LB_d}{2}$ , as noted in [3], linearly decreases the space that the grasshoppers should explore and exploit. Finally function  $s$  defines the strength of social forces, and was established by creators of the algorithm as:

$$s(r) = f e^{\frac{-r}{l}} - e^{-r} \quad (8)$$

with  $l = 1.5$  and  $f = 0.5$ .

To sum up GOA written using pseudocode and symbols introduced in the paper and taking into account all important elements – like initialization or calculation of the best solution – is presented as Algorithm 1.

## III. GOA-BASED CLUSTERING TECHNIQUE

Using any heuristic optimization algorithm requires choosing proper solution representation. In the case of clustering it is natural to represent solution as a vector of cluster centers  $x_p = [u_1, u_2, \dots, u_C]$ . Consequently the dimensionality  $D$  used

**Algorithm 1** Grasshopper Optimization Algorithm

28:  end for
29:   $f(x^*(k+1)) \leftarrow f(x^*(k)), x^*(k+1) \leftarrow x^*(k)$ 
30:   $k \leftarrow k+1$ 
31: until  $k < K$ 
32: return  $f(x^*(k)), x^*(k)$ 

```

---

in the description of GOA, in the case of data clustering problem, is equal to  $C * N$ .

Another important aspect is choosing proper tool of assessing the quality of generated solutions. Here an idea already presented in [9] is implemented. After assigning each data element  $y_i$  to the closest cluster center the solution  $x_p$  (representing those centers) is evaluated according to the formula:

$$f(x_p) = \frac{1}{I_{CH,p}} + \#_{CL_{i,p}=\emptyset, i=1,\dots,C}. \quad (9)$$

It is equivalent to adding to the inverse value of Calinski-Harabasz index – calculated for solution  $p$  – the number of empty clusters identified in  $x_p$  clustering solution written above as  $\#_{CL_{i,p}=\emptyset, i=1,\dots,C}$ . The idea behind appending the second component in (9) is penalizing solutions which do not include desirable number of clusters.

#### IV. EXPERIMENTAL EVALUATION

Evaluating clustering algorithms is in essence a difficult task due to unsupervised character of this problem. It is usually approached by performing cluster analysis on the labeled dataset

containing the information about assignment of data elements to classes. Subsequently, clustering solution understood as a set of cluster indexes provided for all data points should be compared with a set of class labels. Such a comparison can be done with the use of Rand index [17], external validation index which measures similarity between cluster analysis solutions. It is characterized by a value between 0 and 1. Low value of  $R$  suggests that the two clusterings are different and 1 indicates that they represent exactly the same solution – even when the formal indexes of clusters are mixed.

As a point of reference for evaluating performance of clustering methods classic K-means algorithm is being used. It is also the case of this contribution. For the experiments we used a set of benchmark datasets – based on real-world examples taken from the UCI Machine Learning Repository [18]. In the same time a set of standard synthetic clustering benchmark instances known as S-sets was used [19].

TABLE I: Characteristics of investigated datasets

Dataset	$M$	$N$	$C$	Dataset	$M$	$N$	$C$
<i>glass</i>	214	9	6	<i>yeast</i>	1484	8	10
<i>wine</i>	178	13	3	<i>s1</i>	5000	2	15
<i>iris</i>	150	4	3	<i>s2</i>	5000	2	15
<i>seeds</i>	210	7	3	<i>s3</i>	5000	2	15
<i>heart</i>	270	13	2	<i>s4</i>	5000	2	15

Table I provides the description of the datasets used in the numerical experiments. It contains properties like dataset size  $M$ , dimensionality  $N$  and the number of classes  $C$  – used as desired number of clusters for the grouping algorithms.

To evaluate clustering methods they were run 30 times with mean and standard deviation values of Rand index –  $\bar{R}$  and  $\sigma(R)$  – being recorded. For GOA-based algorithm a population of  $P = 20$  swarm members was used. Algorithm terminates when  $C * N * 1000$  cost function evaluations were performed. It is a standard strategy for evaluating metaheuristics – making the length of search process dependent on data dimensionality.

First default values of all GOA parameters were used, with  $c = 0.00001$ . It means that  $c$  quickly approaches values close to zero. Summary of obtained results for this case is provided in Table II. It is easy to observe that GOA-based clustering outperforms K-means on the majority of the datasets – it is also less prone to getting stuck in local minima (it is indicated by the fact that it is less stable in terms of performance). We studied also the effect of using alternative values for parameter  $c_{min}$  (using  $c_{max} = 1$  seems natural for the construction of normalized "schedule"). Table III provides the results of these experiments. First, we have used fixed values for  $c_{min}$  – higher than the one suggested by creators of the algorithm. This approach brings clearly very positive results. For most of datasets the performance of clustering algorithm has improved (as indicated by bold font). Especially the value  $c_{min} = 0.001$  seems to be functioning very well.

We have also studied the possibility of using random values of  $c$  in the interval  $[0, 1]$ . It is a common strategy of "embed-

TABLE II: K-means vs GOA-based clustering (with default parameter values)

	K-means clustering		GOA clustering (default $c_{min} = 0.00001$ )

ding" chaotic behavior into metaheuristic – which should result in enriching the search behavior [20]. In this case this approach does not work well. A decrease in the algorithm performance was predominantly observed. Still, such a "chaotic-enhanced" GOA-based clustering algorithm outperforms K-means in the most of investigated data mining cases.

## V. CONCLUSION

The paper proposes new clustering approach based on recently introduced Grasshopper Optimization Algorithm. Besides the description of the method the results of its experimental evaluation were also discussed. It was established that GOA-based approach offers high performance with respect to the standard K-means algorithm, both in terms of average quality of solutions and their stability. We also examined the impact of important algorithm's parameter – namely value of  $c$ . Possibility of using both fixed values for the lower bound of  $c$  (alternative to the default  $c_{min} = 0.00001$ ) as well as random strategy (which proved to be mostly unsuccessful) were inspected.

Further studies within the scope of this paper should include more detailed analysis of the impact of population size and coefficient  $c$  on the quality of obtained solutions. The importance of the first aspect stems from the fact that

the algorithm is characterized by quadratic time complexity with regards to the population size. It essentially means that choosing proper, compact  $P$  value is important for the success of GOA-based optimization. Choosing the right scheme of  $c$  alteration seems also of great importance. Therefore the idea of using alternative function to the standard linearly decreasing one should be explored.

**Abstract**—This paper presents methods solving MS-RCPSP as a main task-resource-time assignment optimization problem. In the paper there are presented four variants of Evolutionary Algorithm applied to MS-RCPSP problem: concerning prioritization the tasks (or resources), combined task-resources prioritizing approach and co-evolution based approach that effectively solves problem dividing it to two subproblems. All approaches are examined using benchmark MS-RCPSP iMOPSE dataset and results show that the problem decomposition is effective. All experiments are described, statistically verified and summarized. Conclusions and promising areas of future work are presented.

## I. INTRODUCTION

MANY practical problems can be effectively solved by (meta)heuristics. Particularly, the problems that are NP-hard, over-constrained, combinatorial and have huge solution landscape. Scheduling belongs to this group of problems, which is applied in the real-world, where the problem exists with rare and/or expensive resources. In this situation, the project manager role is to find such resource usage to realize set of tasks in the most effective way. Mainly, it is a quite casual definition of Project Scheduling Problem (PSP), where effectiveness measure is the project realization time. The PSP is too general and in real-world usage is extended to Resource Project Scheduling Problem, where generally speaking, resources are not only limited but also not every resource can be applied to each task. In practical application, such problem specialization goes further, e.g. in IT industry to realize product/service several various types of resources must cooperate to build high-quality software. Such (human) resources differ in skills and levels (e.g. “Java programmer – advanced”, “software architect – basic”) and can be employed in various roles that need particular skills. Of course, resources differ also in salaries, which makes the optimization problem focused on time and/or cost. This way Multi-Skill Resource-Constrained Project Scheduling Problem (MS-RCPSP) can be described.

The MS-RCPSP problem is presented in literature (e.g.[3][12][8]) as extension of RCPSP [4]. It is NP-hard [2] and there is no effective algorithm to solve it. Thus, several types of (meta)heuristic methods can be effectively applied. There can be found applications of (MS-)RCPSP in literature based on: heuristics [3][12], tabu search [11], evolutionary algorithms (EA) with specialized operators [10],

(hybridized) ant colony optimization [9], teaching-learning-based optimization algorithm [13], differential evolution [14], hybridized differential evolution [6] and many others.

The MS-RCPSP problem is connected to resource-task-time assignment. Many approaches deal with it using reduced solution space by problem modification. E.g. in hybridized differential evolution [6] metaheuristic DE operates on search space that prioritizes resource and task sequencing is solved by greedy-based method. Such approach is effective, but greedy usage may cause that method to get stuck in local optima. This is not the only way of problem decomposition. Some methods employ a natural co-evolution mechanism which can be applied in RCPSP problems too, e.g.[15]. This paper concerns co-evolutionary algorithms that eliminate greedy usage. In proposed method MS-RCPSP problem is decomposed into two subproblems: effective (1) task prioritizing and (2) resource prioritizing to build a final feasible schedule.

The main motivation of this paper is to examine the effectiveness of co-evolution usage. To do that several EA-based approaches are tested and compared. One approach uses genome, which proposes only resources’ priorities (EA\_R) that are converted by greedy to build schedule. Other reference approach (EA\_T) proposes tasks’ priorities and analogously greedy-like algorithm converts into schedules. To eliminate the greedy usage, an approach is introduced with connected genome that proposes resources’ and tasks’ priorities (EA\_RT). All provided methods use the same problem solution landscape: representation, selection, genetic operators and fitness function. Finally, using co-evolution EA (Co\_RT) two problem are separated (resource- and task- priorities) into two separate populations, and the only connection is kept by selection to build final schedule to get the fitness function value.

The rest of the paper is organized as follows. In section II the MS-RCPSP problem brief statement with constraints and requirements is described. The description of proposed EA-based approaches are given in section III, where details of examined methods are provided, especially details that are connected with adaptation of EA to MS-RCPSP problem. Section IV-B presents experimental procedure, parameters tuning method, used dataset and finally gained results summarized and concluded (see IV-C). Last section V concludes the article and presents potential directions for future work.

occurs when all tasks are performed sequentially in the project - one after another. Disregarding how many and how flexible resources are.

and the cost component  $f_c(PS)$  is defined as follows:

$$f_c(PS) = \frac{\sum_{i=1}^J c_j}{c_{max} - c_{min}} \quad (3)$$

where:  $c_{min}$  – minimal schedule cost – a total cost of all tasks assigned to the cheapest resource,  $c_{max}$  – maximal schedule cost – a total cost of all tasks assigned to the most expensive resource. Note that  $c_{max}$  and  $c_{min}$  do not respect skill constraints. It means that  $c_{min}$  value could be reached also for non-feasible solution, analogously to  $c_{max}$ .

To get feasible schedule some constraints must be provided, as follows:

$$\forall_{k \in K} s_k \geq 0, \forall_{k \in K} Q^k \neq \emptyset \quad (4)$$

$$\forall_{j \in J} F_j \geq 0; \forall_{j \in J} d_j \geq 0 \quad (5)$$

$$\forall_{j \in J, j \neq i, i \in P_j} F_i \leq F_j - d_j \quad (6)$$

$$\forall_{i \in J^k} \exists_{q \in Q^k} h_q = h_{q_i} \wedge l_q \geq l_{q_i} \quad (7)$$

$$\forall_{k \in K} \forall_{t \in \tau} \sum_{i=1}^n U_{i,k}^t \leq 1 \quad (8)$$

$$\forall_{j \in J} \exists_{!t \in \tau, !k \in K} U_{j,k}^t = 1 \quad (9)$$

The first constraint (see Eq. 4) preserves the positive values of resource salaries and ensures that every resource has non-empty set of skills. Eq. 5 states that every task has positive finish date and duration, while Eq. 6 shows the precedence constraints rule. Next two equations: Eq. 7 introduces skill constraints and transforms RCPSP into MS-RCPSP. Constraint given in Eq. 8 describes that resource can be assigned to no more than one task at given time during the project. The last constraint (see Eq. 9) says that each task must be performed in schedule  $PS$  by one resource assignment.

The proposed MS-RCPSP allows to define problem as multiobjective [5] (see Eq. 1): duration- and cost- oriented one. One criteria has to trade off certain other criteria because cheaper schedule is mostly longer in realization. Such problem can be solved as a weighted linear combination, as follows:

Evaluation function is formulated as follows:

$$\min f(PS) = w_\tau f_\tau(PS) + (1 - w_\tau) f_c(PS) \quad (10)$$

where:  $w_\tau$  – it is weight of duration component and has non-negative values:  $w_\tau \in [0; 1]$ . Such definition makes possible to choose which objective is more important in given optimization process. It is made by setting weights both for the duration ( $w_\tau$ ) and cost ( $1 - w_\tau$ ) aspect. It means that setting the weight of duration aspect to 1.0 automatically sets the weight of cost to 0.0 and vice versa. Specifically, both weights can be set to 0.5. In that case, both objectives would be equally important in the optimization process. We proposed three baseline weight configurations: duration optimization (DO,  $w_\tau = 1$ ) [7], [6], balanced optimization (BO,  $w_\tau = 0.5$ ) and cost optimization (CO,  $w_\tau = 0$ ) [8]. As CO is rather a

trivial task that can be solved by greedy-based approach, BO can be analyzed as cost/duration middle ground. In this paper we focus only on the DO – it means that we minimize only schedule makespan. MS-RCPSP reduced to duration-oriented optimization can be considered as a variation of widely studied parallel machine scheduling problem with minimum makespan objective.

As MS-RCPSP is combinatorial NP-hard problem the estimation of the total solution space (feasible and non-feasible solutions included) size ( $SS$ ) can be estimated as follows:

$$SS(n, m) = n! * m^n \quad (11)$$

Computing factorial of tasks number provides the number of combinations of ordering tasks within the timeline. It is easy to notice that such estimation allows setting any order, skipping precedence constraints. The second element of Eq. 11 provides the number of resource-to-task assignments, including situation that the same resource is assigned to all tasks and no skill constraints are preserved (non-feasible solution). To show the size of solution space, let's consider the 'simple' project schedule with 100 tasks and 20 resources – it gives  $SS(100, 20) = 1.19 * 10^{288}$  all possible solutions.

### III. PROPOSED EA-BASED APPROACHES

In this section four EA-based approaches to MS-RCPSP have been presented. Approaches differ in genome interpretation and schedule (as phenotype) build method. Methods of initialization, representation, crossover, mutation, fitness function, selection are common for all. In each approach to MS-RCPSP sequential representation (vector) of the genome has been implemented. Such representation is similar to classical TSP (Travelling Salesman Problem), e.g. vector  $\langle 3, 2, 1, 4 \rangle$  can be represented as the priority for resource or tasks (depends on approach). Such representation allows us to use TSP standard operators: swap as mutation and one-point crossover. Moreover, we use tournament selection and random initialization.

The fitness function is the crucial procedure – e.g. if EA gives an individual priorities for resources, tasks sequence should be proposed by procedure – a schedule builder is used to generate the final schedule. If EA individual gives priorities for tasks and resources the Schedule Generator Scheme (SGS – details in III-A) works. In approach EA\_T (or EA\_R) where resources (tasks) priorities should be proposed, greedy-based algorithm is used selecting first fit element. Mostly, four EA approaches differ in the genome interpretation and schedule build method as follows:

In the **EA\_R** the individual consists of priority for each resource. To evaluate genome SGS builds schedule using greedy approach. Another approach, in **EA\_T** the individual consists of priority for each task. In evaluation procedure the greedy builds schedule. The approach that links such two methods is **EA\_RT** – an individual comprises two parts: priority resource vector and task priority vector. To keep priorities the final schedule is generated by SGS procedure.

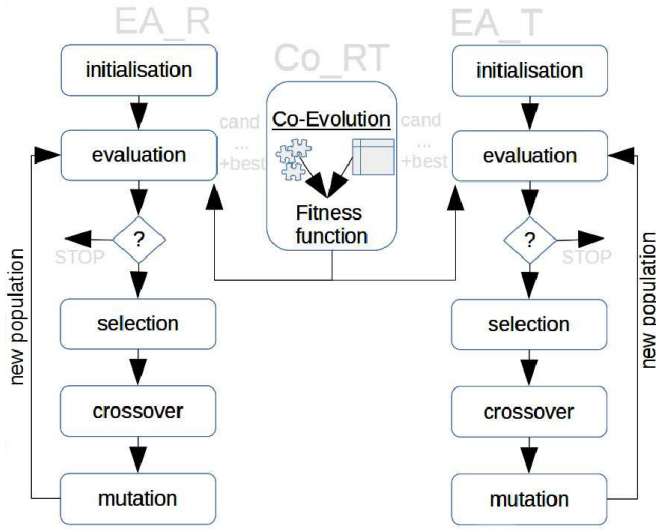

Fig. 2: Evolutionary Algorithms for MS-RCPSP: EA\_T, EA\_R and Co\_RT.

Such approach (EA\_RT) makes that genome “doubled” in size (consists of priorities for tasks and resources), the solution landscape is enlarged and fitness function values may differ significantly for “similar” genomes. Thus, the **Co\_RT** approach links “good” sequence of tasks priorities to resources using natural co-evolution mechanism: in one population evolution processes resources’ priorities, the second one consists of priorities for tasks. Schematically Co\_RT method is presented on Fig. 2. There, two populations are linked by fitness function: to build final schedule, priorities for tasks and resources are needed to run SGS procedure. For every individual, several complementary individuals are selected (it is Co\_RT parameter) from the other population to build schedule – the best-gained value of the fitness function is given. Additionally, to keep Co\_RT more stable for every individual schedule is built using complementary component (resource/tasks sequences) from the best last generation solution.

#### A. Schedule Generator Scheme

To evaluate an individual in EA approaches a procedure that converts genotype to schedule Schedule Generator Scheme (SGS) is needed. Such procedure must deal with three types of individuals, that includes (1) only task priority (EA\_T) (2) only resources priority (EA\_R) and (3) both tasks priority and resource priority (in EA\_RT and Co\_RT). In Pseudocode 1 such procedure has been presented schematically. As an argument, it takes priorities (task and/or resources) and returns final schedule which can be then evaluated. If SGS has not been provided  $T\_pri$  (task priorities sequence), it gets default sequence that is copied from instance definition. In the case of empty resource priorities ( $R\_pri$ ) EA algorithm generates randomly default sequence that is used in the evolution process.

Listing 1: Pseudocode of Schedule Generator Scheme (SGS).

```

Schedule SGS_procedure (  $T\_pri$ ,  $R\_pri$  )
 $T\_seq$  := Tasks
 $R\_seq$  := Resources

while  $T\_seq \neq \text{null}$ 
  if (  $T\_pri \neq \text{null}$  )
     $Task$  :=  $\max(T\_seq.CanBeDone(), Priority)$ 
  else  $Task$  :=  $T\_seq.CanBeDone().first()$ 

  if (  $R\_pri \neq \text{null}$  )
     $R$  :=  $\max(R\_seq.getCapable(), Priority)$ 
  else  $R$  :=  $R\_seq.firstCapable()$ 

   $TimeStamp$  :=  $R.end()$ 
   $Schedule.assign(Task, R, TimeStamp)$ 
   $R.end$  :=  $task.start + task.duration$ 
   $T\_seq = T\_seq / Task$ 
end // while
return schedule .

```

The SGS procedure keeps the task sequence from  $T\_pri$  if it is possible. However, to satisfy the tasks precedence constraints, in each case the *CanBeDone()* method is executed. The same situation occurs in resource selection procedure – it is selected resource that is capable of given task realization and has the highest priority. If SGS doesn’t have prioritized resources/tasks it works like greedy-like algorithm - takes first-fit element.

#### IV. EXPERIMENTS AND RESULTS

This section describes experiments that have been done to empirically verify several research questions:

- Q1. Does the Greedy algorithm guided by metaheuristic has a tendency to stuck in local optima?
- Q2. Is the priority-based sequence vector representation effective?
- Q3. Which priority-based approach using greedy-based SGS (EA\_T or EA\_R), is more effective?
- Q4. How effective is combined approach EA\_RT that eliminates greedy but enlarges the solution landscape?
- Q5. How effective, in comparison to above methods, is co-evolutionary approach that eliminates Greedy usage and keeps standard size of solution landscape?

Above research questions should be answered empirically using the experimental procedure.

##### A. Experiments’ procedure

In experiments iMOPSE benchmark dataset [8] is used – a part of iMOPSE project <sup>1</sup>. Dataset published on the Internet consists of 36 MS-RCPSP iMOPSE instances that differ in number of tasks, resources, skills and relations. The iMOPSE dataset is a part of iMOPSE library supported by instance

<sup>1</sup>iMOPSE project homepage: <http://imopse.ii.pwr.wroc.pl/> . The best schedules generated by EA\_R, EA\_T, EA\_RT and Co\_RT have been published there.

generator, validator, visualization tools and provided use-cases with published java codes (more in [5]).

For empirical comparison of methods results, each method has been tuned (see configurations in Tab. I). However, for each method, the number of births has been reduced to 20,000. It is worth noticing that the Co\_RT method uses multiple candidate resource-task assignment (*cand\_assign* value usually equals to 3) to get better fitness functions. Such method can be treated as some local search procedure that causes Baldwin Effect. However, it doesn't cause strict new solution generation and has no influence on genes. That's why the number of births in Co\_RT is reduced to 20,000 but taking into account number of fitness function calculation such value is bigger than the limit.

Each experiment has been repeated 30 times, and results are averaged, and standard deviation value is given. Comparison of gained results has been statistically examined using Wilcoxon signed-rank test.

### B. Experiments results

Each method is ran 30 times to generate solutions for given problem instances. Data in Tab. II presents results of several proposed methods: EA\_R, EA\_T, EA\_RT and Co\_RT. As reference method hybrid Differential Evolution and Greedy (DEGR) [6] is given in two configurations: using DEGR(*pop\_size*=200, *generations*=500) and DEGR(*pop\_size*=200, *generations*=10,000). The first configuration satisfies the condition of 20,000 births, but in publication [6] the second is given as the best found.

Data presented in Tab. II shows that the best examined method is Co\_RT because sum of all generated (average) schedules equals to 11,639 (sum of *std\_dev*=43.35). However, the second place took method EA\_T where all averaged schedules least 11,681 (sum of *std\_dev*=45.52). It means that the Co\_RT gives solutions 0.35% better than EA\_T – this slight improvement is statistically significant: the Wilcoxon signed-rank test proves it ( $W_{0.05}=443 > W_c=208$ ). It is worth to mention that Co\_RT outperforms other methods giving in four cases the best-found solutions for instances: 200\_40\_45\_9, 200\_40\_133\_15, 200\_10\_135\_9\_D6 and 200\_40\_90\_9. For these instances, we investigated the evolution process. For instance 200\_40\_133\_15 (see Fig.3) the evolution process searches effectively for EA\_T and CO\_RT, but gets stuck very fast for EA\_T. The similar situation is in instances 200\_10\_135\_9\_D6 (see Fig.4), where CO\_RT outperforms other approaches giving solution very fast, EA\_T and EA\_RT need more time to reach a similar solution. The case of 200\_40\_45\_9 (see Fig.5) instance shows that CO\_RT works the most effectively and other methods cannot compete. Quite similar situation occurs on Fig.6 (instance 200\_40\_90\_9), where CO\_RT outperforms other methods, but EA\_T gives near solutions.

Using DEGR method in configuration DEGR(*pop\_size*=200, *generations*=500) is not competitive to Co\_RT, therefore we selected as reference DEGR(*pop\_size*=200, *generations*=10,000) configuration

that gives better results. It can be noticed that in seven instances DEGR gives better solution than Co\_RT and in 9 other cases solutions are similar. But summarized duration of (average) schedules last 11,971 (sum of *std\_dev*=183.15) which means that CO\_RT gives 2.78% of improvement and Wilcoxon signed-rank test results verified positively such difference ( $W_{0.05}=477 > W_c=208$ ). Moreover, the *std\_dev* values show that Co\_RT is more stable method than DEGR – DEGR *std\_dev*=183.15 versus CO\_RT *std\_dev*=43.35.

Results presented in Tab. II show that the worst results are given by EA\_R, where genome proposes priorities for resources and tasks are selected by greedy-like method. The chromosome extension by task priorities (EA\_RT) makes that method return shorter schedules by 8.9% than EA\_R. However, the standard deviation values are higher – EA\_R *std\_dev*=36.98 versus EA\_RT *std\_dev*=84.76.

All the best-found schedules generated by EA\_R, EA\_T, EA\_RT and Co\_RT have been published on iMOPSE project homepage.

### C. Summary

Results of experiments presented in Tab. II showed that the best-examined method is Co\_RT giving several of the best-found solutions. But the results of other methods are very valuable because they help to answer research questions asked at the beginning of this section.

The first question (Q1) cannot be answered easily because results of two approaches that use greedy (EA\_T and EA\_R) compared to EA\_RT results shows that task priorities are more important and greedy gives effective solutions that can compete with Co\_RT results. However, EA\_R is less effective than EA\_T, which answers another research (Q3) question.

Another question (Q2) concerns how effective is the priority-based sequence vector representation. All proposed approaches that use it are compared to DEGR vector with float values representation. Presented results show that such sequence representation is easy in implementation and can compete with more complex used in DEGR.

The answer to question (Q4) only apparently is simple, because EA\_T gives better solutions than EA\_RT. However, provided limit of births (20,000) reduces EA\_RT "space" for evolution process. A quite large standard deviation (*std\_dev*=84.76) value confirms this fact. For EA\_T such value equals to *std\_dev*=45.52.

The last question is the most important aspect of the paper. Is co-evolutionary (Co\_RT) approach to MS-RCPSP effective? This question (Q5) is answered positively, and several arguments are presented in this section. Co\_RT not only outperforms other tested methods but also gives the best-known solutions for four instances.

## V. CONCLUSIONS AND FUTURE WORK

This paper concerns if Co-evolutionary algorithms are effective for solving combinatorial NP-hard problems, MS-RCPSP. Gained results showed that problem decomposition to resource and task assignment using co-evolutionary mechanism is a powerful idea. As reference,

TABLE I: Methods' configurations

Fig. 4: Example of evolution process for MS-RCPSP: EA\_T, EA\_R, EA\_RT and CO\_RT.

results of evolutionary algorithms using the same representation have been compared. Moreover, the reference

method DEGR [6] results also confirm the dominance of Co\_RT.

Fig. 5: Example of evolution process for MS-RCPSP: EA\_T, EA\_R, EA\_RT and CO\_RT.

Fig. 6: Example of evolution process for MS-RCPSP: EA\_T, EA\_R, EA\_RT and CO\_RT.

In the paper, several research questions have been answered, but there are still many open issues. Proposed approaches use simple representation that is not specialized to MS-RCPSP – e.g. how effective can be the approach that uses specialized crossover/mutation operator? In co-evolution, we can see the large potential, and future work should be connected with it: more experiments with parametrization of Co\_RT (without

20,000 births limit), various selection method and scalability. Moreover, the very promising direction is effective clone reduction method, a flexible size of population and adaptation mechanism. And the last but not least, as MS-RCPSP problem is bi-objective, we want to extend proposed co-evolutionary approach to multicriteria optimization.

**Abstract**—This paper presents multiple variances of selection operator used in Non-dominated Sorting Genetic Algorithm II applied to solving Bi-Objective Multi-Skill Resource Constrained Project Scheduling Problem. A hybrid Differential Evolution with Greedy Algorithm has been proven to work very well on the researched problem and so it is used to probe the multi-objective solution space. It is then determined whether a multi-objective approach can outperform single-objective approaches in finding potential Pareto Fronts. Additional modified selection operators and a clone prevention method have been introduced and experiments have shown the increase in efficiency caused by their utilization.

## I. INTRODUCTION

**S**CHEDULING problem plays an important role in today's science and business. It can be met in transportation [1], production [2], project management [3], etc. The problem itself can be informally defined as the function that aims to find the lowest duration and cost of the schedule by assigning resources to tasks. Multi-Skill Resource-Constrained Project Scheduling Problem (MS-RCPSP) is NP-hard and there are no methods capable of finding an optimal solution in polynomial time [4].

The goal of the research presented in this paper is to verify how Differential Evolution hybridized with Greedy (DEGR) and Non-dominated Sorting Genetic Algorithm II (NSGA-II) approaches explore space in the context of multi-objective optimization. DEGR algorithm is a single-objective method, and potential Pareto Front (*PF*) is created by running it multiple times. Each run uses different weights values in the fitness function. Set of points resulting from all runs is considered during evaluation. Moreover, a tournament selection method is investigated in NSGA-II to boost its selective pressure and a clone prevention method is implemented to increase the diversity of the resulting potential *PF*s. Results are evaluated and compared with a set of multi-objective measures. This paper presents the transition from a single to a multi-objective approach to MS-RCPSP and introduces modified selection operators, which have proven to increase efficiency of NSGA-II.

The rest of the paper is organized as follows. Section III lines the MS-RCPSP. Sections IV and V describe implemented methods - NSGA-II and DEGR appropriately. All experiments

along with its results have been presented in section VI. Section VII contains conclusions and directions of future work.

## II. RELATED WORKS

There are many different types of scheduling problem models. PSPLIB library [5] is often used as a baseline to compare methods efficiency. It doesn't support a skill extension of the problem. Additionally, it comprises only one criterion - duration of the schedule, which makes it infeasible for the purpose of this article.

A Software Project Scheduling Problem (SPSP) is another example and was first presented in [6]. It is the most similar problem to the MS-RCPSP as it contains skills and two criteria - duration and cost. Additionally, it allows for tasks to be worked on by multiple resources. It has been more thoroughly described in [7].

Due to NP-hard nature of the problem, researchers have often tackled it with metaheuristics, which often provide satisfactory solution in acceptable time. Many methods have been developed to solve scheduling problems: Differential Evolution [8], Genetic Algorithm [9], Tabu Search [10], Grasp [11] and Teaching-learning-based optimization algorithm [14]. Additionally, swarm optimization techniques have been used: Ant Colony Optimization [12] or Particle Swarm Optimization [13].

The MS-RCPSP is seen as a multi-objective problem. The goal is to minimize both duration and cost of the schedule. It is often difficult to compare different criteria, so it is desired to find a set of equally-good solutions but with different objective values. An existence of populations in evolutionary algorithms perfectly fit the need to find multiple points on the *PF*. There are very few articles that deal with multi-objective MS-RCPSP. Simulated Annealing [15] and Genetic Algorithm [16] have been used for that purpose. The best known results for a single-objective MS-RCPSP have been achieved by a DEGR [8] method and therefore it is used in this paper.

NSGA-II has been proposed in [17] and has proven its efficiency in scheduling problems [18] [19]. The algorithm is often used as a benchmark approach for multi-objective problems.

### III. FORMULATION OF MS-RCPSP

In MS-RCPSP [7] the schedule can be evaluated by both its cost and duration, making the problem multi-objective.

MS-RCPSP comprises a sets of tasks, resources and skills. Each task has a skill required to work on that task, a set of predecessors that have to be completed before the task can be started. Each resource has a set of skills and a cost associated with it. Skill is described by a type and level of expertise. The goal is to create task-resource assignments in a way that satisfies given constraints and minimizes both objectives. Detailed definition can be found in [7].

### IV. NON-DOMINATED SORTING GENETIC ALGORITHM II

Non-dominated Sorting Genetic Algorithm II (NSGA-II) first presented in [17] has proven to be effective approach to multi-objective optimization. It is based on a genetic algorithm, which utilizes populations for space exploration. The use of populations fits the problem very well, as the goal is to find a set of points. NSGA-II uses a comparison operator based on a domination described in formula 1 and a crowding distance operator, which aims to maximize the smallest box which comprises only one individual.

$$i \geq_n j \text{ if } (i_{rank} < j_{rank}) \vee ((i_{rank} = j_{rank}) \wedge (i_{distance} > j_{distance})) \quad (1)$$

where  $i$  and  $j$  are two compared individuals.

NSGA-II utilizes a non-dominated sorting. Individuals created by the genetic operators are added to the same population. At the end of a generation, an entire population is sorted according to the domination operator and then it is truncated to its original size. Detailed description can be found in [17].

#### A. Non-dominated Tournament Genetic Algorithm

In this section, a modification to selection in NSGA-II is presented. This approach uses a tournament selection instead of sorting the population and choosing its better half.

Additional experiments have been performed to check the effectiveness of a tournament selection if an  $\geq_r$  operator, which doesn't regard crowding distance is used. It is defined as:

$$i \geq_r j \text{ if } (i_{rank} < j_{rank}) \quad (2)$$

Non-dominated Tournament Genetic Algorithm (NTGA) is a method, which uses modified selection and  $\geq_r$  operator.

#### B. Clone prevention

A clone prevention method has been designed and introduced after the initial results of the tournament selection. The results have shown a decrease in diversity of the population in comparison to NSGA-II approach with tournament size equal to 2. It was caused by stronger selective pressure. The idea is to enforce a mutation of every newly created individual which happens to be a clone. An individual is a clone of another individual if all their genes are equal.

### V. DIFFERENTIAL EVOLUTION HYBRIDIZED WITH GREEDY

DEGR has been successfully applied to the MS-RCPSP in [8]. It's an evolutionary method operating in real space. Evolution creates a real-valued phenotype, which represents a task-resource assignments. Then the greedy algorithm puts tasks on a timeline.

DEGR has been proven to be efficient in single-objective MS-RCPSP and so it is used to probe space and create a potential  $PF$ . It is compared to both regular NSGA-II and NTGA approaches. It is worth noting that DEGR is inherently not a multi-objective method.

Differential Evolutions uses a weighted fitness function (presented in 3), which allow the algorithm to focus on different parts of the solution space and potentially create a good coverage, even though this approach is Pareto blind - has no concept of the PF, but it is the simplest approach to a multi-criteria problem.

$$f(S) = w_\tau * f_\tau(S) + (1 - w_\tau) * f_c(S) \quad (3)$$

where  $w_\tau$  is a weight associated with the duration of the schedule and its values can vary between  $[0,1]$ ,  $S$  is the schedule,  $f_{tau}$  and  $f_c$  are time and cost of the schedule, both of which are minimized. The function is implemented in a library made public on [21].

Using equation 3 a potential  $PF$  is created by running the method multiple times with different weights to allow for exploration of space and to ensure good coverage.

### VI. EXPERIMENTS AND RESULTS

The goal of this paper is to present a transition from a single-objective to multi-objective approach to MS-RCPSP. Additionally novel selection methods have been proposed to further increase the efficiency of multi-objective method. The results are evaluated by a set of chosen measures. They take convergence and diversity of the found PF under consideration.

#### A. Measures

A set of measures [20] has been chosen to evaluate the results. The choice has been dictated by the need of evaluating both convergence and diversity of the algorithms. Selected measures are commonly used for this purpose.

An Euclidean Distance ( $ED$ ) is an average Euclidean distance between the points on the potential  $PF$  and a perfect point (built by the best possible values of every criteria).

A HyperVolume ( $HV$ ) is a volume of the rectangle constructed from the potential  $PF$  and a Nadir Point (point built by the worst possible values of every criteria).

A Pareto Front Size ( $PFS$ ) is a number of unique points on the potential  $PF$ .

#### B. Dataset

For the experiments an iMOPSE [7] dataset has been used, which is located on [21]. It contains 36 data instances, all varied by the number of tasks, resources and precedence relations. 2 subsets of instances could be identified. In the

first group all instances have 100 tasks, and in the second group, they have 200 tasks. Instances in those groups have been created to preserve an average resource load and number of tasks per number of resources. The idea behind formulation of this dataset was to achieve variety between the instances.

### C. Procedure

A DEGR approach has been used to establish a baseline. It's been executed multiple times with weights values from 0.0 to 1.0, incremented by 0.1 and resulting points been collected. Parameters chosen for DEGR: population size ( $P_s$ ) = 100, 500 generations (gen), mutation probability ( $P_m$ ) = 0.1, crossover probability ( $P_x$ ) = 0.1 and a one-to-one selection.

Four different variants of NSGA-II have been checked. The following parameters have been chosen for NSGA-II:  $p_s$  = 50, 500 gen,  $P_m$  = 0.01,  $P_x$  = 0.6, tournament size ( $t_s$ ) = 5. Parameters chosen for NTGA:  $p_s$  = 50, 500 gen,  $P_m$  = 0.002,  $P_x$  = 0.9,  $t_s$  = 4. We compared classic NSGA-II approach with its modifications: a tournament selection, modified comparison operator, which disregards crowding distance and clone prevention method. The goal was to increase the convergence and diversity of the method. All procedures has been repeated 30 times and results were averaged.

### D. Results

An experiment has been performed to check the influence of a tournament size on chosen measures. The best values of both  $ED$  and  $PFS$  are achieved for tournament size equal to 4. Interestingly higher values improve the  $HV$ . High  $PF$  Size means high diversity of the population and also suggest good coverage of  $PF$ . Therefore  $PFS$  has been chosen as the most important measure.

A clone removal method have been introduced to increase low diversity of the population. Since clone removal increases the distance between the individuals, a crowding distance has become redundant. Another approach has been investigated with modified comparison operator, which considers only the rank of the individual. Due to a huge volume of the table, standard deviations have been omitted and only classical NSGA-II, best variant of NTGA and DEGR approaches have been presented - table II. Additionally averaged results have been gathered and are presented in table I.

The increased size of the tournament improved all measures and standard deviations. Clone prevention method has a positive effect on average results but increases standard deviation. Checking crowding distance is not crucial when used with clone prevention method. This approach resulted in a better

convergence, represented by  $ED$ , a bit lower diversity, represented by  $HV$ , but average  $PFS$  has dramatically increased. Interestingly NSGA-II(t6,pc) has achieved the highest  $PFS$  for most instances, but NTGA(t6,pc,r) has achieved the best  $PFS$ . It is caused by the fact, that their results were very close, but the latter has achieved a huge lead on a couple of instances. DEGR approach achieved relatively low  $ED$  and the worst  $PFS$  of all investigated methods but at the same time the best  $HV$ . It is caused by the fact, that it was executed multiple times with various weight values, which allowed for searching different parts of solution space and is connected with the fact that DEGR achieved the best edge values.

## VII. CONCLUSIONS AND FUTURE WORK

This paper presents how a single and a multi-objective approaches are capable of exploring the space of MS-RCPSP. It's been shown that a classic Pareto approach (NSGA-II) has a much better efficiency concerning convergence, however, lack diversity of DEGR - it's worth noting that DEGR has been executed multiple times with different weights. A modified selection operators and a clone prevention method have been presented and experiments have shown that they are capable of further increasing efficiency of NSGA-II.

Two potential directions for future work can be considered. On the one hand, an initial population, which better covers the solution space could improve achieved results. On the other hand, the selection method, which rewards better spread of individuals could occur the more diverse PF.

The used DEGR approach is hybridized with a Greedy Algorithm, which potentially is a bottleneck for the method. A very promising direction would be to remove the Greedy Approach and let an Evolutionary Algorithm take its place. In this co-evolutionary approach, there would be populations communicating with each other - one would assign the task to resources, while other would assign timestamps to tasks. DEGR has proven to be an effective method for single-objective optimization. As an extension of these works, DEGR could be introduced dominance relation and PF concept to compete with existing multi-objective methods even better.

# Hybrid Multievolutionary System to Solve Function Optimization Problems

Krzysztof Pytel

Faculty of Physics and Applied Informatics

University of Lodz, Poland

Email: kpytel@uni.lodz.pl

**Abstract**—Evolutionary algorithms are optimization methods inspired by natural evolution. They usually search for the optimal solution in large space areas. In Evolutionary Algorithms it is very important to select an appropriate balance between the ability of the algorithm to explore and exploit the search space. The paper presents a hybrid system consisting of a Genetic Algorithm and an Evolutionary Strategy designed to optimize the function of many variables. In this system, we combined the ability of the Genetic Algorithm to explore the search space and the ability of the Evolutionary Strategy to exploit the search space. Optimization performed by the Genetic Algorithm and the Evolutionary Strategy runs at the same time, so it is possible to perform parallel computations. The results of the experiments suggest that the proposed system can be an effective tool in solving complex optimization problems.

## I. INTRODUCTION

**E** VOLUTIONARY Algorithms (EA) are widely used in solving complex problems of optimization. This is a group of methods inspired by observation of nature. These methods are based on the principles of natural selection of living organisms developed by Charles Darwin. According to this principle, well-adapted individuals have more chances of survival - and transfer of their genetic material to the next generation. A list of terms which are used to describe Evolutionary Algorithms is closely related to genetics and evolution. The Evolutionary Algorithm processes the population of individuals (each individual in the form of a chromosome represents a potential solution to the problem). The Evolutionary Algorithm works in certain environments, which can be defined on the basis of the problem solved by the algorithm. Depending on how much a given individual (ie. chromosome) is adapted to the environment in which it is located, a numeric value that determines the quality represented by its solution is assigned to it. This number is called fitness of the individual and is a major factor that describes the ability of an individual to act as a parent for the next generation of population. Evolutionary Algorithms do not guarantee finding the global optimum, but generally provide a good enough solution in an acceptable period of time. Hence, the main use of these algorithms is in very sophisticated problems in a large search space for which there are no specialized techniques. A characteristic feature of Evolutionary Algorithms is that in the process of evolution they do not use the knowledge specific for a given problem, except for the fitness function assigned to all individuals. The Evolutionary Algorithm must keep the

right balance between exploration and exploitation of the search space. Exploration is the process of searching for a new region of a search space where an optimum can exist. Exploitation is the process of searching for regions within the neighborhood of previously visited points. Examples of Evolutionary Algorithms are Genetic Algorithms (GA) and Evolutionary Strategies (ES).

The Genetic Algorithm is an optimization method that simulates the process of natural evolution. The GA uses the mechanism of natural evolution (selection, mutation, cross-over of individuals and reproduction). The individuals of the GA could be coded by binary strings (binary representation), real numbers (a real number representation) or composite structures of genes. The main parameters of the GA, affecting the ability to explore and exploit of the search space, are probability of selection and probability of mutation. The type of cross-over and mutation operators are very important. Reproduction in GAs is closely related to maintaining the diversity of the population, the selection pressure and avoiding premature convergence to the local optima. In Genetic Algorithms the exploitation is done through the selection process. Cross-over and mutation are both methods of exploring the search space. Very important problem is always finding the right balance between exploration and exploitation. If the exploration ability is too large, the algorithm can get stuck in the local optima. If the exploration ability is too large, the algorithm will waste time on poor solutions and cannot focus on solutions found till now.

More information on Genetic Algorithms can be found in publications [3][5][7].

Evolution Strategies uses primarily mutation and selection as search operators. These operators are applied in a loop until the termination criterion is met. ES are based on the principle that small changes have small effects. The mutation is usually performed by adding a normally distributed random value to each individual's genes. After a certain number of fitness function calls or a number of generations, it is essential to adjust the parameters of mutation. At first, the ratio of successful mutations over all mutations is evaluated. If the ratio is less than the specified threshold, the mutation parameters are increased to obtain greater diversity of individuals. If the ratio is greater than the specified threshold, the mutation parameters are decreased to increase the accuracy of the search and accelerate the convergence of the algorithm. The simplest

Evolution Strategy  $(1 + 1) - ES$  operates on a population of two individuals: the current point (a parent) and the result of its mutation (a child). If the child's fitness is equal to or better than the parent's fitness, the child becomes the parent in the next generation. Otherwise, the new child is created in the next loop. In strategy  $(1 + \lambda) - ES$ ,  $\lambda$  children can be generated and compete with the parent. In  $(1, \lambda) - ES$  the best child becomes the parent in the next generation while the current parent is always disregarded. Evolution Strategies  $(\mu/\rho+, \lambda) - ES$  can use the population of  $\rho$  parents and also recombination as an additional operator. This makes them less prone to get stuck in the local optima.

More information on Evolution Strategies can be found in publications [1][2].

Hybrid intelligent system is a system which employs, in parallel, a combination of methods and techniques from artificial intelligence subfields, for example Genetic Algorithms, the Fuzzy Logic, Artificial Neural Networks etc. Such systems are able to take advantage of the methods and techniques of artificial intelligence while avoiding their disadvantages. They can be used to improve effectiveness of the methods or where simple methods do not produce the expected results.

Hybrid intelligent systems using artificial intelligence methods can be used in different optimization problems, for example in multiobjective optimization [10] [11], Connected Facility Location Problem [12] or Clustering Problem [13].

## II. PROBLEM FORMULATION

Optimization is the process of finding the greatest or the smallest value. The Function Optimization Problem (FOP) is a problem in which certain parameters (variables) need to be determined to achieve the best measurable performance (objective function) under given constraints. For function  $f(x)$ , called the objective function, that has a domain of real numbers of set  $S$ , the maximum optimal solution occurs where  $f(x_0) > f(x)$  over set  $S$  and the minimum optimal solution occurs where  $f(x_0) < f(x)$  over set  $S$ .

Formally, optimization is the minimization or maximization of a function subject to constraints on its variables. Let's denote:

- $x$  is the vector of variables (parameters);
- $f(x)$  is the objective function that we want to maximize or minimize;
- $c$  is the vector of constraints that the variables must satisfy. It may consist of several restrictions that we place on the variables.

The function optimization problem (e.g a function maximization problem) can be stated as follows:

$$\begin{cases} \max & f(x) \\ \text{subject to:} & c_i \leq 0 \text{ for } i = 1, 2, \dots, k \\ & x \in S \end{cases} \quad (1)$$

where:

- $x = [x_1, x_2, x_3, \dots, x_n] \in \mathbb{R}; n \in \mathbb{N}$  - is an  $n$ -dimensional vector of decision variables,

- $f(x)$  - is the objective function of variables  $x$ ,
- $c_i(x)$  - are constraints,
- $S$  - the search area.

The FOP problem can be used as a benchmark for testing optimization methods. Various methods of solving the FOP are discussed in literature, for example [4][6].

## III. THE PROPOSED MULTIEVOLUTIONARY SYSTEM

Genetic Algorithms use cross-over and mutation operators to search the space for possible solutions. One of the drawbacks of Genetic Algorithms is low efficiency in the final search stage. The Evolutionary Strategy uses primarily mutation and selection operators. Evolutionary Strategies are at risk of getting stuck in sub-optimal solutions. The proposed system (GA-ES) consists of a Genetic Algorithm and an Evolutionary Strategy. It combines the ability of a GA to find the areas of possible optima and the ability of ESs to quickly converge to the optima. Both of them are types of Evolutionary Algorithms and can use the same individuals' representation, operators of selection and mutation.

In the system, both algorithms start with the same initial population and work in parallel. After a predetermined number of generations, the best individuals from both algorithms will be compared. Depending on the result of this comparison, transposition of individuals between the algorithms may be performed:

- if the best individual in the GA is better than the best individual in the ES, then the new area of the optima is found. The best individual in the GA replaces the parent in the ES.
- if the best individual in the ES is better than the best individual in the GA, then it means that a new optimal solution is found as a result of the ES. The best individual in the ES replaces the worst individual in the GA population.

The system block diagram is shown in Figure 1.

## IV. COMPUTATIONAL EXPERIMENT

The goal of our experiments is verification of the idea of the hybrid multievolutionary algorithm in solving the function optimization problem. We used functions of a wide range of complexity in a diverse environment. For tests we used a set of 3 functions:

- $f1(x_1, x_2)$  - an easy function of two variables (similar to cosinemixture [14] function). The function has many local optima and was used for testing the algorithm's ability to find the global optimum. The function is given by formula:

$$f1(x_1, x_2) = (\sin(x_1) + 0.6 * \sin(20 * x_1)) * \sin(x_2) \quad (2)$$

where:

$$x_1, x_2 \in (0, \pi) \quad (3)$$

The value of maximum 1.6 at point  $(\pi/2, \pi/2)$ .

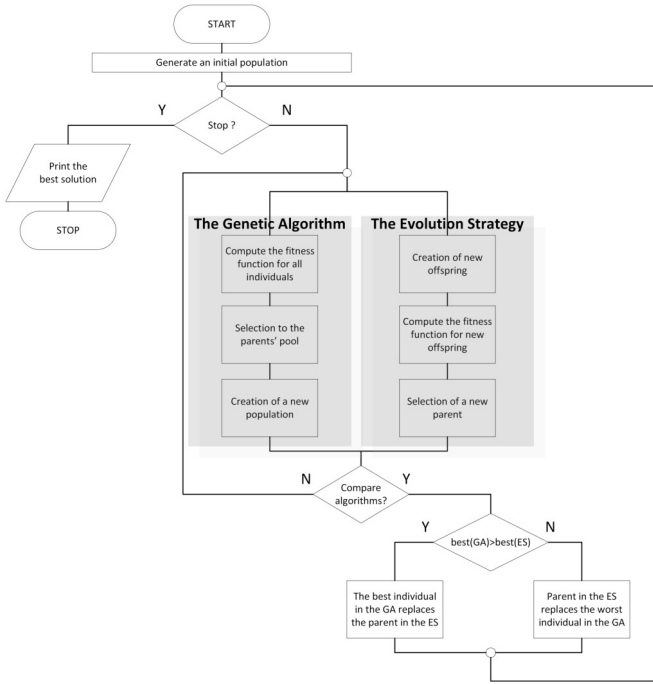

Fig. 1. The system block diagram

- $f_2(x_1, x_2, \dots, x_{10})$  - the function of multiple variables (similar to alpine2 [14] function). A low inclined function, used for testing the ability of the algorithm to determine the exact solution. The function is given by formula:

$$f_2(x_1, x_2, \dots, x_{10}) = \prod_{i=1}^{10} \sin(x_i) \quad (4)$$

where:

$$x_1, x_2, \dots, x_{10} \in (0, \pi) \quad (5)$$

The value of maximum 1 at point  $(\pi/2, \pi/2, \pi/2, \pi/2, \pi/2, \pi/2, \pi/2, \pi/2, \pi/2, \pi/2)$ .

- $f_3$  - the function proposed in [9]. It is a sophisticated function with many local optima with different values, which permits to estimate the ability of the algorithm to solve difficult optimization problems. The first generation of individuals was placed in the local optimum (point [5, 5]). The algorithm should find the total optimum (point [50, 50]), avoiding the local optima. The function is given by formula:

$$f_3(x_1, x_2) = \sum_{i=1}^7 h_i * e^{-\mu_i * ((x_1 - x_{i1})^2 + (x_2 - x_{i2})^2)} \quad (6)$$

where:  $h_1 = 1.5, h_2 = 1, h_3 = 1, h_4 = 1, h_5 = 2, h_6 = 2, h_7 = 2.5$

$$\mu_1 = \mu_2 = \mu_3 = \mu_4 = \mu_5 = \mu_6 = \mu_7 = 0.01$$

$$(x_{11}, x_{12}) = (5, 5), (x_{21}, x_{22}) = (5, 30), (x_{31}, x_{32}) = (25, 25), (x_{41}, x_{42}) = (30, 5), (x_{51}, x_{52}) = (50, 20), (x_{61}, x_{62}) = (20, 50), (x_{71}, x_{72}) = (50, 50)$$

Fig. 2. Function  $f_3$ 

TABLE I  
THE AVERAGE TIME AND NUMBER OF FITNESS FUNCTION CALLS NEEDED TO REACH THE PREDETERMINED VALUE OF THE OPTIMIZED FUNCTION

Function	The predetermined value of algorithm termination	SGA		GA-ES	
		Time [s]	The number of fitness function calls	Time [s]	The number of fitness function calls
f1	1.596	0.210	37960	0.092	3978
f2	0.999	1.378	80158	0.480	8450
f3	2.499	0.307	56940	0.072	7124

The value of maximum 2.5 at point (50,50).

The function  $f_3$  is shown in Figure 2.

The values of parameters of the Genetic Algorithm and the Evolution Strategy was fixed during the initial experiments. In the experiments we accepted the following values of parameters of the Genetic Algorithm:

- the genes of individuals are represented by real numbers,
- the probability of cross-over = 0.8,
- the probability of mutation = 0.15,
- the number of individuals in the population = 25.

For the Evolutionary Strategy, model  $(1+1) - ES$  was chosen and the mutation performed by adding a number generated randomly according to normal distribution.

The best individuals from both algorithms were compared after every 50 generations and, depending on the result of this comparison, transposition of individuals was performed between the algorithms. The system was stopped when the best individual reached the predetermined value of the optimized function.

In the experiment, we compared the results of the proposed GA-ES and the standard genetic algorithm (SGA) described in [8], and adapted it to optimize the test functions. Each algorithm was executed 10 times on a standard PC computer (CPU: Intel i3, RAM: 8GB, Windows 10 operating system). Table 1 shows the average time and number of fitness function calls needed to reach the predetermined value of the optimized function.

The graph in Figure 3 shows the average running time of the Genetic Algorithm (SGA) and the proposed system (GA-ES).

The graph in Figure 4 shows the average number of fitness function calls in the Genetic Algorithm (SGA) and the

Fig. 3. The average running time of the Genetic Algorithm (SGA) and the proposed system (GA-ES)

Fig. 4. The average number of fitness function calls in the Genetic Algorithm (SGA) and the proposed system (GA-ES)

proposed system (GA-ES).

## V. CONCLUSIONS

The proposed Genetic Algorithm-Evolution Strategy system was able to find a solution near the optimum for all tested functions. Optimization of function F2 (a low inclined function) has shown that the system has greater convergence and accuracy in comparison to the SGA. Optimization of function F3 (a sophisticated function with many local optima) has shown that the system is more resistant to premature convergence to the local optimum compared to the ES.

The GA-ES running time on a PC was very short (less than 2 seconds). The time was 56, 65 and 76 percent shorter than the running time of SGA for function f1, f2 and f3 respectively.

The number of fitness function calls in GA-ES system was decreased by nearly 90 percent in relation to the number of fitness function calls in the SGA.

In the proposed system it is possible to perform parallel calculations by the Genetic Algorithm and the Evolutionary Strategy, eg. by using multiple processors or processor cores.

The proposed system is an efficient tool for solving function optimization problems. It could be used for solving very wide range of optimization problems.

**Abstract**—There is an overwhelming variety of multimedia ontologies used to narrow the semantic gap, many of which are overlapping, not richly axiomatized, do not provide a proper taxonomical structure, and do not define complex correlations between concepts and roles. Moreover, not all ontologies used for image annotation are suitable for video scene representation, due to the lack of rich high-level semantics and spatiotemporal formalisms. This paper presents an approach for combining multimedia ontologies for video scene representation, while taking into account the specificity of the scenes to describe, minimizing the number of ontologies, complying with standards, minimizing reasoning complexity, and whenever possible, maintaining decidability.

## I. INTRODUCTION

IN THE last 15 years, narrowing the notorious *semantic gap* in video understanding has very much been neglected compared to image interpretation [1]. For this reason, most research efforts have been limited to frame-based concept mapping so that the corresponding techniques could be applied from the results of the research communities of image semantics. However, these approaches failed to exploit the temporal information and multiple modalities typical to videos.

Most domain ontologies developed for defining multimedia concepts with or without standards alignment went from one extreme to the other; they attempted to cover either a very narrow and specific knowledge domain that cannot be used for unconstrained videos, or an overly generic taxonomy for the most commonly depicted objects of video databases, which do not hold rich semantics.

Further structured data sources used for concept mapping include commonsense knowledge bases, upper ontologies, and Linked Open Data (LOD) datasets. Very few research have actually been done to standardize the corresponding resources, without which combining low-level image, audio, and video descriptors, and sophisticated high-level descriptors with rule-based video event definitions cannot be efficient. An early implementation in this field was a core audiovisual ontology based on MPEG-7, ProgramGuideML,

and TV Anytime [2]. A more recent research outcome is the core reference ontology VidOnt,<sup>1</sup> which aims to act as a mediator between de facto standard and standard video and video-related ontologies [3].

## II. PROBLEM STATEMENT

Despite the large number of multimedia ontologies mentioned in the literature, there are very few ontologies that can be employed in video scene representation. Most problems and limitations of these ontologies indicate ontology engineering issues, such as lack of formal grounding, failure to determine the scope of the ontology, overgeneralization, and using a basic subset of the mathematical constructors available in the implementation language [4]. Capturing the associated semantics has quite often been exhausted by creating a taxonomical structure for a specific knowledge domain using the Protégé ontology editor,<sup>2</sup> and not only domain and range definitions are not used for properties, but even the property type is often incorrect.

As a result, implementing multimedia ontologies in video scene representation is not straightforward. For this reason, a novel approach has been introduced, which captures the highest possible semantics in video scenes.

## III. TOWARDS A METHODOLOGY FOR COMBINING MULTIMEDIA ONTOLOGIES FOR VIDEO SCENE REPRESENTATION

The representation of video scenes largely depends on the target application, such as content-based video scene retrieval and hypervideo playback. Hence, the different requirements have to be set on a case-by-case basis. Nevertheless, there are common steps for structured video annotation, such as determining the desired balance between expressivity and reasoning complexity, capturing the intended semantics for the knowledge domain featured in the video or required by the application, and standards compliance. The proposed approach guides through the key factors to be con-

<sup>1</sup> <http://vidont.org>

<sup>2</sup> <http://protege.stanford.edu>

sidered in order to achieve the optimal level of semantic enrichment for video scenes.

#### A. *Intended Semantics*

In contrast to image annotation, in which the intended semantics can typically be captured using concepts from domain or upper ontologies, the spatiotemporal annotation of video scenes requires a wide range of highly specialized ontologies.

The numeric representation of audio waveforms, the edges, interest points, regions of interest, ridges, and other visual features of video frames and video clips employ low-level descriptors, usually from an OWL mapping of MPEG-7's XSD vocabulary. They correspond to local and global characteristics of video frames, and audio and video signals, such as intensity, frequency, distribution, pixel groups, and low-level feature aggregates, such as various histograms and moments based on low-level features. Some examples for audio descriptors include the zero crossing rate descriptor, which can be used to determine whether the audio channel contains speech or music, the descriptors of formants parameters, which are suitable for phoneme and vowel identification, and the attack duration descriptor, which is used for sound identification. Two feature aggregates frequently used for video representation are SIFT (Scale-Invariant Feature Transform), which is suitable for object recognition and tracking in videos [5], and HOF (Histogram of Optical Flow) [6], which can be used for, among others, detecting humans in videos. The most common motion descriptors include the camera motion descriptor, which can characterize a video scene in a particular time according to professional video camera movements, the motion activity descriptor, which can be used to indicate the spatial and temporal distribution of activities, and the motion trajectory descriptor, which represents the displacement of objects over time.

The MPEG-7 descriptors can be used for tasks such as generating video summaries [7] and matching video clips [8], however, they do not convey information about the meaning of audiovisual contents, i.e., they cannot provide high-level semantics [9]. Nevertheless, MPEG-7 terms can be used for low-level descriptors. However, using partial mappings of MPEG-7 limits semantic enrichment, because video representation requires a wide range of multimedia descriptors. Therefore, an ontology supporting only the visual descriptors of MPEG-7, such as the Visual Descriptor Ontology (VDO) [10], for example, omits audio descriptors that can be used for describing the audio channel of videos. In fact, even a complete mapping of MPEG-7 does not guarantee semantic enrichment, such as the ones created via a transparent XSD-OWL translation (e.g., Rhizomik),<sup>3</sup> particularly when the mathematical constructors are not exploited to their full potential [11].

Common high-level video concepts can be utilized from Schema.org.<sup>4</sup> For example, generic video metadata can be provided for video objects using `schema:video` and `schema:VideoObject`. Movies, series, seasons, and episodes of series can be described using `schema:Movie`, `schema:MovieSeries`, `schema:CreativeWorkSeason`, and `schema:Episode`. Analogously, video metadata can be described using `schema:duration`, `schema:genre`, `schema:inLanguage`, and similar properties. Rich video semantics can be described using specialized ontologies, such as the STIMONT ontology, which can capture the emotional responses associated with videos [12]. The use of more specific high-level concepts depends on the knowledge domain to represent, and often includes Linked Data [13].

#### Criteria

- A1. The ontology or dataset captures the intended semantics or the semantics closest to the intended semantics in terms of concept and property definitions.
- A2. The terms to be used for annotation are defined in a standardized ontology or dataset. If this is not available, or there are similar or identical definitions available in multiple ontologies or datasets, the choice is determined by the following precedence order: 1) standard, 2) standard-aligned, 3) de facto standard, 4) proprietary.

#### B. *Quality of Conceptualization*

Another important consideration beyond capturing the intended semantics is the quality of conceptualization. For example, the MPEG-7 mappings known for the literature transformed semistructured definitions to structured data, but this did not make them suitable for reasoning over visual contents. Since MPEG-7 provides low-level descriptors, their OWL mapping does not provide real-world semantics, which can be achieved through high-level descriptors only. The MPEG-7 descriptors provide metadata and technical characteristics to be processed by computers, so their structured definition does not contribute to the semantic enrichment of the corresponding multimedia resources. To demonstrate this, take a closer look at a code fragment of the Core Ontology for Multimedia (COMM):<sup>5</sup>

```
<owl:Class rdf:about="#cbac-coefficient-14">
  <rdfs:comment rdf:datatype="xsd:string">
    >Corresponds to the &quot;CbACCoeff14&#8221;
    element of the &quot;ColorLayoutType&quot;
    (part 3, page 45)</rdfs:comment>
  <rdfs:subClassOf>
    <owl:Class rdf:about="#cbac-crac-
    coefficient-14-descriptor-parameter"/>
  </rdfs:subClassOf>
</rdfs:subClassOf>
```

<sup>3</sup> <http://rhizomik.net/ontologies/2017/05/Mpeg7-2001.owl>

<sup>4</sup> <https://schema.org>

<sup>5</sup> <http://multimedia.semanticweb.org/COMM/visual.owl>

```
<owl:Class rdf:about="&pl;unsigned-5-
vector-dim-14"/>
</rdfs:subClassOf>
</owl:Class>
```

This part of the ontology is related to the color layout descriptor (CLD) of MPEG-7, which is used for capturing the spatial distribution of colors in images. To compute the CLD, RGB images are typically converted to the YCbCr color space, partitioned into 8×8 subimages, after which the dominant color of each subimage is calculated. Applying the discrete cosine transform (DCT) of the 8×8 dominant color matrix to the luminance (Y), the blue chrominance (Cb), and the red chrominance (Cr) results in three sets of 64 signal amplitudes, i.e., DCT coefficients DCTY, DCTCb, and DCTCr. The DCT coefficients can be grouped into two categories: those with a waveform mean value of 0 and those that have non-zero frequencies (DC and AC coefficients). Finally, the DCT coefficients are quantized and zig-zag scanned. This means that the `cbac-coefficient-14` listed above is suitable for the representation of blue chrominance AC coefficients, which can be used, among others, to filter video keyframes [14], however, they do not convey high-level semantics about the visual content. The `cbac-coefficient-14` class is defined in COMM as a subclass of `cbac-crac-coefficient-14-descriptor-parameter` and `unsigned-5-vector-dim-14`, neither of which correspond to any real-world object class. Apparently, these coefficients would have been better defined as roles rather than concepts to enable them to hold the corresponding values. In this case, the OWL definitions do not advance the corresponding XSD vocabulary definitions with richer semantics, due to the previous modeling issues and the limited use of mathematical constructors in the implementation language.

Beyond the aforementioned OWL mappings of MPEG-7 that suffer from design issues, there is a more advanced MPEG-7 ontology, which does not inherit conceptual ambiguity issues from the standard and has been implemented in OWL 2.<sup>6</sup> This ontology has been grounded using a description logic formalism, covers the entire range of concepts and properties of MPEG-7 with property domains and ranges, and complex role inclusion axioms. Also, it captures correlations between properties.

#### Criteria

- B1. The ontology to be used correctly conceptualizes the terms related to the scene and has a correct taxonomical structure.
- B2. The ontology is axiomatized in a way that it can be used for reasoning.
- B3. The ontology provides rich semantics for the concepts and/or events.

<sup>6</sup> <http://mpeg7.org>

#### C. Specificity

Video scene representation employs not only domain ontologies, but also upper ontologies, application ontologies, commonsense ontologies, and core reference ontologies. For example, the Large Scale Concept Ontology for Multimedia (LSCOM) collects high-level concepts commonly depicted in videos (based on the comprehensive TRECVID dataset), however, many of the concepts are too general for precise high-level video scene descriptions. Also, video contents are not limited to concepts, and there are no events defined in LSCOM. The Linked Movie Database<sup>7</sup> is too specific, and can be used only for categorizing Hollywood movies, and even for this intended application it is not comprehensive enough.

The four fundamental ontologies that can be employed in video representation, and are imported by several higher-level video ontologies, are the SWRL Temporal Ontology,<sup>8</sup> the Event Ontology,<sup>9</sup> the Timeline Ontology,<sup>10</sup> and the Multitrack Ontology.<sup>11</sup>

There are many common terms that are defined by multiple ontologies (which is discouraged according to Semantic Web best practices [15]), sometimes with a slightly different name. These have to be assessed, and it has to be determined whether the represented concept or role corresponds to the same real-world entity or property. This should not be confused with those terms that are similar, but have been defined for different application scenarios, such as `dc:creator` and `foaf:maker`.<sup>12</sup>

#### Criteria

- C1. The ontology clearly falls into one of the standard ontology categories.
- C2. The ontology terms are not overly generic.
- C3. Specific ontology terms are used from a highly specialized domain ontology or application ontology.
- C4. The ontology terms used for annotation are defined by only one ontology or dataset. If there are similar or identical definitions available in multiple ontologies or datasets, the choice is determined by the following precedence order: 1) standard, 2) standard-aligned, 3) de facto standard, 4) proprietary.

#### D. DL Expressivity

A common issue with multimedia ontologies is the lack of formal grounding, which is crucial not only for capturing the intended semantics, but also to reach high levels of, or maximize, reasoning potential. For example, the Visual De-

<sup>7</sup> <http://www.linkedmdb.org>

<sup>8</sup> <http://swrl.stanford.edu/ontologies/built-ins/3.3/temporal.owl>

<sup>9</sup> <http://purl.org/NET/c4dm/event.owl#>

<sup>10</sup> <http://purl.org/NET/c4dm/timeline.owl#>

<sup>11</sup> <http://purl.org/ontology/studio/multitrack>

<sup>12</sup> For creators described using a string literal, and without domain and range, `dc:creator` should be used, while `foaf:maker` is ideal for those creators who are identified by a URI.

scriptor Ontology (VDO),<sup>13</sup> which was published as an “ontology for multimedia reasoning” [16] has a very low DL expressivity (corresponds to  $\mathcal{AL}$ ). This prevents capturing the correlation of classes and properties. In fact, VDO has fundamental problems with its concept definitions. For example, `colorSpace` is defined as an object property using the class `ColorSpaceDescriptor` as the range:

```
<owl:ObjectProperty
rdf:about="&VDO;colorSpace">
  <a:comment></a:comment>
  <a:range
rdf:resource="&VDO;ColorSpaceDescriptor"/>
  <a:subPropertyOf
rdf:resource="&VDO;DEFAULT_ROOT_RELATION"/>
  <a:domain
rdf:resource="&VDO;DominantColorDescriptor"/>
</owl:ObjectProperty>
```

Depending on the granularity of the ontology, `colorSpace` could be defined as a concept instantiated with individuals, or a datatype property with all the permissible string values enumerated.<sup>14</sup> In VDO, neither of these is the case, and `colorSpace` is an object property, despite that it does not define a relation between classes or individuals. Moreover, there is no formal definition provided in VDO about the color spaces defined in the MPEG-7 standard the ontology is based on. Without rich semantics, no simple statements can be inferred, let alone complex statements, therefore VDO has a very limited potential in multimedia reasoning.

While one might argue that many ontologies have a low expressivity by design (in order to be lightweight and computationally cheap to reason over), in most cases low expressivity is the result of limiting the ontology to a taxonomical structure, which prevents advanced reasoning altogether.

#### Criteria

- D1. The ontology is formally grounded.
- D2. The ontology exploits all the mathematical constructors needed to formally describe constraints, complex roles, and correlations, rather than providing a class hierarchy and roles only.
- D3. The ontology is as lightweight as possible.
- D4. The ontology is underpinned by a decidable formalism.

#### E. Standards Alignment

While international standards should be preferred over proprietary implementations, even ISO-standard-based ontologies are most often exposed through a nonstandard namespace URI, and standards alignment is often partial only.

General video metadata, such as title and language, can be represented using Dublin Core (ISO 15836-2009).<sup>15</sup> Low-level image, audio, and video descriptors can be annotated using the aforementioned MPEG-7 (ISO/IEC 15938).<sup>16</sup>

The most common de facto standards used in structured video annotations are W3C's Ontology for Media Resources,<sup>17</sup> DBpedia,<sup>18</sup> and the aforementioned Schema.org.

#### Criteria

- E1. The ontology defines terms according to the corresponding standard specification and schema, and does not redefine them if an official ontology file is available.
- E2. Standardized terms are used via the standard or, if this is not available, the de facto standard namespace URL.
- E3. The ontology from which standardized terms are used covers the entire vocabulary of the standard with all datatypes and constraints adequately defined.

#### F. Namespace and Documentation Stability

Many of the multimedia ontologies mentioned in the literature do not have a reliable namespace, making video annotations obsolete if the namespace becomes unavailable. A best practice to prevent this is to use a permanent URL, such as PURL,<sup>19</sup> which corresponds to a pointer that can be changed if the ontology file is moved. Another issue regarding ontology namespaces is that many of the namespace URLs are symbolic URLs only.

#### Criteria

- F1. The namespace URL of the ontology to be used is preferably an actual web address (not a symbolic URL) and by using content negotiation, it
  - a. serves the machine-readable ontology file (RDFS or OWL) to semantic agents, and
  - b. serves a human-readable description of the ontology to web browsers (HTML5).
- F2. The ontology namespace URL is a permanent URL.
- F3. The human-readable content behind the URL is a comprehensive and up-to-date documentation of the ontology that reveals the intended implementation for each ontology term.

#### G. Spatiotemporal Annotation Support

Although the mathematical constructors available in OWL 2 are not exploited in most multimedia ontologies, and they can express not only 2D, but also 3D information [17], vid-

<sup>13</sup> <https://github.com/gatemezing/MMOntologies/blob/master/ACEMEDIA/acedia-visual-descriptor-ontology-v09.rdfs.owl>

<sup>14</sup> In MPEG-7, the following color spaces are supported: RGB, YCbCr, HSV, HMMD, and Monochrome. Linear transformation matrix with reference to RGB is also allowed.

<sup>15</sup> <https://www.iso.org/standard/52142.html>

<sup>16</sup> <https://www.iso.org/standard/34230.html>

<sup>17</sup> <https://www.w3.org/TR/mediaont-10/>

<sup>18</sup> <http://wiki.dbpedia.org/>

<sup>19</sup> <https://archive.org/services/purl/>

eo events require an even higher expressivity than what is supported by *SRONTQ*<sup>(2)</sup>, the description logic underpinning OWL 2. Rule-based mechanisms, such as SWRL rules, are proven efficient in expressing video events [18], however, they often break decidability. Another option to push the expressivity boundaries is to employ formal grounding with spatial and temporal description logics, although many of these are not decidable either [19].

Spatial description logics vary greatly in terms of expressivity, and not all support qualitative spatial representations, which can address different aspects of space, including topology, orientation, shape, size, and distance. Some spatial description logics implement a Region Connection Calculus, such as RCC8 (see  $\mathcal{ALC}(\mathcal{D}_{RCC8})$ , for example [20]), while others, such as  $\mathcal{ALC}(\mathcal{CDC})$ , employ the Cardinal Direction Calculus (CDC) [21].

Temporal description logics also vary greatly, because some feature datatypes for time points, others for time intervals or sets of time intervals. Temporal description logics, such as  $\mathcal{TL-F}$  and  $\mathcal{T-ALC}$ , are suitable for the formal representation of video actions and video event recognition via reasoning [22, 23].

#### Criteria

- G1. Spatial annotations employ a formalism that supports qualitative spatial representation and reasoning.
- G2. Temporal annotations use a formalism that allows both point-based and interval-based annotations.
- G3. Spatiotemporal annotations employ a formalism that supports not only still regions, but also moving regions.
- G4. Not only visual, but also audio descriptors are available to support video understanding via information fusion.
- G5. If the description of a video scene requires spatiotemporal annotation, the formalism underlying the implemented ontology or ontologies is decidable, unless this would limit the semantics of the annotation.

#### H. Annotation Support for Uncertainty

Video contents are inherently ambiguous. Fuzzy description logics can be used to express the certainty of the depiction of concepts [24], events, and video scenes [25]. This can be achieved by enabling normalized certainty degree values assigned to objects of fuzzy concepts.

#### Criteria

- H1. The ontology is grounded in a formalism that supports fuzzy concept and fuzzy role axioms, and defines the associated semantics and interpretation.
- H2. The formalism behind the fuzzy ontology is decidable.

- H3. The core TBox axioms that represent background knowledge are formally grounded in a standard description logic.

#### IV. EXPERIMENTAL CASE STUDY

To evaluate the efficiency of the proposed approach, ontologies have been assessed, selected, and implemented for the spatiotemporal annotation of 10 video scenes, one of which is briefly presented here.

The iconic scene of the movie “Life of Pi” has been annotated with the regions of interest depicting Pi Patel and the tiger, Richard Parker (see Fig. 1).

Fig. 1 Regions of interest coordinates and dimensions in a 4K Blu-Ray video scene. Movie scene by 20th Century Fox [26]

How the most suitable vocabularies and ontologies have been selected is demonstrated here via concepts related to this scene. Searching for vocabularies and ontologies that contain the corresponding terms is not adequate, because the ad-hoc selection of vocabularies and ontologies will not give satisfactory results, even if the selection is limited to high-quality structured data resources that have been checked for consistency. The Linked Open Vocabularies (LOV)<sup>20</sup> catalogue is maintained to help determine which vocabularies and ontologies to use for formal descriptions. Even though the list of rigorous criteria to meet before a vocabulary or ontology will be listed on LOV assures design quality [27], it does no guarantee that the best vocabulary will be selected for a particular scenario. For example, when searching for the term “video,” the LOV website suggests OpenGraph in the first, the Library extension of Schema.org in the second, and the NEPOMUK File Ontology in the third place. Among these, OpenGraph supports a URL to a video file without any semantics whatsoever, while the other two ontologies have not even been available at the time of writing (404 Not found).

Therefore, the proposed approach complements automated assessment with human judgment. Table I shows a comparison of three ontologies from the literature for representing the low-level video features of video scenes, namely the aforementioned VDO, COMM, and the only formally grounded MPEG-7 ontology, using the proposed approach, upon which the MPEG-7 Ontology has been selected.

<sup>20</sup> <http://lov.okfn.org/dataset/lov/>

By using the criteria of the proposed approach for other video scene aspects, further ontologies and datasets have been selected for the video scene representation, including DBpedia, Schema.org, VidOnt, and the SWRL Temporal Ontology. For datatype definitions, the XML Schema vocabulary has been used to maximize interoperability. By declaring the corresponding namespaces, the background knowledge has been formalized as follows:

```
@prefix dbpedia:
<http://dbpedia.org/resource/> .
@prefix mpeg-7: <http://mpeg7.org/> .
@prefix rdf: <http://www.w3.org/1999/02/22-
rdf-syntax-ns#> .
@prefix schema: <http://schema.org/> .
@prefix vidont: <http://vidont.org/> .

dbpedia:Life_of_Pi_(film) a schema:Movie ;
vidont:filmAdaptationOf dbpedia:Life_of_Pi ;
mpeg-7:Video .
dbpedia:Suraj_Sharma a schema:Actor .
vidont:PiPatel a vidont:MovieCharacter ;
vidont:portrayedBy dbpedia:Suraj_Sharma ;
vidont:characterFrom
dbpedia:Life_of_Pi_(film) .
```

```
vidont:RichardParker a vidont:MovieCharacter
; vidont:portrayedBy dbpedia:Bengal_tiger ;
vidont:characterFrom
dbpedia:Life_of_Pi_(film) .
```

In this case study, the scene description utilized the previous individuals and highly specific concepts via spatiotemporal annotation and moving regions as follows:

```
@prefix mpeg-7: <http://mpeg7.org/> .
@prefix rdf: <http://www.w3.org/1999/02/22-
rdf-syntax-ns#> .
@prefix temporal:
<http://swrl.stanford.edu/ontologies/built-
ins/3.3/temporal.owl> .
@prefix vidont: <http://vidont.org/> .
@prefix xsd:
<http://www.w3.org/2001/XMLSchema#> .

<http://example.com/lifeofpi.mp4#t=1:14:38,1:
14:41> a vidont:Scene ;
vidont:sceneFrom dbpedia:Life_of_Pi_(film) ;
temporal:hasStartTime "01:14:38"^^xsd:time ;
temporal:duration "PT00M03S"^^xsd:duration ;
temporal:hasFinishTime "01:14:41"^^xsd:time ;
vidont:depicts vidont:PiPatel ,
vidont:RichardParker .
<http://example.com/lifeofpi.mp4#t=1:14:40&xy
wh=690,372,1232,1154> a mpeg-7:MovingRegion ;
vidont:depicts vidont:RichardParker ;
vidont:inFrontOf vidont:PiPatel ; vidont:isIn
dbpedia:Lifeboat_(shipboard) .
<http://example.com/lifeofpi.mp4#t=smpete:01:
14:40:03> mpeg-7:width
"3840"^^xsd:positiveInteger ;
mpeg-7:height "1620"^^xsd:positiveInteger .
<http://example.com/lifeofpi.mp4#t=1:14:40&xy
wh=2080,138,1036,388> a mpeg-7:MovingRegion ;
vidont:depicts dbpedia:PiPatel ; vidont:isIn
dbpedia:Lifeboat_(shipboard) .
```

Note that the spatiotemporal segmentation employs not only the SWRL Temporal Ontology, but also Media Fragment URI 1.0 identifiers,<sup>21</sup> where the URL identifies the minimum bounding boxes of the regions of interests using the top left corner coordinates and the dimensions, so that the media segments are globally unique and dereferencable.

Based on the previous video scene description, reasoners can infer new, useful information by utilizing axioms of the vocabularies and ontologies selected using the proposed approach. For example, based on the statement that `<http://example.com/lifeofpi.mp4#t=1:14:40&xywh=690,372,1232,1154>` is a moving region, and the axiom of the MPEG-7 Ontology that defines moving regions as subclasses of spatiotemporal video segments, it can be inferred using concept subsumption reasoning, according to which concept *D* subsumes concept *C* with reference to knowledge base *K* if and only if  $C^{\mathcal{I}} \subseteq D^{\mathcal{I}}$  for all interpretations *I* (that are models of knowledge base *K*), that `<http://example.com/lifeofpi.mp4#t=1:14:40&xy`

<sup>21</sup> <https://www.w3.org/TR/media-frags/>

wh=690,372,1232,1154> is a spatiotemporal decomposition, which was not explicitly stated. This could not have been deducted using terms from VDO or COMM, because they do not define moving regions at all, let alone doing so in a taxonomical structure.

More complex information can be automatically inferred using the RDFS entailment rules,<sup>22</sup> the Ter Horst reasoning rules [28], and the OWL reasoning rules.<sup>23</sup> For example, based on the axiom of the MPEG-7 Ontology that defines Frame as the domain of the height property and the height declaration for the screenshot of the Life of Pi video file, i.e.,

```
mpeg-7:height rdfs:domain mpeg-7:Frame .
<http://example.com/lifeofpi.mp4#t=
smpte:01:14:40:03> mpeg-7:height
"1620"^^xsd:positiveInteger .
```

and using the OWL 2 reasoning rules for axioms about properties, it can be automatically inferred that this temporal video segment corresponds to a video frame, formally,

```
<http://example.com/lifeofpi.mp4#t=smpte:01:
14:40:03> a mpeg-7:Frame .
```

which was not explicitly stated. Considering that these concepts and roles are not defined in the other MPEG-7-aligned ontologies, and therefore their reasoning potential would be inadequate for this scenario, it can be confirmed that the MPEG-7 Ontology suggested by the presented approach is the best choice.

## V. CONCLUSION

Based on the comprehensive review of the state of the art, an approach has been proposed to determine the list of DL-based multimedia ontologies to be used for the annotation of video scenes while taking into account all major aspects of ontology implementation. Some of these correspond to core requirements all selected ontologies have to meet, such as high-quality conceptualization and having a stable namespace. For others, such as spatiotemporal annotation support, it may be adequate if at least one of the ontologies qualifies. Some video scenes do not require fuzzy concepts. The integration of multimedia ontologies using the proposed approach can not only guide through selecting the most appropriate ontologies to obtain the formalism needed to describe a particular video scene, but also ensures standards alignment, avoids overgeneralization, eliminates overlapping definitions, and optimizes reasoning complexity.

**Abstract**—The paper uses machine learning methods to deal with the problem of reducing the cost of applying mutation testing. A method of classifying mutants of a program using structural similarity is proposed. To calculate such a similarity each mutant is firstly converted into a hierarchical graph, which represents the mutant's control flow, variables and conditions. Then using such a graph form graph kernels are introduced to calculate similarity among mutants. The classification algorithm is then applied for prediction. This approach helps to lower the number of mutants which have to be executed. An experimental validation of this approach is also presented.

## I. INTRODUCTION

ARTIFICIAL intelligence has a long history and has been successfully applied in different domains. While the use of artificial intelligence methods in medical applications, image processing or even art has been widely accepted, the domain of software engineering has taken longer to start using such methods. As they are faced with a complex task of designing, building and testing systems at large scales, software engineers have started to adopt and use many of the practical algorithms and techniques that have been proposed by the AI community. AI algorithms are well suited to such complex software engineering problems, as they are designed to deal with one of the most demanding challenges of all; the replication of intelligent behavior. In particular in software engineering community three areas of AI are mostly used. The first one can be described as based on computational search and optimization techniques (the field known as Search Based Software Engineering (SBSE)). In SBSE based approach, the aim is to re-formulate software engineering problems as optimization problems that can then be dealt with by using search algorithms. This approach has been widely used with applications from requirements and design to maintenance and testing [1], [2].

The other two are related to fuzzy and probabilistic methods for reasoning in the presence of uncertainty and methods using classification, learning and prediction algorithms. In classification and prediction research there has been great interest in modeling and predicting software production costs as part of project planning. A wide variety of traditional machine learning techniques such as artificial neural networks, case based reasoning and rule induction have been used for

example in software project prediction, and defect prediction [3].

The paper presents a continuation of an ongoing research on using methods of machine learning to reduce the costs of applying mutation testing [4], [5]. Mutation testing [6] is a recognized software testing technique used to support selection of tests [7], [8]. It provides means and an adequacy measure to assess the quality of the tests and thus it helps to obtain a suite of tests being adequate to provide dependable testing results. Testing results are one of the main sources of information used to establish the degree to which a developed system meets certain requirements and to decide whether the system is ready to be deployed or should undergo further improvements.

The concept behind mutation testing is fairly simple, yet it yields useful results. The assessment of the tests quality is carried out by checking their ability to detect faulty versions of a tested system [6]. The faulty versions (called mutants) are generated from the original version of the system (usually its source code or model) by inserting into a copy of the original system small syntactic changes, one per mutant, and then executed with the tests under assessment. When results of executing a mutant differs from results of executing the original system for at least one test from the assessed suite the mutant is considered to be killed by the test otherwise it stays alive. The ratio of mutants detected (killed) by the tests to the total number of the generated mutants (called a mutation score) is considered to be the most reliable measurement of the tests adequacy [6]. Presence of alive mutants, if they are not equivalent mutants [8], indicate inadequacy of the assessed suite that should be dealt with to increase its quality.

Mutation testing is the most reliable test assessment technique [7], but unfortunately its application can be very time consuming [8]. The main reason of the problem is a large number of mutants that are typically generated and executed. The approaches presented in [5] and in this paper focus on providing some solution to the problem.

In this paper a classification based approach is proposed as a tool to lower the cost of software testing with the use of mutation testing by limiting the number of times a test suite has to be executed. The approach proposed is based on the structural similarity of mutants. To calculate such a

similarity each mutant is firstly converted into a hierarchical graph, which represents the mutant's control flow, variables and conditions. Then using such a graph form graph kernels are introduced to calculate similarity among mutants. The kernels are then used in predicting whether test suite, provided for the program, would detect (kill) a given mutant or not. The classification algorithm is then applied for prediction. This approach helps to lower the number of mutants which have to be executed. Moreover, as the similarity calculations have to be done only once for a given set of mutants, they can be used for any new test suite developed for the same system. An experimental validation of this approach is also presented in this paper. An example of a program used in experiments is described and the results obtained, especially classification errors, are presented.

## II. RELATED WORK

Mutation testing was originally introduced to assess tests ability to detect faults in programs [6], but with the time its application area has expanded. It is currently used at both, implementation and model level, to assess the quality of existing test suites, to improve such suites or to generate new ones [9], [10], [11], [12], [14], [15], [16]. Mutation testing provides a very reliable measurement of a test quality [7]. The effectiveness of the technique can be partially attributed to the systematic and unbiased way of generating the mutants by applying so called mutation operators [6]. The mutation operators controlling the mutants generation process are rules that specify syntactic changes that can be introduced into the mutated artifact and the elements that can be changed, so that the mutants are executable. However, the number of mutants generated by applying such mutation operators can be very large and thus their generation and execution can take a huge amount of time. Several costs reductions techniques have been proposed so far. They can be roughly divided into two groups: approaches targeting the mutants generation phase (selective mutations [17]) and approaches targeting the mutants execution phase (e.g. mutant sampling [21], mutant clustering [20], [19] or parallel processing [18]). A short surveys of costs reduction approaches can be found in [8].

The approach presented in this paper belong to the second group and shares some similarities with mutant sampling and mutant clustering. The mutant sampling, as proposed by Acree [21] and Budd [22], consists in generating all mutants and executing only their randomly selected subset. However, random selection may decrease the reliability of test assessment results. More sophisticated approaches using clustering algorithms were proposed by Hussain [19] and Ji et al. [20]. Ji et al. [20] proposed to weight mutants using a domain specific analysis, divide them into groups basing on the weighting results and then execute only some mutants being representative for the groups. Hussain [19] applied clustering algorithms to group mutants accordingly to their detectability and used the results to minimize a suite of tests.

In our approach the mutants are also first generated, and then their fraction is selected to be a training group. Only

mutants belonging to the training group are executed. The detectability of the remaining mutants is predicted basing on their similarity to mutants from a training group.

As in our approach the mutants are represented by graphs to calculate the similarity among them some form of graph based measure must be used. The problem of graph similarity has already been the subject of research in various contexts. In the current literature three major approaches can be observed.

One of the approaches uses mainly standard graph algorithms, like finding a maximal subgraph or, in more recent years, mining for frequently occurring subgraphs. The approach based on frequent pattern mining in graph analysis has been researched mainly within the context of bioinformatics and chemistry [25], [26], [27], [28]. The main problem with this approach results from a huge number of frequent substructures often found what leads to high computational costs.

Other approach is based on transforming graphs into vectors. This is done by finding some descriptive features in graphs and enumerating them. A lot of research using this method, called vector space embedding of graphs, have been done by Bunke and Riesen [29], [30]. The main benefit of such transformation of a graph into a vector is the possibility to use standard statistical learning algorithms. This approach suffers from the difficulty in finding appropriate features in graphs and then in enumerating them. It often causes problems similar to those in frequent pattern mining. Nevertheless, this approach has successfully been applied in many domain [29].

Finally the use of the theory of positive defined kernels and kernel methods [29] was proposed, among others, by Kashima and Gartner [32], [33]. A lot of research is available on the defining and use of kernels for structured data, including tree and graph kernels [32], [33], [34], [35], for example the tree kernels proposed by Collins and Duffy [34] that were applied in natural language processing.

Considering graphs we have several choices of different kernels proposed so far. One of them is the so called all subgraph kernel which requires enumerating all subgraphs of given graphs and the calculating the number of isomorphic ones. This kernel is known to be NP-hard [32]. An interesting group of graph kernels consists of different variants of kernels based on computing random walks on compared graphs. This group includes the product graph kernel [30] and the marginalized kernels [33]. These kernels are computable in polynomial time ( $O(n^6)$  [30]).

Many of the graphs kernels are based on the so called convolution kernels proposed by Haussler [37]. The main idea of these kernels is to use the number of substructures of any structured object. This approach was extended by Shin et al [38], who proposed a mapping kernel for tree data.

Currently the main research focus in kernels is on improving the performance of the kernel algorithms for simple graphs, mainly in bioinformatics. This paper on the other hand is focused on the application of kernel methods in software testing domain.

### III. KERNEL METHODS FOR STRUCTURED DATA

Many of machine learning algorithms require the input data to be in a vector or matrix format. It is usually assumed that there is a number of features that can describe a given problem. In case of classification problems the data would contain vectors of values for all the features and a correct output value. The input can then be divided into training and test sets used to find the model describing the problem. Unfortunately it is not always easy to represent a given problem in vector format without losing some internal relationships within the data. There are situations when some form of structured representation fits better than a numerical, vector based data, yet we still would like to use machine learning algorithms for this problems.

One of the structure that is becoming more and more important is a graph. There is a wide acceptance of the fact that it is important to represent some internal relationships in data in a form of graphs, yet using machine learning approach in problems where data has a graph representation is rather limited.

There has been research on transforming graphs into vectors by finding some descriptive features in graphs and enumerating them. This approach has been carried out for example by Bunke and Riesen [29], [30]. The obvious benefit of transforming a graph into a vector is the possibility to use standard statistical learning algorithms.

Another approach, which allows for the direct use of structured data is based on the application of kernel methods. In order to apply kernel methods to structured data objects, firstly a kernel function between two structured objects must be defined. However, defining a kernel function is not an easy task, because it must be designed to be positive semi-definite, and some ad hoc similarity functions are not always positive semi-definite.

#### A. Kernel methods for graph data

In order to use kernel methods for non-vector data a so called kernel trick is often used. It consists in mapping elements from a set  $A$  into an inner product space  $S$  (with a natural norm), without having to compute the mapping, i.e. in case of graphs they do not have to be mapped into some objects in target space  $S$ , but only the way of calculating the inner product in that space is needed. The results of the linear classification algorithm in target space are then equivalent with classifications in source space  $A$ . To be able to use this approach and avoid actual mapping the learning algorithms which need only inner products between the elements (vectors) in target space are used. Moreover, the mapping has to be defined in such a way that these inner products can be computed on the objects in the source space by means of a kernel function. To use classification algorithms a kernel matrix  $K$  must be positive semi-definite (PSD) [32], although there are empirical results showing that some non PSD kernels may still do reasonably well, if only they well approximate the intuitive perception of similarity among given objects.

In case of graph data the first kernel was based on comparing all subgraphs of two graphs and then the value of such a kernel was calculated as the number of identical subgraphs. This is a very good similarity measure but enumerating all subgraphs has a high cost. Another approach proposed by Kashima et al. [33] uses kernel on sequences of labels of nodes and edges along each path. It is defined as a product of subsequent edge and node kernels. Computing this kernel requires summing over an infinite number of paths but it can be done efficiently by using the product graph and matrix inversion [32].

A more general approach was proposed by Haussler in the form of convolution kernels [37], which are a generic method for different types of structured data, not specific to graph data. This approach is based on the fact that any structured object can be decomposed into components, then kernels can be defined for those components and the final kernel is calculated over all possible decompositions.

Let  $X$  be the space of all possible structures in a given problem. Formally, for any two points  $x, y$ , from the space  $X$ , a convolution kernel is defined by equation 1 :

$$K(x, y) = \sum_{(x', x) \in R} \sum_{(y', y) \in R} k(x', y'), \quad (1)$$

where  $R \subseteq X' \times X$  is a decomposition relation and  $k$  is a base kernel. Haussler [37] proved that if  $k$  is positive semi-definite then also  $K$  is positive semi-definite.

By defining  $X'_x$  as a set  $\{x' \in X' | (x', x) \in R\}$  the equation 1 can be reformulated into equation 2 :

$$K(x, y) = \sum_{(x', y') \in X'_x \times Y'_y} k(x', y'). \quad (2)$$

#### B. Mapping kernels

Looking at the equation above it can be observed that the main problem with this approach is that the kernel has to be computed over the whole cross product of  $X'_x \times Y'_y$ . To deal with this problem a so called mapping kernel was introduced by Shin et al. [38]. It has been successfully used for trees and it allows to limit the calculations to the subset of the cross product. This subset is defined as  $M_{x,y} \subset X'_x \times Y'_y$ . Then, the mapping kernel is defined by equation 3:

$$K(x, y) = \sum_{(x', y') \in M_{x,y}} k(x', y'). \quad (3)$$

It has to be noticed, however, that while for the convolution kernel if  $k$  is PSD then  $K$  is always PSD, in case of the mapping kernel for  $K$  to be PSD  $k$  has to be PSD and  $M$  has to be transitive [36]. Thus the deciding factor here is the choice of the mapping system  $M$ .

### IV. STRUCTURAL REPRESENTATION OF PROGRAMS

Programs are usually graphically represented in a form of a so called control flow diagram (CFD). An example of a CFD is depicted in Fig. 1 (It was obtained from a Java source

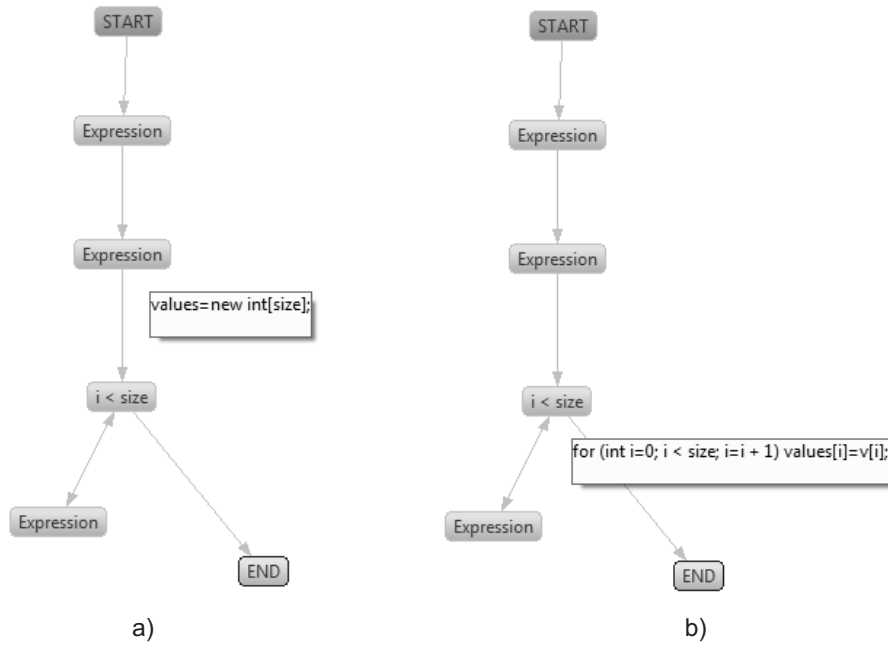

Fig. 1. Examples of control flow diagrams for program from Fig. 2a showing a) internal elements of an expression and b) of a condition

code by an Eclipse plug-in). In the figure it can be observed that it labels the nodes representing expressions with the term "expression" and the actual expression is only available as an attribute (Fig. 1a). Also loops are labelled only by conditions without information on the loop type; this data is also only available as attributes (Fig. 1b). Moreover this attribute contains the whole expressions, and thus it cannot be directly used to compare programs, as for that reason we need to compare each element of any expression or condition separately. However, this information can be parsed to obtain a structural representation better suited for comparing programs.

#### A. Hierarchical graphs

In this paper we propose to use a so called hierarchical control flow graph (HCFG), which is a combination of CFD and hierarchical graphs [40], [4]. Such a graph adds a level of hierarchy to the traditional control flow diagram. As a result it facilitates the representation of each element of a method in a single node. Such a structural representation is much more adequate for comparing.

In Fig. 2b an example of such a hierarchical control flow graph (HCFG) is depicted. This graph represents a method *search(...)* presented in Fig. 2a. It can be noticed that each non-hierarchical node (i.e. a node that does not contain child nodes) represents the most basic elements of a program, such as variables, constants, operators. Hierarchical nodes, on the other hand, represent expressions or composed statements such as conditions or loops. The hierarchical nodes not only simplify the representation but also reflect the context in which the basic elements are placed within the program. Edges of the graph represent flow of control between nodes, both hierarchical and non-hierarchical as well as internal structure

of expressions.

A hierarchical graph consists of nodes and edges, that can be labeled and attributed. As opposed to simple graphs, nodes in hierarchical graph can contain other nodes. More formally, let  $R_V$  and  $R_E$  denote the sets of node and edge labels, respectively and  $\epsilon$  be a special symbol used for unlabelled edges. The set  $R_V$  consists of the set of all possible keywords, names of variables, operators, numbers and some additional grouping labels (like for example *declare* or *array* shown in Fig. 2b). The set of edge labels  $R_E$  contains  $Y$  and  $N$ . Then a hierarchical control flow graph is defined formally in the following way:

**Definition 1:** A labelled hierarchical control flow graph  $HCFG$  is a 5-tuple  $(V, E, \xi_V, \xi_E, ch)$  where:

- 1)  $V$  is a set of nodes,
- 2)  $E$  is a set of edges,  $E \subset V \times V$ ,
- 3)  $\xi_V : V \rightarrow R_V$  is a function assigning labels to nodes,
- 4)  $\xi_E : E \rightarrow R_E \cup \{\epsilon\}$  is a function assigning labels to edges,
- 5)  $ch : V \rightarrow P(V)$  is a function, which assigns to each node a set of its children, i.e. nodes directly nested in  $v$ .

As in further consideration an access to a node of which a given node is a child may be needed we have to formally define such a node- called a parent. Let  $ch(v)$  denotes the set of children of  $v$ , and  $|ch(v)|$  the size of this set. Let  $par$  be a function assigning to each node its parent (i.e. a direct ancestor) and let  $\lambda$  be a special empty symbol (different from  $\epsilon$ ),  $par : V \rightarrow V \cup \{\lambda\}$ , such that  $par(v) = w$  if  $v \in ch(w)$  and  $\lambda$  otherwise.

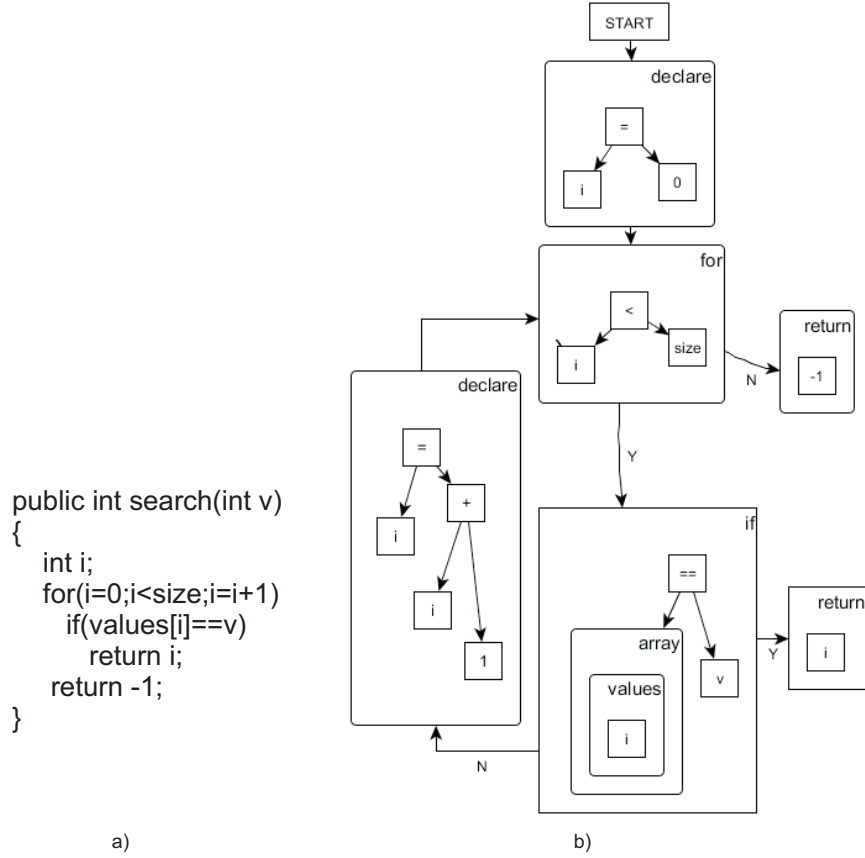

Fig. 2. a) Source code of a part of the example program b) a hierarchical flow graph for this source code

### B. Kernel methods for programs

In this paper new kernel functions, based on the convolution kernel [37] and on mapping kernel template proposed by Shin et al ([38]) are introduced for hierarchical control flow graphs.

These kernels are based on the decomposition of a HCFCG into substructure composed of a node, its parent, the set of its children and all its first level neighbors. For the kernel calculations the label of a given node, number and labels of its children (and thus its internal complexity), the label of its parent (and thus its position within the structure of the program), the number and labels of edges connecting this node with its neighborhood nodes (both incoming and outgoing edges are taken into account) and the labels of the neighboring nodes are taken into account. This kernel uses two node kernels, an edge kernel and a tree kernel as base kernels. The way the node and edge kernels are defined is presented below. The tree kernel, used within the node kernel to compare expression trees, is a standard one [36].

The first node kernel is a binary kernel and is used for a simple comparison of two nodes on the basis of the identity of their labels.

**Definition 2:** A binary node kernel, denoted  $k_{node}(v_i, v_j)$ , where  $v_i$ , and  $v_j$  are nodes of a hierarchical control flow graph, is defined in the following way:

$$k_{node}(v_i, v_j) = \begin{cases} 1 & : \xi_V(v_i) = \xi_V(v_j) \\ 0 & : \xi_V(v_i) \neq \xi_V(v_j) \end{cases}$$

The second node kernel uses the hierarchical structure of some nodes and is denoted  $k_V(v, w)$ , where  $v$ , and  $w$  are nodes of a hierarchical control flow graph.

**Definition 3:** A node kernel, denoted  $k_V(v, w)$ , where  $v$ , and  $w$  are nodes of a hierarchical control flow graph, is defined in the following way:

$$k_V(v, w) = \begin{cases} K_T(ch(v), ch(w)) & : \xi_V(v) = \xi_V(w) \\ 0 & : \xi_V(v) \neq \xi_V(w) \end{cases}$$

It can be observed that if the nodes have children, thus containing an expression trees, a tree kernel  $K_T$  is used to compute the actual similarity. For nodes having different labels the kernel returns 0.

**Definition 4:** An edge kernel, denoted  $k_E(e_i, e_j)$ , where  $e_i$ , and  $e_j$  are edges of a hierarchical flow graph, is defined in the following way:

$$k_E(e_i, e_j) = \begin{cases} 1 & : \xi_E(e_i) = \xi_E(e_j) \\ 0 & : \xi_E(e_i) \neq \xi_E(e_j) \end{cases}$$

### C. Decomposition kernel for HCFCGs

On the basis of the above kernels a similarity for HCFCG is computed by a decomposition kernel denoted  $K_{Ker2HCFCG}$ .

**Definition 5:**

$$K_{Ker2HCFCG}(G_i, G_j) = \sum_{i=1}^m \sum_{j=1}^n K_S(S_i, S_j), \quad (4)$$

where  $m$  and  $n$  are the numbers of nodes in each graph and

$$K_S(S_i, S_j) = k_V(v_i, v_j) + k_{node}(par(v_i), par(v_j)) + \sum_{w_i \in Nb(v_i)} \sum_{w_j \in Nb(v_j)} k_{edge}((v_i, w_i), (v_j, w_j)) k_{node}(w_i, w_j), \quad (5)$$

where each  $S_i$  is a substructure of  $G_i$  centered around node  $v_i$  and consisting of this node, its parent  $par(v_i)$ , and its neighbourhood  $Nb(v_i)$  (containing nodes and edges linking them with  $v_i$ ).

The kernel defined by equation (4) is a modification of the one proposed in [4], [41], as it uses a binary node kernel given by definition 2 to compare the neighbouring nodes rather than the more complex  $k_V$  kernel which was previously used. It lowers the number of times a tree kernel is computed and does not affect the accuracy of the classification.

#### D. Mapping kernels for HCFGs

The above kernel has to compute the substructure kernel over all possible combinations of substructures but a mapping kernel can limit the number of this calculation by taking into account only those pairs of substructures which belong to the mapping  $M$ . In this paper two mappings are proposed.

The first one is relatively straightforward; two substructures  $S_i$  of  $G_1$  and  $S_j$  of  $G_2$  belong to mapping only if the labels of the nodes around which they are centered (i.e.  $v_i \in V_{G_1}$  and  $v_j \in V_{G_2}$ , respectively), have identical labels. Thus  $M_1 = \{(S_i, S_j) | \xi_V(v_i) = \xi_V(v_j)\}$ . Such a mapping is transitive, as it is based on the equality of labels.

*Definition 6:*

$$K_{Map1HCFG}(G_i, G_j) = \sum_{(S_i, S_j) \in M} K_S(S_i, S_j), \quad (6)$$

where  $K_S(S_i, S_j)$  is defined as above.

For the second mapping we take into account the position of a given node within the structure of the hierarchical control flow graph. This can be done by taking into account the label of a given node and the label of its parent. Then the mapping  $M_2 = \{(S_i, S_j) | \xi_V(v_i) = \xi_V(v_j) \wedge \xi_V(par(v_i)) = \xi_V(par(v_j))\}$ . As this mapping is also defined on the basis of the equality relation it is also transitive. The second mapping kernel is defined in the following way:

*Definition 7:*

$$K_{Map2HCFG}(G_i, G_j) = \sum_{(S_i, S_j) \in M_2} K_S(S_i, S_j), \quad (7)$$

where  $K_S(S_i, S_j)$  is defined as above.

## V. EXPERIMENTS AND RESULTS

### A. Data Preparation

The experiment was carried out on two simple, but representative example programs. Both examples are modified versions of benchmarks commonly used in mutation testing related research [23], [24], [42], [43]. A part of one of the

example programs is shown in Fig. 2a. The following two steps were performed for each example:

- generation of mutants
- generation of hierarchical control flow graphs for the mutants

All mutants were generated by muJava tool [39]. For the first example the tool generated 38 mutants, and for the second one - 67 mutants. The tool uses a set of traditional and object-oriented mutation operators [39], [44]. The traditional mutation operators usually modify expressions by replacing, inserting or deleting arithmetical, logical or relational operators or some parts of expressions. Mutation operators related to object-oriented features of Java implemented into the tool refer to the object-oriented features such as encapsulation, inheritance, polymorphism and overloading.

Examples of mutants generated for the method *search(...)*, depicted in 2a are shown in Figs. 3a and b. The one depicted in Fig. 3a is an example of applying a Relational Operator Replacement (ROR), that in this case replaced the condition *values[i] == v* within the *if* instruction by *false*. The mutant in Fig. 3b is an example of using an Arithmetic Operator Insertion (AOI). Here the short-cut operator *--* was inserted into variable *i* in a *return* statement. In Figs. 4a and b the hierarchical control flow graphs for the above mutants are depicted. It can be observed in Fig. 4a that the subtree representing the condition within the *if* instruction was replaced by a single node labeled with value *false*. The HCFG representation of the second mutant (in Fig. 4b) differs from the graph representation of the original by the replacement of a single node labelled *i*, inside the node representing one of the *return* statements, by the subtree representing the expression *--i*.

The experimental data includes also test suites. For the first example three test suites were provided and for the second example (more complex one) - five test suites were used.

### B. Classification results

The  $k$ -NN classification algorithm was used on mutants generated for the two examples. Previously graph edit distance and a distance computed from simple HCFG kernel were used in this algorithm [4]. In this paper distances are computed from the three new kernels described in sections IV-C and IV-D. (Denoted as Ker2HCFG - defined by equation 4 and Map1HCFG and Map2HCFG - by equations 6 and 7, respectively).

In the experiments for the first example all three test suites provided were used. The set of mutants was divided into three parts of similar size, the first was used as a training set and the remaining two as instances to classify. The division of mutants was guided by the type of mutation operators used to obtain particular mutants. That is each set was generated in such a way that it consisted of mutants generated by all operators. Moreover the proportion of mutants generated by a given operator in each set was related to the proportion of such mutants in the full set. The process of dividing the set of mutants was repeated five times resulting in obtaining different

```

public int search(int v)
{
    int i;
    for(i=0;i<size;i=i+1)
        if(false)
            return i;
    return -1;
}
a)

```

```

public int search(int v)
{
    int i;
    for(i=0;i<size;i=i+1)
        if(values[i]==v)
            return --i;
    return -1;
}
b)

```

Fig. 3. An example of a) the ROR mutant and b) one of the AOI mutants of the method from Fig. 2a

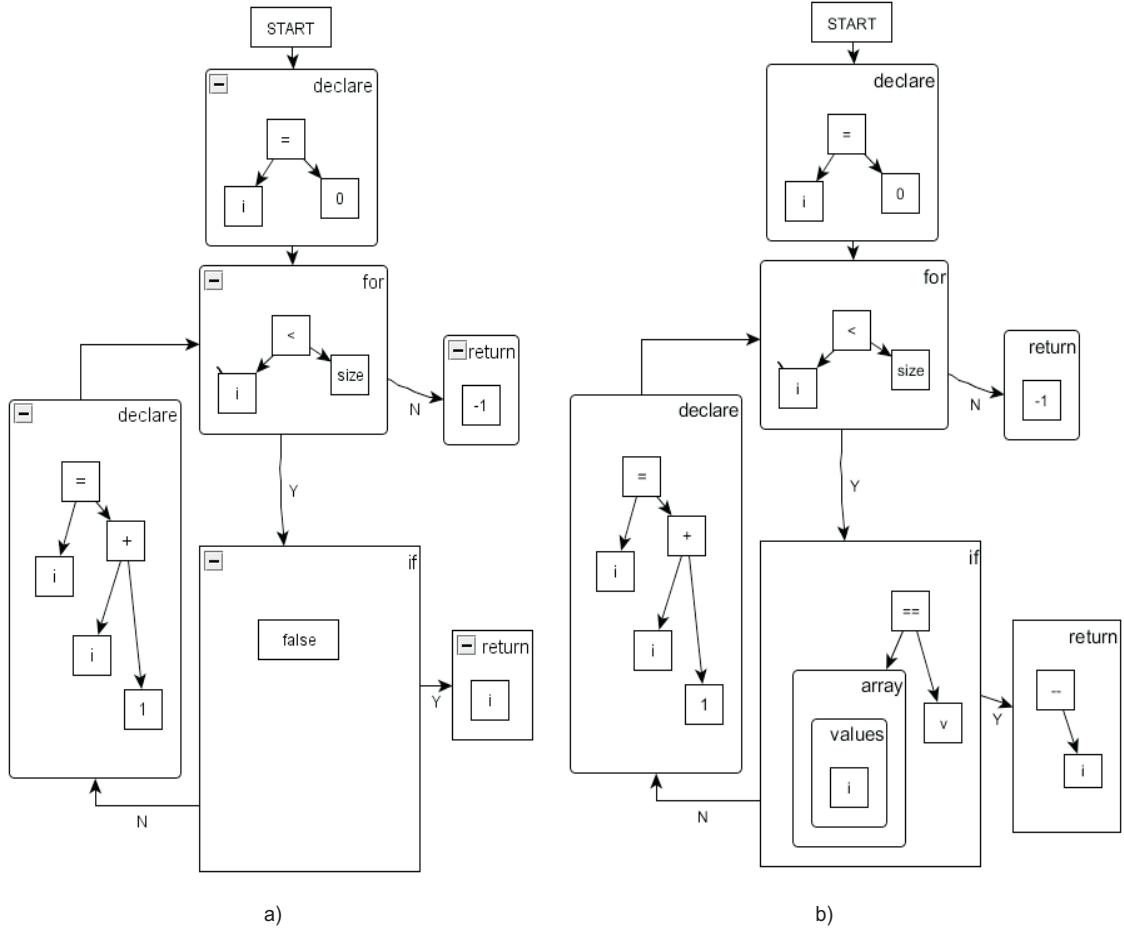

Fig. 4. Examples of flow graphs a) a graph for ROR mutant from Fig. 3a, b) a flow graph for AOI mutant from Fig. 3b

partitions of this set and the classification results obtained were averaged.

Table I presents the results obtained for this example using all three kernels introduced in this paper, and compares them to results obtained with edit distance (from [4], [41]). Parameter  $k$  for  $k - NN$  was, after some experimental tuning, set to 5 for all experiments. In the first column of the table the percentage of instances classified correctly, i.e. classification accuracy, is shown. The percentage of mutants classified incorrectly is given separately for those classified as detectable, while actually they are not (column labelled incorrect killed) and for those classified as not detected, while they actually are

detected by a given test suite (column labelled incorrect not killed). Separating these two values was done because of the meaning of these misclassifications. Misclassifying a mutant not to be detected may lead to overtesting, while the misclassification of the second type is potentially more dangerous as it can result in missing some faulty code. Especially, taking into account that the results are to be used to evaluate the quality of test suites provided for the application. Thus incorrectly classifying a mutant as not detected leads to giving a test suite lower score than actual one, why the second misclassification leads to overvaluation of a given test suite.

As it can be observed in table I the classification performed

TABLE I  
THE CLASSIFICATION OF MUTANTS OF EXAMPLE 1

	method	correct	incorrect killed	incorrect not killed
TS 1	GED	65.2%	13.06%	21.74%
	Ker2HCFG	76.1%	5.3%	18.6%
	Map1HCFG	79.2%	4.2%	16.6%
	Map2HCFG	84.5%	3.1%	12.4%
TS 2	GED	78.25%	8.5%	13.25%
	Ker2HCFG	84.9%	5.8%	9.3%
	Map1HCFG	87.6%	5.1%	7.3%
	Map2HCFG	91.3%	5.2%	3.5%
TS 3	GED	82.6%	8.7%	8.7%
	Ker2HCFG	83.1%	4.5%	12.4%
	Map1HCFG	86.4%	4.1%	9.5%
	Map2HCFG	89.8%	3.8%	6.4%

TABLE II  
THE CLASSIFICATION OF MUTANTS OF EXAMPLE 2

	method	correct	incorrect killed	incorrect not killed
TS 1	GED	75.7%	12.1%	12.2%
	Ker2HCFG	79.3%	7.1%	13.6%
	Map1HCFG	82.4%	5.5%	12.1%
	Map2HCFG	86.1%	4.5%	9.4%
TS 2	GED	73.4%	6.5%	20.1%
	Ker2HCFG	79.1%	5.3%	15.6%
	Map1HCFG	79.2%	4.8%	16.0%
	Map2HCFG	82.5%	4.5%	13.0%
TS 3	GED	60.5%	26.2%	16.3%
	Ker2HCFG	61.2%	23.7%	15.1%
	Map1HCFG	70.2%	18.4%	11.4%
	Map2HCFG	73.8%	16.1%	10.1%
TS 4	GED	78.2%	10.3%	11.5%
	Ker2HCFG	84.5%	4.25%	11.25%
	Map1HCFG	88.6%	3.5%	7.9%
	Map2HCFG	92.1%	3.1%	4.8%
TS 5	GED	76.4%	11.3%	12.3%
	Ker2HCFG	79.6%	8.2%	12.2%
	Map1HCFG	83.3%	7.6%	9.1%
	Map2HCFG	88.2%	5.0%	6.8%

reasonably well for all test suites. All three new kernels proposed in this paper gave better classification results than results obtained by using graph edit distance. It can be explained by the fact that graph edit distance captures only the structural difference in a graph i.e. it takes into account only a change but not the location of this change. For example the mutant shown in Fig. 4b, where variable  $i$  was replaced by  $--i$ , what resulted in replacing a node by a subtree, and another one, in which variable  $i$  in different location undergone the same change would result in identical graph edit distance from other mutants. In the domain of mutation testing the location of the change is as important as the kind of change itself.

The results obtained by the use of the decomposition kernel (*Ker2HCFG*) and the first mapping kernel (*Map1HCFG*) are similar in case of classification accuracy, but the mapping kernel results in a bit smaller number of mutants incorrectly predicted to be detected. But the most important difference between these two kernels is related to the number of kernel calculations which have to be performed. In case of the decomposition kernel it is calculated for each node of each control flow graph, while in case of mapping kernel it is limited to a small subset of the nodes. While the actual number of the calculations can not be estimated, as it depends on

the program structure, in typical program no given element or construction should constitute more than several percent of all the elements of the program.

The second mapping kernel (*Map2HCFG*) shows improvement over both previous kernels. It can be explained by the observation concerning the nature of the mutants. Mutant obtained by the introduction of a particular change in a particular location is not necessarily detectable by the same test as the mutant obtained by the introduction of the identical change in different location. The second mapping system contains substructures centered around nodes not only representing identical constructs, but also located within nodes representing identical elements, thus the results obtained for this kernel are more accurate. Moreover, as it takes into account less pairs of the substructures the number of calculations decreases further.

In the second example five test suites were used and the set was divided into four parts of similar size, because of the higher number of mutants. The process of dividing the set of mutants was carried out according to the same criteria as in the first example. And the classification was done in the same way.

Table II presents the results obtained for this example. It may be observed that the results follow similar pattern as for

the first example. It can be noticed that the results for TS 3 were visibly worse than for other suites. Closer inspection seems to suggest that this results from the fact that TS 3 detects only 22 out of 87 mutants and there may occur an over-representation of detectable mutants in the training set thus leading to incorrectly classifying many mutants as detectable.

### C. Using the results

Typical use of classification results is predicting the class membership of new elements, in this case new mutants. While it of course would be possible to generate new mutants for a given program and predict whether they would be killed by a given test suite the typical scenario here is different. After the classification is finished for each mutant not in the training set its  $k$  nearest neighbours are stored. Then, when a new test suite for the program is provided its needs to be run only against the mutants belonging to the training set, the detectability of the other mutants is decided on the basis of the stored neighbours.

## VI. CONCLUSIONS AND FUTURE WORK

The research presented in this paper deals with the problem of reducing the number of mutants to be executed and thus reducing the cost of applying mutation testing by using the classification algorithm. In contrast to other mutant reduction approaches, which are based on some programming language related knowledge, this approach limits the number of mutants to be executed in a dynamic way i.e. depending on the structure of the program for which the mutants were generated.

The application of the mapping kernel template allowed for comparing control flow graphs with better use of the knowledge of the nature of the mutants and at the same time significantly reduce the number of elements to be compared, thus reducing the time required to compute the similarity of programs.

The results of the classification allow to assess new test suites. During the application building process it is common that tests suites are iteratively updated. Each newly updated test suite has to be assessed to check if it fault detection ability is improved. Thus having to run each new test suite only on a fraction of all mutants significantly reduces the time a developer needs to provide a high quality test suite for an application.

Although the results are satisfactory and allow for using this method in practice there are several possible directions for future research on using classification in mutation testing. One of them is related to better use of the knowledge of the way tests are executed. When a test is executed it follows one of many possible paths within the program flow. Using this fact in the way a training set of mutants is selected could possibly improve the classification. This information could also be incorporating into the way the substructures in the kernel function are defined, for example limiting the neighbourhood of the node taken into account only to the nodes on the same path.

Another possible improvement could be based on replacing an arbitral choice of  $k$  by a more flexible approach such as

the one proposed in [45]. Future research are also planned to involve trying to define a set of features allowing for the description of programs in a vector form. Such a representation would allow for the use of non-kernel based classifiers.

**Abstract**—Deep neural networks enjoy high interest and have become the state-of-art methods in many fields of machine learning recently. Still, there is no easy way for a choice of network architecture. However, the choice of architecture can significantly influence the network performance.

This work is the first step towards an automatic architecture design. We propose a genetic algorithm for an optimization of a network architecture. The algorithm is inspired by and designed directly for the Keras library [1] that is one of the most common implementations of deep neural networks.

The target application is the prediction of air pollution based on sensor measurements. The proposed algorithm is evaluated on experiments on sensor data and compared to several fixed architectures and support vector regression.

## I. INTRODUCTION

**D**EEP neural networks (DNN) architectures have become the state-of-art methods in many fields of machine learning in recent years [2], [3].

While the learning of weights of the deep neural network is done by algorithms based on the stochastic gradient descent, the choice of architecture, including a number and sizes of layers, and a type of activation function, is done manually by the user. However, the architecture has an important impact on the performance of the DNN. Some kind of expertise is needed, and usually a trial and error method is used in practice.

In this work we exploit a fully automatic design of deep neural networks. We investigate the use of genetic algorithms for evolution of a DNN architecture. There are not many studies on evolution of DNN since such approach has very high computational requirements. To keep the search space as small as possible, we simplify our model focusing on implementation of DNN in the Keras library [1] that is a widely used tool for practical applications of DNNs.

As a target application, we use a real dataset from the area of sensor networks for air pollution monitoring. We work with data from De Vito et al [4], [5].

The paper is organized as follows. Section II brings an overview of related work. Section III briefly describes the main ideas of our approach. In Section IV our algorithm GAKeras is described. Section V summarizes the results of our experiments. Finally, Section VI brings conclusion.

## II. RELATED WORK

There were quite many attempts on architecture optimization via evolutionary process (e.g. [6], [7]) in previous decades.

Successful evolutionary techniques evolving the structure of feed-forward and recurrent neural networks include NEAT [8], HyperNEAT [9] and CoSyNE [10] algorithms.

On the other hand, studies dealing with evolution of deep neural networks and convolutional networks started to emerge only very recently. They usually focus only on parts of network design, due to limited computational resources. The training of one DNN usually requires hours or days of computing time, quite often utilizing GPU processors for speedup. Naturally, the evolutionary techniques requiring thousands of training trials were not considered a feasible choice. Nevertheless, there are several approaches to reduce the overall complexity of neuroevolution for DNN and provide useful and scalable algorithms.

For example, in [11] CMA-ES is used to optimize hyperparameters of DNNs. In [12] the unsupervised convolutional networks for vision-based reinforcement learning are studied, the structure of CNN is held fixed and only a small recurrent controller is evolved. However, the recent paper [13] presents a simple distributed evolutionary strategy that is used to train relatively large recurrent network with competitive results on reinforcement learning tasks.

In [14] automated method for optimizing deep learning architectures through evolution is proposed, extending existing neuroevolution methods. Authors of [15] sketch a genetic approach for evolving a deep autoencoder network enhancing the sparsity of the synapses by means of special operators. Finally, the paper [16] presents two version of an evolutionary and co-evolutionary algorithm for design of DNN with various transfer functions.

## III. OUR APPROACH

The main idea of our approach is to keep the search space as small as possible. Therefore only architecture is a subject to evolution, the weights are learnt by gradient based technique.

Further, the architecture specification is simplified. It directly follows the implementation of DNN in Keras library, where networks are defined layer by layer, each layer fully connected with the next layer. A layer is specified by number of neurons, type of an activation function (all neurons in one layer have the same type of an activation function), and type of regularization (such as dropout).

#### IV. GENETIC ALGORITHM FOR KERAS ARCHITECTURES

Genetic algorithms (GA) [17], [18] represent a robust optimization technique. They work with the population of feasible solutions represented by *individuals*. Each individual is associated with *fitness* value that evaluates its quality. New generations are created iteratively by means of GA operators *selection*, *crossover* and *mutation*.

Individuals are coding feed-forward neural networks implemented as Keras model *Sequential*. The model implemented as *Sequential* is built layer by layer, similarly an individual consists of blocks representing individual layers.

$$I = ([size_1, drop_i, act_1]_1, \dots, [size_H, drop_H, act_H]_H),$$

where  $H$  is the number of hidden layers,  $size_i$  is the number of neurons in corresponding layer that is dense (fully connected) layer,  $drop_i$  is the dropout rate (zero value represents no dropout), and  $act_i \in \{\text{relu}, \text{tanh}, \text{sigmoid}, \text{hardsigmoid}, \text{linear}\}$  stands for activation function.

The operator *crossover* combines two parent individuals and produces two offspring individuals. It is implemented as one-point crossover, where the cross-point is on a border of block.

The operator *mutation* brings random changes to the individual. Each time an individual is mutated, one of the following mutation operators is randomly chosen:

- *mutateLayer* - introduces random changes to one randomly selected layer. One of the following operation is randomly chosen: *changeLayerSize* (the number of neurons is changed; either one neuron is added, one neuron is deleted, or completely new layer size is generated), *changeDropOut* (the dropout rate is changed), *changeActivation* (the activation function is changed), *changeAll* (the whole block is discarded and new one is randomly initialized).
- *addLayer* - one randomly generated block is inserted at random position.
- *delLayer* - one randomly selected block is deleted.

Fitness function should reflect the quality of the network represented by an individual. To assess the generalization ability of the network represented by an individual we use a crossvalidation error. The lower the crossvalidation error, the higher the fitness of the individual. Classical k-fold crossvalidation is used and the mean squared error is used as an error function.

The tournament selection is used, i.e. each turn of the tournament  $k$  individuals are selected at random and the one with the highest fitness, in our case the one with the lowest crossvalidation error, is selected.

Our implementation of the proposed GAKeras algorithm is available at [19].

#### V. EXPERIMENTS

##### A. Data Set

The dataset used for our experiments consists of real-world data from the application area of sensor networks for air

pollution monitoring. The data contain measurements of gas multi-sensor MOX array devices recording concentrations of several gas pollutants. There are altogether 5 sensors as inputs and 5 target output values representing concentrations of  $CO$ ,  $NO_2$ ,  $NOx$ ,  $C_6H_6$ , and  $NMHC$ .

In the first experiment, the whole time period is divided into five intervals. Then, only one interval is used for training, the rest is utilized for testing. We considered five different choices of the training part selection. This task may be quite difficult, since the prediction is performed also in different parts of the year than the learning.

In the second experiments, the data are shuffled randomly and one third is used for testing and the rest for training.

Table I brings overview of data sets sizes. All tasks have 8 input values (five sensors, temperature, absolute and relative humidity) and 1 output (predicted value). All values are normalized between  $(0, 1)$ .

TABLE I  
OVERVIEW OF DATA SETS SIZES.

Task	First experiment		Second experiment	
	train set	test set	train set	test set
CO	1469	5875	4896	2448
NO2	1479	5914	4929	2464
NOx	1480	5916	4931	2465
C6H6	1799	7192	5994	2997
NMHC	178	709	592	295

##### B. Parameter Setup

The GAKeras algorithm was run for 100 iterations for each data set, with the population of 30 individuals.

During fitness function evaluation the network weights are trained by RMSprop for 500 epochs. For fitness evaluation, the crossvalidation error is computed. When the best individual is obtained, the corresponding network is built and trained on the whole training set and evaluated on test set.

##### C. Results

The testing error values of the best individuals are listed in Table II. There are average, standard deviation, minimum and maximum errors over 10 computations. The values are compared to results obtained by support vector regression (SVR) with linear, RBF, polynomial, and sigmoid kernel function. SVR was trained using Scikit-learn library [20], hyperparameters were found by grid search and crossvalidation.

The GAKeras network achieved best results in 16 cases, it in average outperforms the SVR.

Since this task does not have much training samples, also the networks evolved are quite small. The typical evolved network had one hidden layer of about 70 neurons, dropout rate 0.3 and ReLU activation function. In case of C6H6 there were two layers, about 100 neurons together, the first linear and the second ReLU without dropout.

Table III shows comparison of testing errors of GAKeras network and several fixed architectures (for example 30-10-1 stands for 2 hidden layers of 30 and 10 neurons, one neuron

TABLE II

in output layers, ReLU activation is used and dropout 0.2). The one with most (10) best results is the GAKeras network.

The results of the second experiment are listed in Table IV. In this case the GAKeras has best results in 4 cases from 5. The training sets are bigger and also the evolved architectures contained several layers. Again the dominating activation function is ReLU.

## VI. CONCLUSION

We have proposed genetic algorithm for automatic design of DNNs. The algorithm was tested in experiments on the real-life sensor data set. The solutions found by our algorithm outperform SVR and selected fixed architectures. The activation function dominating in solutions is the ReLU function. Evolved architecture depends on the task size, for tasks with small number of training points networks with only one hidden layer were evolved, for bigger tasks architectures with several hidden layers were found.

In our future work we plan to extend the algorithm to work also with convolutional networks and to include more parameters, such as other types of regularization, the type of optimization algorithm, etc. The importance of this direction is supported also by the recently conceived library [21] which combines genetic algorithm with models obtained by means of Keras and TensorFlow libraries.

## ACKNOWLEDGMENT

This work was partially supported by the Czech Grant Agency grant 15-18108S and institutional support of the Institute of Computer Science RVO 67985807.

Access to computing and storage facilities owned by parties and projects contributing to the National Grid Infrastructure MetaCentrum provided under the programme "Projects of Large Research, Development, and Innovations Infrastructures" (CESNET LM2015042), is greatly appreciated.

# Measurement of the appropriateness in career selection of the high school students by using data mining algorithms: A case study

Hidayet Takci, Kali Gurkahraman, Ahmet Firat Yelkuvan  
Cumhuriyet University  
Sivas, Turkey  
Email: htakci, kgurkahraman, aftyelkuvan@cumhuriyet.edu.tr

**Abstract**—Less than optimal choice of the university department is one of the serious problems Turkish high school students have been suffering. There are a number of potential factors affecting the student's choice of her future profession. Some of these have received attention in the literature, but such studies do not always involve an investigation of the relationship between the factors analyzed and subsequent levels of academic achievement. The present study examines the relationship between the level of academic achievement and the students' abilities, interests and expectations, by using different data mining methods and classifiers, as a preliminary work to develop a system that will guide the student to selecting a career that will be a better match for her in the future. C4.5, SVM, Naive Bayes and MLP algorithms are used for the analysis; 10-fold cross validation and train-test validation are used as models to evaluate the classifiers results. The student feature set is obtained through questionnaires and psychometric tests. The questionnaire and the psychometric test were applied to 210 and 52 students respectively, from the Computer Engineering Department at Cumhuriyet University. The class was labeled either "successful" or "unsuccessful" with reference to the grades received by each student in computer engineering courses. The comparisons of various data mining algorithms, different data set results, and models used are presented and discussed.

## I. INTRODUCTION

IN Turkey, all high school students are subjected to a central multiple choice examination in order to establish whether he or she is sufficient to study in a predetermined field. The examination is organized by an institution called in Turkish language "Oğrenci Seçme ve Yerleştirme Merkezi" (OSYM). OSYM prepares a guide to introduce the departments and universities to the candidates. The candidates specify their choices for the suitable departments by examining the information in this guide as well as other factors.

Although there is no information in the OSYM guide, the important factors for choosing a department are student ability, interest, and demographic data. For example, there is a close relation between mechanical ability and some engineering fields. The abilities of the candidate such as abstract thinking, understanding the shape relations, mechanical skills, hand-eye coordination and creativity should be measured properly. Determining the student interests is also important since considering only the ability of the student to find out the

proper profession may not be enough. Therefore, searching for matches between two sets, one of which include abilities, interests, and demographic data and the other one includes student success, should be done. The interests of a student may be sciences, social sciences, agriculture, and business trade. A suitable situation for the student is to have a profession in which he or she is interested as well.

Relatively more studied subject in the literature is student expectations from the profession [1,2]. The prominent factors of the student expectations are for example allowance of his or her family, social benefit, social expectations, career opportunities, and salary. Once profession choice is made, there may be many options of university in which the student will study. For this reason, possibilities and sufficiency of the university department should meet the student expectations. The quality and quantity of teaching staff, whether the university has a student exchange agreements, scholarships, success level are examples of factors that a student takes into consideration in order to choose the suitable university. Another criterion is the expectations of the department from the student. This is an important subject for student success in this department. A profession field specifically requires a competence to such as math, social or art. Other possible expectations from the students are ability to cope with stress, sex, health status, educational level of the family, type of high school, grade point average in high school etc.

In Turkey, in most of the high schools, the guidance counselors or teachers practically only examine the student grades in different lessons to determine suitable departments that the student can choose. The lack of professional guidance system which determines possible proper carriers by considering all the parameters related to student may cause low academic performance or dropouts in the future.

In this study, preliminary study has been done in order to build a system that can reveal the relationship between student and department features. For this purpose, educational data mining (EDM) algorithms have been run on data collected from students and departments. EDM can help to take into account many parameters, recognize the most important ones and figure out their relationship in order to understand and

solve educational questions [3,4]. Input data of our model are the information of students, and the output is basically whether this choice is suitable or not.

## II. RELATED WORKS

Data Mining (DM) is a field that finds out new and useful information from a high volume data [5]. Having many application areas such as marketing, medicine and real estate etc. it has also suitable techniques for educational practices as well. Many data mining techniques are applicable to educational fields and it is specifically called EDM. Shu-Hsien et al. [3] reviewed the EDM studies of period between 2000 and 2011 in 9 different categories while Romero and Ventura [4] reviewed the studies of period between 1995 and 2010 as DM and Computer Based Educational System (CBES) categories.

In addition to DM techniques, statistical and machine-learning algorithms are also used in EDM in order to process the educational information for two main objectives which are improving student performance and educational environment by studying students' approaches and examining the educational methods. For these aims, EDM makes some evaluations and predictions by using many types of data from different sources such as student information system which may include student grades and other personal information, questionnaires about learning process and lessons, tutoring systems, on-line educational web applications and some educational software that students use, such as for following the lecture notes and homework. For instance, determination of common lessons taken by students, whether a student can pass a specific lesson or not and classification of students can be made by using dense pattern mining [6], classifiers [7] and prediction models [8] respectively. Apart from the classical data mining applications, psychometric properties of students are also used in educational implementations [9].

DM has been dealing on student performance more than other subjects since it is an important and popular topic in education. Recently, various studies have also been made to improve the quality of lecture books [10], to increase the student attendance to lessons by using social network analysis [11] and to integrate the students' information in educational software [12]. For a more detailed example, Maria et al. [13] studied on log files of a free web-based tutoring system for middle school mathematics which was being used by 3,747 students in New England to predict student attendance to college by using logistic regression. They reported that their system can distinguish a student who will enroll in college 68.60% of the time. In India, Yadav and Pal [14] applied C4.5, ID3, and CART decision tree algorithms on engineering student's data to predict whether a student will pass, fail or promote to next year. Accurate classification rate of the study reached 67.78% for C4.5. Quadri and Kalyankar [15] studied on student dropouts features according to student risk factors such as gender, attendance, previous semester grade and parent income etc. Their hybrid method uses combination of the decision tree algorithms and logistic regression.

The studies in EDM field have concentrated on student performance and how to enhance learning process. Although these topics are very important for educational life, one of the main failure causes is the student incorrect department or career choice. In this study, we proposed a model using EDM techniques to help high school students in their career choices by considering different student information including student interests, abilities, student, and department expectations, demographic and, psychometric test data.

## III. PREDECTION MODEL

The test data and the output of the model are temporarily limited to our student still studying in Computer Engineering Department in Cumhuriyet University. The information of students and departments were collected from questionnaire and psychometric tests applied to our students, student information system in our computer engineering department. All the raw data should be preprocessed in order to eliminate redundancy and to convert them in suitable formats for processing by data mining techniques. Pre-processing stage also includes extracting features of students.

Processed data are analyzed by using data mining algorithms to obtain rules and patterns. C4.5 and regression analysis are suitable algorithms within rule-based and score-based classifiers respectively. The outputs of data mining stage are rules and patterns. In assessment stage, these rules and patterns are reviewed to eliminate the weak rules. Obtained valuable rules and patterns are used in EDM process.

The characteristic properties of students such as demographic information, their psychometric features, and information obtained from the guidance department and the factors affecting the department choice are the predictor variables for the model. The output variable is about relevance or achievement of the student for the department.

Prediction models have been used for testing the proposed system. In this study, historical data consisting of student abilities, interests, demographic information and student expectations from the department were obtained by questionnaires and psychometric tests applied to the students. Psychometric tests were basically used in order to be able to find out the student abilities while questionnaires included questions to provide the entire student related features. The achievement of the student in the department was used as the class label. The class label was "successful" or "unsuccessful" according to the computer related lecture grades of each student.

Two important components of the system which are feature set for matching and machine learning algorithms used in the system are presented.

### A. Feature Set

We have features for both questionnaire and psychometric test. While feature selection was made for 115 questions of questionnaire, no feature selection was needed in psychometric test since there were already 20 features in the test. Backward-logit, forward-logit, fisher filtering and reliefF methods have been used for feature selection.

1) *Questionnaire feature set*: Typeset sub-subheadings in medium face italic and capitalize the first letter of the first word only. There are totally 115 questions in the questionnaires and the categorization is as the following according to their measurement objective.

- 16 questions for student abilities
- 14 questions for student expectations
- 10 questions for demographic information
- 75 questions for student interests

The titles for category of measuring student abilities are as follows.

- Hand-eye coordination • Visual-spatial relation
- Logical-mathematical • Verbal-linguistic

Student expectations are related to factors affecting the profession such as career, salary, job opportunities, flexible working etc. The category of measuring student interests which contains most of the questions is considered as having following interest titles.

- Verbal-linguistic • Logical-mathematical
- Social sciences • Agriculture
- Foreign languages • Art • Music
- Literature • Sciences • Business and trade etc.

Although some of interest fields are not related to this study, the aim of DM analysis is to find out the relationship between the factors that are not easily noticeable. Although some of interest fields do not seem to be related to this study, the aim of DM analysis is to find out the relationship between the factors that are not easily noticeable. Therefore, the analysis was performed with interest titles mentioned above in the study.

In Table 1, grade column indicates the grading method of the questionnaires. Linear scale method is used in our questionnaires. In both talent related perception questionnaire and interest areas questionnaire 1 means "always", 2 means "often", 3 means "sometimes", 4 means "rarely" and 5 means "never". Also in expectations questionnaire 1 means "very high", 2 means "high", 3 means "average", 4 means "low" and 5 means "very low".

2) *Psychometric data feature set*: The quality of questionnaire-based measurement is no doubt dependent on the student answers. Therefore, psychometric test which has answers with naturally less indiscrimination was decided to perform in order to compare its analysis results with the ones obtained by questionnaire. Psychometric test with 20 questions aims to reveal student abilities such as logical-mathematical, comprehending visual-spatial relation, eye-hand coordination, and memory usage. The skills and the number of related questions are as follows.

- Logical-mathematical(4) • Verbal-linguistic(2)
- Imagination(2) • Memory usage(3)
- Visual-spatial relation(4) • Attention(3) • Mechanical(2)

For example, a student is asked to look at a village image for a while. Then some questions asked to the student such as "What is the number of houses?" and "What is the color of the bridge?" in the picture. With these questions, the memory usage and attention ability of the student is measured.

TABLE I  
EXAMPLES QUESTIONS OF QUESTIONNAIRES

Questionnaire	Questions	Grades				
Talent Related Perception Questionnaire	I can do simple mathematical operations in the mind.	1	2	3	4	5
	I try to learn the meanings of the words I just heard.	1	2	3	4	5
Expectations Questionnaire	How important is a peaceful business environment to you?	1	2	3	4	5
	How important is economic prosperity for a profession to you?	1	2	3	4	5
Interest Areas Questionnaire	Do you enjoy reading novels in history?	1	2	3	4	5
	Would you like to take apart a tool and reassemble it?	1	2	3	4	5
	Would you like to try growing new flower species?	1	2	3	4	5

## B. Predictive Data Mining Algorithms

Different DM models can be applied to student-department matching. In this study, prediction models were used. One of them that was used is called C4.5 and it is based on decision tree analysis. Statistical-based Naive Bayes algorithm and a successful classifier called Support Vector Machine (SVM) are the other models that were used in this study.

C4.5 is a classifier based on Quinlan ID3 algorithm and usually used in classification studies [16]. It constructs decision trees from a set of labeled data by using information gain. C4.5 is usually used in EDM since it is easily comprehensible and its results are relatively simple to conclude [17,18]. Naive Bayes classifier approaches the problem in probabilistic manner. While it is generally used in pattern recognition, it has been using also in EDM applications [17,19]. It considers each feature as independent of the others. It is also known to be fast algorithm and have high accuracy results.

SVM was first introduced by Vapnik and et al. [20] and it has been used in many classification applications in view of obtaining high accuracy results. In SVM, linear separability is a manner issue. First, the input space is mapped to a kernel space. Then, kernel space is used to constitute a linear space. In SVM based classification model, the classes are separated as the farthest possible points from each other.

## IV. EXPERIMENT DESIGN

In this section, the details of dataset and feature sets, a brief explanation of the experiment design, and the experiment results are presented.

### A. Data Set

We have two data sources which are from questionnaires and psychometric test results. The questionnaire and psychometric test were applied to 210 and 52 students from Computer Engineering Department in Cumhuriyet University. There were totally 210 students under questionnaire but 4 of them were lost data. The 52 students who were tested psychometrically are a subset of the surveyed students. The reason for this small number of elements in the lower cluster is that the test takes a long time.

### B. Experiment Design and Results

Using three different DM algorithms mentioned above, the results were obtained by analyzing both questionnaire data consisting of 5 different categories and psychometric basic feature dataset for each algorithm.

TABLE II  
THE CLASSIFIERS' ACCURACY RESULTS OF QUESTIONNAIRE DATASET  
CONSISTING OF 5 DIFFERENT CATEGORIES

Variables	Validation Method	C4.5	SVM	Naive Bayes	MLP
All Variables	10-fold validation	59.50	62.00	61.50	59.00
	Train-test validation	61.29	54.84	67.74	70.97
Ability Based	10-fold validation	55.00	69.50	64.50	63.00
	Train-test validation	48.39	67.74	69.35	62.90
Student expectations based	10-fold validation	55.00	69.00	70.50	68.50
	Train-test validation	64.52	72.58	67.74	72.58
Demographic data based	10-fold validation	62.50	-	63.00	-
	Train-test validation	69.35	-	69.35	-
Student interest based	10-fold validation	59.00	59.50	62.00	57.50
	Train-test validation	50.00	64.52	59.68	56.45

TABLE III  
ACCURACY RESULTS FOR QUESTIONNAIRE DATASET

	10-fold cross validation	Train-test validation
Algorithm	Accuracy(%)	Accuracy(%)
C4.5	59.50	61.29
SVM	62.00	54.84
Naive Bayes	61.50	67.74
MLP	59.00	70.97

For each feature set, accuracy ratios are given and ROC analyses are performed. In the experiments C4.5, Support Vector Machine (SVM), Naive Bayes, and Multilayer Perception (MLP) algorithms were used. 10-fold cross validation and train-test validation were used for model evaluation. 90% of the data set was used for training, and the remaining 10% was used for test. 10-fold cross validation is repeated ten times and averaged.

Since accuracy rate may not be competent in some cases, ROC analysis was also performed on both questionnaire and psychometric data. Thus, the classifier producing the best results for each data set was found out.

1) *Analysis of Questionnaire Dataset:* In this study, for the comparison of algorithms, the variables in the questionnaire dataset were analyzed in 5 categories according to their bases which are ability, student expectation, demographic data, student interest and all variables including all the bases. The analysis results are shown in Table 2.

However, since some of the demographic data such as residence region of the student's family and high school that the student graduated, are not numerical or categorical variables, were not used in SVM and MLP classifiers. For this reason, results were obtained only from C4.5 and Naive Bayes algorithms for demographic data. In addition, demographic data are not also used in questionnaire dataset consisted of all variables because of the same problem. MLP algorithm achieved the highest accuracy values according to train-test validation according to the results in Table 2.

As a first step, performances of machine learning algorithms were measured according to questionnaire data based on all variables. The accuracy value was preferred as performance criteria for the algorithms. 10-fold cross validation and train-test validation were used to evaluate the classifiers results. The analysis results can be seen in Table 3.

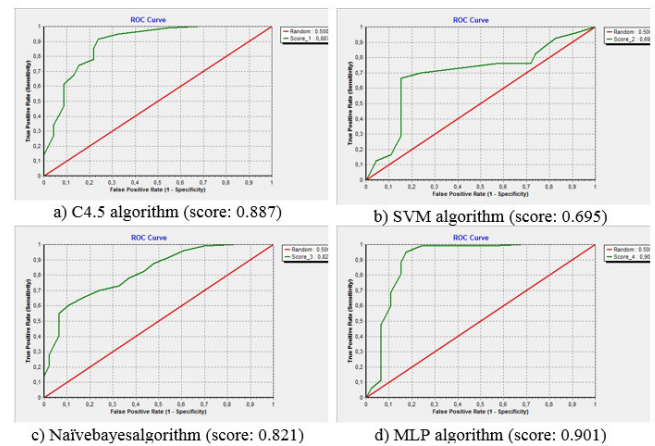

Fig. 1. ROC analysis results for the algorithms applied to questionnaire dataset

TABLE IV  
THE CLASSIFIERS' RESULTS OF PSYCHOMETRIC DATASET

	10-fold cross validation	Train-test validation
Algorithm	Accuracy(%)	Accuracy(%)
C4.5	54.00	62.50
SVM	56.00	68.75
Naive Bayes	56.00	56.25
MLP	48.00	50.00

According to the results for 10-fold cross validation, although SVM which produced the highest accuracy value as 62.00%, it is not possible to describe it as the best classifier since the values of all algorithms are close to each other. In train-test validation, the result of MLP is significantly superior to other algorithms. In 10-fold cross-validation, a further ROC analysis was needed because close values were seen. The ROC curves obtained for each algorithm are presented in Figure 1.

The method used to evaluate ROC curves is to find the area under the curve (AUC). In Figure 1, score values refer to these AUC values. As in the train-test validation, according to the score values, MLP algorithm gave the best classification result. Therefore, MLP can be accepted as the most suitable algorithm for the questionnaire dataset.

2) *Analysis of Psychometric Dataset:* Both the accuracy and ROC analysis were also performed for psychometric test dataset. According to the accuracy ratios, both questionnaire and psychometric test results are similar. The classifiers' results for psychometric test dataset can be seen in Table 4.

SVM algorithm gave the best accuracy value as 68.75% according to train-test validation in Table 3. However, SVM algorithm could not perform high result in 10-fold cross validation. Therefore, ROC analyses were also used to measure classifiers' performance.

As can be seen in Figure 2, although SVM has the highest accuracy ratio, AUC value of C4.5 algorithm is the best value as 0.823 according to ROC curves. This result is also different to questionnaire dataset analysis which selected MLP algorithm.

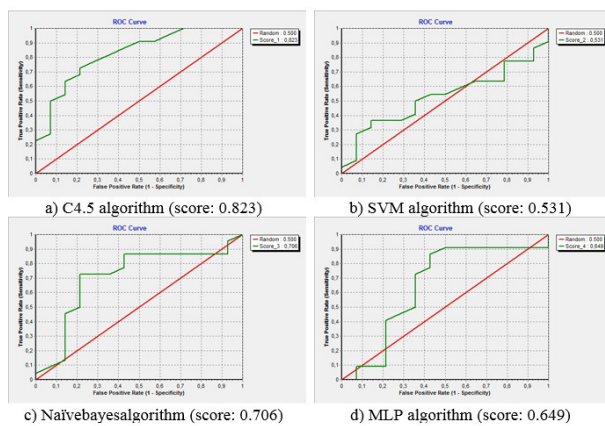

Fig. 2. ROC analysis for the algorithms applied to psychometric test dataset

## V. CONCLUSION

The analysis results of the questionnaire data were better than the ones obtained from psychometric data. The main reason for the superiority of the analysis results is that the questionnaire data was obtained from the many aspects of students such as abilities, interests, demographic data, and expectations. Among questionnaire data, demographic data gave more discriminative information than the others. Besides, the relationship between ability and success appeared to be more valuable than the relationship between interest and success. Although SVM generally has mentioned as it is superior in literature, C4.5 and MLP algorithms gave better results in this study.

According to model comparison, the success obtained by Train-Test method is quite better than the result obtained by 10 fold cross-validation method.

In the literature on the educational studies, as far as we can know, there is no study investigating the relationship between academic achievement and the topics covered in this study by using EDM algorithms. On the other hand, there are studies that are relevant in terms of their contents. The main axis of the studies is what the students take into consideration when choosing a university department and a career or what are the factors that influence them [1,2]. The studies in this area have generally examined the variables that influence the choice of the students and attempted to find out which factor is more discriminative. In both studies, in order to reveal the effective factor, the students' interests and expectations as well as other factors are scaled in the questionnaire. Misran et al. also includes student demographic information in the study. The difference of our study from the others is to focus on the proper choice of the student which otherwise could lead to low academic performance in the future.

## ACKNOWLEDGMENT

We would like to thank Turkish Scientific and Technological Research Council (TUBITAK) for providing the research support (Project Number: 115E837).

# **AAIA'17 Data Mining Competition: Prediction model which would help AI to play the game of Hearthstone: Heroes of Warcraft**

AAIA'17 Data Mining Challenge is the fourth data mining competition organized within the framework of International Symposium Advances in Artificial Intelligence and Applications. This time, the task is to come up with an efficient prediction model which would help AI to play the game of Hearthstone: Heroes of Warcraft. The competition is kindly sponsored by Silver Bullet Solutions and Polish Information Processing Society (PTI).

## **SPECIAL SESSION**

As in previous years, a special session devoted to the competition will be held at the conference. We will invite authors of selected reports to extend them for publication in the conference proceedings (after reviews by Organizing Committee members) and presentation at the conference. The publications will be treated as short papers and will be indexed by IEEE Digital Library and Web of Science. The invited teams will be chosen based on their final rank, innovativeness of their approach and quality of the submitted report.

## **AWARDS**

Authors of the top-ranked solutions (based on the final evaluation scores) will be awarded prizes funded by our sponsors (Silver Bullet Solutions and PTI):

- First Prize: 1000 USD + one free FedCSIS'17 conference registration
- Second Prize: 500 USD + one free FedCSIS'17 conference registration,
- Third Prize: one free FedCSIS'17 conference registration.

## **CONTEST ORGANIZING COMMITTEE**

- **Andrzej Janusz**, University of Warsaw
- **Maciek Świechowski**, Silver Bullet Solutions
- **Damian Zieniewicz**, Silver Bullet Solutions
- **Krzysztof Stencel**, University of Warsaw
- **Jacek Puczniewski**, Silver Bullet Solutions

**Abstract**—This paper summarizes the AAIA'17 Data Mining Challenge: Helping AI to Play Hearthstone which was held between March 23, and May 15, 2017 at the Knowledge Pit platform. We briefly describe the scope and background of this competition in the context of a more general project related to the development of an AI engine for video games, called Grail. We also discuss the outcomes of this challenge and demonstrate how predictive models for the assessment of player's winning chances can be utilized in a construction of an intelligent agent for playing Hearthstone. Finally, we show a few selected machine learning approaches for modeling state and action values in Hearthstone. We provide evaluation for a few promising solutions that may be used to create more advanced types of agents, especially in conjunction with Monte Carlo Tree Search algorithms.

**Keywords**—data mining competition; AI in video games; MCTS; artificial neural networks; Hearthstone: Heroes of Warcraft;

## I. INTRODUCTION

**H**EARTHSTONE: HEROES OF WARCRAFT is a free-to-play online video game developed and published by Blizzard Entertainment. It is an example of a turn-based collectible card game played between two opponents. During a game, players use their custom decks of thirty cards, along with a selected hero with a unique power. They spend mana points to cast spells or summon minions to attack the opponent, with the goal to reduce the opponent's health to zero. Building efficient decks is an essential skill and many archetypes of decks exists. These archetypes are characterized by different distributions of the cards' mana cost and thus are meant for players with different play styles. There are also sets of cards, which synergize well due to their unique properties and can be used in many different decks.

In recent years, Hearthstone has become a testbed for AI research. A community of passionate players and developers have started the HearthSim project (<https://hearthsim.info/>) and created many tools that allow simulating the game for the purpose of AI and machine learning experiments. Several researchers have already used this game in their studies [1], [2]. Moreover, our research team decided to use Hearthstone as one of case studies which aim to demonstrate capabilities of our video game's AI designing framework, called Grail. For this reason, one objective of this article is to explain how some powerful heuristic search algorithms can be combined with prediction models that derive from the machine learning domain, in order to construct a smart and cunning artificial Hearthstone player.

The paper is organized as follows: in the next section, we describe the specificity of the AAIA'17 Data Mining Competition. In Section III, the approach of using the collected data to effectively play the game of Hearthstone is presented. The approach is based on the so-called Monte Carlo Tree Search algorithm (Section III-A) coupled with machine learning models (Sections III-B – III-D). The last section is devoted to conclusions.

## II. AAIA'17 DATA MINING CHALLENGE

AAIA'17 Data Mining Challenge: Helping AI to Play Hearthstone (<https://knowledgepit.fedcsis.org/contest/view.php?id=120>) took place between March 23 and May 15, 2017. It was organized under the auspices of the 12<sup>th</sup> International Symposium on Advances in Artificial Intelligence and Applications (AAIA'17, <https://fedcsis.org/2017/aaia>) which is a part of the FedCSIS conference series.

The main objective in this competition was to construct a prediction model which would be able to foresee who is going to win, using only information about a single game state. The ability to accurately assess winning chances of a player in different game states is substantial for designing efficient and challenging AI opponents in many video games. The most famous example is the AlphaGo program, which used two neural networks to evaluate possible moves and game states of Go games [3]. In our competition, we challenged participants with the task to design such models for Hearthstone.

In particular, the dataset provided to participants contained examples of game states extracted from Hearthstone play outs between weak AI players (i.e. the agents which were used to generate the data were choosing their in-game decisions at random). The participants were asked to predict winning chances of the first player from game states belonging to the test set and submit their predictions to the Knowledge Pit competition platform [4]. In order to give participants a freedom of choosing a representation of the data which they want to use, the datasets were provided in two formats: in a tabular format (with simplified representation) and as raw JSON files (with detailed game states).

The training part of the data was made available along with the corresponding information regarding the actual game winners. These labels were removed from the test set which was also made available to participants. Initially, the training set consisted of 2000000 game states, however, after detecting an unwitting data leakage [5], after first few weeks of the

TABLE I. BASIC CHARACTERISTICS OF DATASETS USED IN AAIA'17 DATA MINING CHALLENGE.

characteristic	training set	test set
no. examples	3250000	750000
no. games	65000	180000
no. used decks	9	27
percent of wins	50.46%	57.27%
min. win rate per hero (percent/hero_id)	50.07%/326	37.53%/754
max. win rate per hero (percent/hero_id)	50.85%/981	75.34%/25

challenge, it was extended by additional 1250000 cases from the original test set (in total, there were 3250000 training examples). The final test set consisted of 750000 game states. Test set examples were obtained from a different set of Hearthstone play outs than the training cases. In fact, while the training data contained game states from  $\approx 65000$  simulations, more than 180000 play outs were simulated to generate the test set. It is also important to note that while in the training games there were used only 9 different sets of cards (one deck for every hero type), the test games were played using 27 different decks. As a consequence, the test data contained Hearthstone cards which had never appeared in the training set. Table I shows a summary of basic characteristics of datasets used in the challenge.

#### A. Evaluation of results and participation in the challenge

Participants of the competition had to prepare their solutions in a form of a file with predictions of a likelihood that *player 1* will win, given a corresponding description of a game state. The files with predictions had to be sent using the submission system of Knowledge Pit [4]. Each of the competing teams could submit multiple solutions. Quality of the submissions was measured using Area Under the ROC Curve (AUC) [6]. The submitted solutions were evaluated on-line and the preliminary results were published on the competition leaderboard. The preliminary score was computed on a subset of the test set, fixed for all participants. Size of this subset corresponded to randomly chosen 5% of the test set. The final evaluation was conducted after completion of the competition using the remaining part of the test data.

Apart from submitting their predictions, each team was also obligated by competition rules to provide a brief report describing its approach. Only the final solutions from teams which sent a valid report could undergo the final evaluation and be published among the competition results. In this way, we were able to collect a vast amount of information regarding efficient representation methods of Hearthstone game states and state-of-the-art approaches to this type of prediction problems.

#### B. Summary of the competition

Even though AAIA'17 Data Mining Challenge lasted for less than two months, it attracted attention of many researchers from domains of machine learning and artificial intelligence in video games. By the end of competition there were 296 teams from 28 countries registered in the challenge. Among them, 188 teams submitted at least one solution to the leaderboard and 114 teams described their solution in a report uploaded to the Knowledge Pit platform. In total, we received 4067

TABLE II. FINAL RESULTS AND NUMBER OF SUBMISSIONS FROM THE TOP RANKED TEAMS. THE LAST ROW SHOWS THE RESULT OBTAINED BY OUR BASELINE SOLUTION – A FULLY-CONNECTED NEURAL NETWORK WITH TWO HIDDEN LAYERS, TRAINED ON THE TABULAR DATA.

team name	rank	# of submissions	final result
iwannabetheverybest	1	139	0.8019
hieuvg	2	384	0.7992
johnpateha	3	143	0.7990
vz	4	11	0.7973
jj	5	75	0.7971
...	...	...	...
baseline	94	–	0.7846

submission, which makes this competition the most popular one among challenges organized at Knowledge Pit to this day.

The large number of submitted reports gave us a unique opportunity to review the most effective prediction methods for the assessment of Hearthstone game states. The most successful approach in this regard turned out to be artificial neural networks [7] and particularly, the deep learning methods [8]. In fact, all top-ranked teams used neural networks in their solutions and the winners focused particularly on the convolutional neural networks [9]. Another popular approach was the utilization of *xgboost* algorithm [10]. There were also much simpler approaches which turned to be efficient, such as the logistic regression models. Moreover, all of these methods were often combined – techniques such as averaging, bagging or stacking were commonly used to obtain better prediction results [11]. Table II presents scores obtained by the five top-ranked teams. Noticeable is the fact that the difference in scores between the best solution and the baseline is less than 2%.

Many teams decided to use data in the JSON format in order to construct richer representations of game states than the one which was available in the provided tabular data. Feature engineering [12] turned out to be an important aspect of the most efficient solutions. Extracted features were often a reflection of participant's experience and domain knowledge about Hearthstone. Their descriptions included in reports turned out to be a valuable source of knowledge which can be used to improve our artificial Hearthstone players.

### III. AUGMENTATION OF GAME STATE SEARCH HEURISTICS WITH NEURAL NETWORKS

#### A. Monte-Carlo Tree Search

Monte Carlo Tree Search (MCTS) [13] is a method of learning an optimal policy for solving problems such as game-playing. For the first time, it was used for games in Go [14] as an improvement over a Monte Carlo sampling technique (without the tree search). The algorithm led to a breakthrough in the game of Go, which had been previously regarded as intractable for computer programs [15]. Driven by this success, MCTS became the state-of-the-art approach in various game domains, such as General Game Playing [16] and General Video Game Playing [17]. The idea of MCTS is to repeatedly simulate the game (problem) and build statistics about states and actions. Each iteration of the algorithm consists of four phases as depicted in Figure 1.

**(1) Selection.** In this phase, the algorithm starts from the root node and searches the tree down by choosing subsequent

Fig. 1. Depiction of four phases which comprise the MCTS algorithm.

children nodes. The child node at each node down the path is chosen according to the so-called selection policy. The selection phase ends when there is no child node to choose, i.e., a leaf node has been reached.

**(2) Expansion.** One of the possible actions is applied to a node selected in the previous step and the tree is grown by adding a child node representing the resulting state.

**(3) Simulation.** The algorithm starts from the new node and performs a complete game simulation, i.e., reaching a terminal state. This phase is done outside the game-tree and no nodes are added to it. Once the simulation reaches the terminal state, the obtained goals (outcomes) of each player are fetched.

**(4) Back-propagation.** Here, the statistics are recalculated inside all nodes along the path from the root to the leaf (containing the starting state for the simulation) in the game tree. The statistics include the average scores of each player and the number of visits to a node. An average score is computed as the total score achieved in iterations going through a particular node divided by the number of visits to that node.

In the classic implementation, actions in the simulation phase are chosen with respect to uniform random distribution. In the selection phase, a more sophisticated formula (selection policy) is typically used. The most common one, which was also employed in this paper for all MCTS-based programs used during the experiments is called Upper Confidence Bounds applied for Trees (UCT) [18].

$$a^* = \arg \max_{a \in A(s)} \left\{ Q(s, a) + C \sqrt{\frac{\ln[N(s)]}{N(s, a)}} \right\} \quad (1)$$

where  $A(s)$  is a set of actions available in state  $s$ ,  $Q(s, a)$  denotes the average result of playing action  $a$  in state  $s$  in the simulations performed so far,  $N(s)$  - a number of times state  $s$  has been visited in previous simulations and  $N(s, a)$  - a number of times action  $a$  has been sampled in this state in previous simulations. Constant  $C$  controls the balance between exploration and exploitation.

The MCTS algorithm using the UCT selection formula is proved to converge to the min-max theoretical optimum [18]. However, it poses several advantages over a classic min-max search. For instance, it does not require any game specific evaluation function and constructs the tree in an asymmetric manner, focusing at the most promising lines of play. It scales better with the depth of the tree, it can be stopped at anytime to return the best action found so far.

## B. Monte-Carlo Tree Search with Heuristics

Despite the wide usage in a variety of game domains, the MCTS method has bottlenecks and limitations. It is both computationally demanding and memory intensive. Games with huge branching factor, i.e., the total number of actions available to players, in average, often inhibit the usage of MCTS and other tree-search methods. This weakness has motivated us to combine this algorithm with heuristics represented by prediction models. Such prediction models can be trained to either predict the outcome of the game by looking at a potential next state (candidate state) of the game or at a potential action (candidate action). In the scope of this paper, we will use the terms “machine learning prediction models” and “heuristic evaluation” interchangeably.

There is a couple of ways to combine external heuristics with the MCTS algorithm. The authors of paper [19] give a nice review of four common methods:

**(1) Tree Policy Bias** - here the heuristic evaluation function is included together with the  $Q(s, a)$  in the UCT formula (see Eq. 1) or its equivalent. A typical implementation of this idea is called *Progressive Bias* [20], in which the standard UCT evaluation is linearly combined with the heuristic evaluation with the weight proportional to the number of simulations. The more simulations are performed, the more statistical confidence, and therefore, the higher weight is assigned to the standard UCT formula.

**(2) Move Ordering** - the heuristic defines the order, in which actions in the tree are expanded (chosen for the first time). This method has the most significant impact on the deeper parts of the tree, because the MCTS is less likely to visit them again, so the order matters. If better moves are expanded first, their neighbourhood in the tree has a higher chance to be visited in subsequent simulations.

**(3) Simulation Policy Bias** - in the baseline version of the MCTS algorithm, the actions during the simulation phase are chosen randomly. With a good heuristic evaluation, a sensible approach is to infer this knowledge in the action selection process, while still leaving some degree of randomness. The two most common implementations are pseudo-roulette selection with probabilities computed using Boltzmann distribution (where the heuristic evaluation is used) or the so-called epsilon-greedy approach [21]. In the latter, the action with the highest heuristic evaluation is chosen with the probability of  $\epsilon$  or a random one with the probability of  $1 - \epsilon$ .

**(4) Early Cutoff** - the authors of [19] achieved the best results with terminating Monte Carlo simulations before the game ends and returning the heuristic evaluation of the current state. This variant is called Early Cutoff and the cutoff is done typically at fixed depth or with certain small probability (e.g.  $P=0.1$ ) in each step.

The aforementioned AlphaGo program employs both, Tree Policy Bias and Simulation Policy Bias. Motivated by its success, we decided to apply a similar approach for Hearthstone.

## C. Generality of models trained on random simulations

Both Tree Policy Bias and Simulation Policy Bias methods utilize a heuristic function which provide the value of a game state or an action. Various machine learning methods may be used to obtain these evaluations, including supervised

Fig. 2. A comparison between performance of a neural network trained on AAIA17 Data Mining Challenge dataset when tested on game states generated by random and MCTS agents.

prediction models [6]. Since random simulations are used in the classic version of MCTS, it is natural to train such models on game states obtained from play outs between agents making random decisions.

The datasets used in AAIA17 Data Mining Challenge constitute an example to this type of data. It can be used to train prediction models for the purpose of evaluation of Hearthstone game states during MCTS simulations. However, a question arises whether such models could be also effective in games played by more intelligent opponents. To check that, we conducted a series of experiments. First, we generated an additional dataset containing game states from duels between strong MCTS agents. Each agent was making decisions after performing 15000 random simulations before a single action. In total, there were 28604 play outs generated in this way, which resulted in a dataset consisting of 814407 game states. We trained a simple neural network with two hidden layers on the training set used in our competition and we checked its performance on the available test set. Next, we constructed another model using all competition data and we tested it on the additional dataset. Figure 2 shows a comparison of the obtained AUC scores in consecutive turns. Surprisingly, total AUC dropped only slightly (from  $\approx 0.79$  to  $\approx 0.75$ ) when the test was done on the data generated by MCTS players. It shows that predictive models can be successfully used for evaluation of game states, even in a case when they are trained on random simulations.

#### D. Learning a playing strategy from sequences

In practice, it is often desirable to have a function that provides the policy rather than the value of a particular action. The policy  $\pi(a|s)$  specifies the probabilities for all actions available in a given state, thus it enables the selection of the best action candidate in a single state evaluation.

Fig. 3. LSTM policy network. A sequence of states and actions from previous game steps are provided as the input to the LSTM network. The LSTM network is trained to output probabilities for actions available after the last step in the sequence.

Reinforcement Learning is used in particular for cases where the optimal policy is unknown and needs to be learned based on sparse reward signals. However, a supervised learning approach may be used, when examples of policies are available (e.g. from human players or other algorithms). In our case, we may use MCTS to generate Hearthstone matches and obtain state-action pairs i.e. record what action was chosen by MCTS as a response to given game state. Next, we may train a model that predicts the action that MCTS would choose for a given state. Training such a model is basically a classification task, well fitted for deep neural networks (DNN).

Long short-term memory (LSTM) is a type of recurrent neural network [22] dedicated for use with sequences. The architecture of LSTM enables it to learn long and short term temporal dependencies. LSTM provides superior performance in tasks such as speech recognition, machine translation or language modeling. A deep LSTM network may be created by stacking multiple LSTM layers.

A DNN may be trained to approximate a policy from examples of state-action pairs - we will refer to this network as to *policy network* [3]. However, in case of Hearthstone, a single state may not provide enough information to the model for a valid action prediction. This is due to the fact that a single turn in Hearthstone consists of many moves. Moreover, a single move is decomposed into a few atomic actions in order to be efficiently implemented in the Hearthstone simulator. For example, putting a minion on the board consists of two actions: selecting a card from hand and selecting the slot on the board where the minion should be placed. To improve the accuracy of the policy predictions, rather than using a single state, we chosen to use a sequence of states and previous actions as the input to the policy network.

Our policy network is presented in figure 3. LSTM network is provided with a sequence of  $K = 10$  vectors created from concatenating a state vector for state  $s_{t-k}$  and an action vector for action  $a_{t-k-1}$ , for  $k \in [0, 1, \dots, K-1]$ . The state vector includes 403 values representing the state of the game from the point of view of a selected player. The action vector is of length 91 and contains a one-hot encoded action. The output of the LSTM is a single vector with probabilities assigned to each of all available 91 actions (the probabilities are provided also for actions that are illegal in a certain state). The LSTM in our experiments consisted of 3 layers of 256 LSTM cells with dropout

To obtain the training data, we first used MCTS with 1000

TABLE III. EVALUATION RESULTS OF AGENTS USING LSTM POLICY NETWORK.

greedy agent type	wins vs random agent	wins vs MCTS(1000)
seqMCTS1k	96.2%	23.0%
seqMCTS10k	98.6%	26.4%
seqMCTS1k retrained with seqMCTS10k	98.2%	50.4%

iterations to generate 7000 games between randomly selected decks. Using this data we obtained 528365 sequences of length 10 where each element of the sequence included 494 values. We will refer to this dataset as to *SeqMCTS1k*. Next, we generated 1500 games using MCTS with 10000 iterations. As a result we created a second dataset: *SeqMCTS10k*, that consists of 149521 sequences.

To evaluate the policy network, we created a greedy DNN agent that always selects the most promising action from the predictions of the policy network. We confronted this agent against a random agent and an agent using MCTS with 1000 iterations. Greedy DNN agents were using policy networks trained in three variants: 1) using only *SeqMCTS1k* dataset, 2) using only *seqMCTS10k* dataset and 3) trained first on the *SeqMCTS1k* dataset and then retrained on the *SeqMCTS10k* dataset. The results are presented in Table III. Each score is calculated based on 500 games played between the agents.

#### IV. CONCLUSIONS

In the paper we provided a summary of AIA'17 Data Mining Challenge which was held at the Knowledge Pit platform. Results of this competition clearly show that learning from Hearthstone game logs is feasible and has a potential to facilitate a construction of intelligent artificial agents which play that game. We explained how prediction models can be combined with game state search heuristics to improve their performance. We also demonstrated results of experiments showing that models trained on data obtained from random simulations can be successfully applied for the assessment in games between intelligent agents. Finally, we showed that more advanced approaches such as the supervised action policy learning based on game state sequences are feasible and deserve further investigation.

# Predicting Unpredictable: Building Models Handling Non-IID Data, A Hearthstone Case Study

Dominik Deja

Polish-Japanese Academy of Information Technology  
Warsaw, Poland

dominik.deja@pjwstk.edu.pl

**Abstract**—The following article is created as a result of the *AAIA'17 Data Mining Challenge: Helping AI to Play Hearthstone*. The Challenge goal was to correctly predict which bot would win a bot-vs-bot Hearthstone match based on what was known at the given time. Hearthstone is an online two-players card game with imperfect information (unlike chess and go, and like poker), where the goal of one player is to defeat their opponent by decreasing their "life points" to zero (while not allowing the opponent to do the same to oneself). Two main challenges were present: the transformation of hierarchically structured data into a two-dimensional matrix, and dealing with Non-IID data (certain cards were present only in test data). A way of how to successfully cope with those complications while using state-of-the-art machine learning algorithms (e.g. *Microsoft's LightGBM*) is presented.

## I. INTRODUCTION

### A. Hearthstone

**D**EVELOPED and published by *Blizzard Entertainment*, *Hearthstone* (initially *Heartstone: Heroes of Warcraft*) is a free-to-play turn-based online collectible card video game. It was released on March 11, 2014, and it is available for Windows, Mac, iPad, Android and Windows 8 tablets, as well as iOS and Android mobile phones<sup>1</sup>.

Fig. 1. Screenshot from an actual game

The game is a turn-based card game between two players (naming convention: "player", "opponent" will be used in this article), using constructed decks of thirty cards along with a selected hero. Each hero possesses a unique power which allows them to either draw a card, summon a minion, heal or

deal damage. Furthermore, usable cards differ for each hero. For example, Mage class offers more spells, while Paladin has access to stronger minions. Players use their limited mana crystals (indicated by a hexagon, at the bottom right for the player in Figure 1, and top right counter for the opponent) to cast spells or summon minions to attack the opponent, with the goal to reduce the opponent's health to zero. Each spell has a unique effect such as: dealing damage to one or more minions, dealing damage to champion(s), changing the statistics of minions or champions, etc. Each minion can deal a certain amount of damage (indicated at the bottom left of its card), has a certain amount of hp (indicated at the bottom right of its card), possesses additional features (such as "windfury" enabling it to attack twice per turn, "charge" enabling it to attack the same turn it was cast, or "taunt" which makes a minion a priority target for the enemy's attacks), and can cast additional effects depending on other circumstances.

While the mechanics of the game is rather simple, a high number of available cards (by 2017, there are over 1000<sup>2</sup>), a wide range of possible, often unique traits possessed by each minion, and imperfect information (the player does not see the opponent's cards, decks are randomly shuffled, and random effects are common) increase the complexity of the game<sup>3</sup>.

This complexity makes it a perfect case study for AI experts to try out new methods and approaches.

### B. Contest

The *AAIA'17 Data Mining Challenge: Helping AI to Play Hearthstone* was a data mining competition organized by Silver Bullet Solutions and the Polish Information Processing Society (PTI) within the framework of the International Symposium Advances in Artificial Intelligence and Applications<sup>4</sup>.

The goal was to predict a binary outcome (win/lose) of bot-versus-bot Heartstone matches. The cost function used for evaluating the participants predictions was AUC (Area Under Curve). There was a two-step score evaluation. First, AUC scores based on a fixed 5% of test data were provided for each contestant's set of predictions. Then, after the contestants

<sup>1</sup><http://us.battle.net/hearthstone/en/>

<sup>2</sup><http://hearthstone.gamepedia.com/Card>

<sup>3</sup>[https://en.wikipedia.org/wiki/Hearthstone\\_\(video\\_game\)](https://en.wikipedia.org/wiki/Hearthstone_(video_game))

<sup>4</sup><https://fedcsis.org/2017/aaia>

shared their reports, a final leaderboard (based on the whole test set) was provided.

For data preprocessing, the author used Python 2.7 (IPython Notebooks). For the rest of this work R version 3.3.3 (RStudio) was used. The author used Windows 8.1 Pro, Intel i7-4710MQ 2.50 GHz (4 cores), 32GB RAM, NVIDIA GeForce GTX 870M.

## II. DATA PROCESSING

Data for this contest was generated by Peter Shih's Hearthstone simulator<sup>5</sup>. From each match, random snapshots were taken, aggregated, and saved as JSON files. The creators provided two datasets - a training dataset and test one (2000000 and 750000 snapshots respectively) formatted as multiple JSON files.

For each game, short overall statistics, player and opponent statistics, statistics on cards played (by both player and opponent) and cards at hand (only for player) were provided. For the training set, 90 unique cards (78 at hand, and 42 played), and 12853295 cards in total (8996725 at hand, and 3856570 played) were used. Cards at hand are the ones owned by the player which they can cast (in case of spells), or summon (in case of minions). Cards played are minions summoned and still living. Interestingly, there are 38 new unique cards in the test set (38 at hand and 22 played). In total, 642985 (417607 at hand, and 225378 played) out of 5500047 (3264847 at hand, and 1592215 played) cards in the test sets are new. This means that 11.69% of cards present in test set are new, and they are present (to various extents) in 415793 out of 750000 games (55.44%) played using the test set.

The fact that over 55% of observations from the test set contained new cards dismantled the assumption of identical distributions of data and played an important role in data processing and modeling.

### A. From Attribute-Value to Matrix Format and Feature Engineering

In order to construct a two-dimensional matrix, where each row is a snapshot and each column is a different feature, JSONs were processed one by one.

First, all the statistics on each game and participant were extracted (final outcome, turn, participant's hero type, hp left, armor, crystals left, crystals in total, #cards at hand, #cards played, etc). This produced 26 columns.

Then, the counts of the players cards at hand were saved in separate columns (one for each card type). For the cards played, as they consist of minions only, the sums of their hp were saved in unique columns (per minion type and player/opponent). The rationale behind it is that the minion's health can be changed by both participants during a match and it highly impacts how much influence a minion will have on the outcome of a game. This produced 162 columns.

In order to overcome the fact that new, unseen cards were present in the test set, features based on aggregates were

added. They included respectively for each participant's minions overall hp and attack situation: max, min, sum, product, mean, median, and counts for the minions special characteristics, such as "charge", "taunt", or "freeze", additional features such as "max damage doable to an enemy in this turn" amongst them. Because a player usually has more minions that can be summoned than they can afford to summon, a knapsack problem was solved in order to find an optimal configuration of minions to summon in order to maximize damage done to an enemy champion (the "taunt" trait was taken into an account in its simplified form - instead of solving an optimization problem of finding the best way on how to attack minions and then the hero, the "taunt" minions hp was subtracted from the maximum damage doable to an enemy in the same turn). Unsurprisingly, this feature came out to be one of the strongest predictors (all models agreed on this) of the final outcome. Yet, it wasn't sufficient to simply check whether a player can decrease an opponent hp to values equal to or less than zero (in the same turn), as the relation between the game status and the outcome turned out to be more complex (or bots are not as smart as we would like them to be). This produced 42 columns.

Depending on a run, the cards from the test set which were non-present in a training set, where either mapped to their closest neighbour (using Euclidean distance on their crystal cost, hp, and attack for hand, as well as current hp and current attack for played card), or were omitted. Additionally, a couple of diffs were provided (player hp - opponent hp, maximum potential damage to enemy - enemy hp, and so on).

### B. Final preparation

Since constructing this many features results in introducing collinearity into data, additional measures were taken to minimize the negative consequences of feature engineering.

Thus, constant features, highly correlated ones ( $> 0.95$ ), and those which could be presented as a linear combination of others were deleted. This resulted in 241+1 final variables used for training models. Finally, the data was scaled in order to improve the efficiency of algorithms (especially logistic regression with regularization).

Fig. 2. Final Model

In order to obtain reliable results and avoid overfitting, training data was split into three parts (as shown on Figure 2):

- A : First layer data (1500000 observations)

<sup>5</sup><https://github.com/peter1591/hearthstone-ai>

- B : Second layer data (400000 observations)
- C : Internal test data (100000 observations)

Splitting it into three parts (instead of the usual training, and validation set) helped to train a more complex, two-layered model.

### III. MODELING

Amid various methods of improving the overall efficiency of modeling, such as obtaining good understanding of data (via solid explanatory analysis done before applying actual models), feature engineering, or adjusting models to directly optimize cost function, one of the most common and important is stacking. It is based on the observation that combining predictions of several good, uncorrelated models will result in an even stronger prediction [1].

#### A. Initial Two-Layered Model

Therefore, the first model used consisted of a number of machine learning algorithms stacked in two layers. All models are shortly described in Table I. The pipeline was as follows: first, each of the algorithms from the first layer was trained on part A of the training data and provided predictions for part B and part C. Then, using first layer predictions for part B as an input, the LightGBM model from the second layer was trained and provided predictions for part C. Predictive power was compared between each single algorithm, and the overall model using part C.

Fig. 3. Typical Two Layered Stack Model

Since most of the algorithms used have a number of parameters that need to be optimized, a Bayesian approach was used to estimate them as proposed by Snoek, Larochelle, and Adams [2]. In short, parameter tuning can be seen as a Bayesian optimization problem, in which a model's performance is modelled as a sample from a Gaussian process. Since the posterior distribution induced by the Gaussian process is traceable, we can efficiently use information from past runs to optimally choose new parameters worth trying.

As training a number of models tends to take a lot of time, the author first checked for optimal ranges of parameters using a small subset of part A of training data (from 10000 to 100000 observations), and then ran it on bigger chunks (up to 1000000 observations). A Bayesian optimization package in R as proposed by [2], usually takes less than 30 iterations (in case of 5 or less parameters).

TABLE I  
MODELS USED FOR STACKING

Algorithm	Specification
Random Forest	One of the best tree-based algorithms(using bagging)as invented and implemented by Breiman [3]. Run two times. The first time, it was trained on whole data, the second time it was trained only on 100 top features (their importance was asserted by the first model). This allows to reduce noise and increase prediction power. ntree = 1000. The number of features used in the second forest can also be optimized.
XGBoost	A still fairly new, tree-based algorithm (using boosting) created by Tianqi Chen [4]. Basic parameters to be optimized: <i>eta</i> , <i>colsample_bytree</i> , <i>subsample</i> , <i>max_depth</i> , <i>min_child_weight</i> .
Extra Trees	Extremely Randomized Trees, as proposed by Geurts, Ernst, and Wehenkel [5].
LightGBM	One of the newest and strongest algorithms accessible via R. <i>Microsofts</i> LightGBM as a part of their Distributed Machine Learning Toolkit <sup>6</sup> . Alike XGBoost it's a tree-based boosting algorithm with multiple parameters to be optimized. Using bins instead of vectors, and optimizing the code, LightGBM is one of the fastest and strongest algorithms available.
Logistic Regression with variables selected via L1	Logistic regression trained on variables selected by logistic regression with L1 penalization.

#### B. Dealing with Non-IID Data

Since test data is Non-IID, and over 55% of observations contain new cards, the more optimized the parameters are, the worse the score obtained on the test set is.

From a statistical learning theory point of view, it can be shown as a bias-variance trade-off dilemma [1]. The more we try to optimize our models, the more their complexity and variance will increase, and thus, their sensitivity to any shifts in data distribution. By finding the right set of parameters, one may decrease the bias and improve the models effectiveness, but it is always done at the price of the models stability.

Tables II, and III show this phenomenon using LightGBM algorithm trained on 1000000 observations from part A (learning rate = 1). As the number of leaves increases, the model becomes more complicated. As the number of minimal observations required in each leaf increases, the model is pushed to be simpler. Here, as it is shown only for illustrative purposes, data used for obtaining scores comes from part B, and C (for iid data), and from the test set (for non-iid data).

TABLE II  
AUC FOR IID DATA

#Leaves	10000	0.9073	0.8594	0.9395		
	1000	0.8624	0.8119	0.8883	0.9414	
	100	0.8231	0.8100	0.8434	0.9181 <sup>†</sup>	0.8915 <sup>†</sup>
	10	0.8044	0.8001	0.8146	0.8483 <sup>†</sup>	0.8331 <sup>†</sup>
		1	10	100	1000	10000
		Min #Observations in Leaf				

<sup>†</sup>Algorithm didn't converge in 3000 iterations and could be further trained.

Two main things are interesting here. The first one is that

parameter optimization is a non-convex problem. While a model with 10000 leaves is over 0.9 AUC for both, 1 and 100 minimal observations in a leaf, for 10 it drops to 0.86 AUC.

The second one is that the more optimized the model is, the more sensitive it becomes, and that different parameters indicate a different "threat" to the stability of the model. While a minimal number of observations in leaf seems not to be strongly linked to model's sensitivity, the number of leaves plays a major role in making a model fine-tuned.

TABLE III  
AUC FOR NON-IID DATA

#Leaves	10000	0.7261	0.709	0.7537		
	1000	0.7016	0.7293	0.7262	0.7439	
	100	0.7347	0.7471	0.7361	0.7354 <sup>†</sup>	0.7401 <sup>†</sup>
	10	0.7754	0.7807	0.7667	0.7482 <sup>†</sup>	0.7631 <sup>†</sup>
		1	10	100	1000	10000
		Min #Observations in Leaf				

<sup>†</sup>Algorithm didn't converge in 3000 iterations and could be further trained.

### C. Final Conditional Model

This knowledge was used to build a final model. In fact, two models were built, and depending on whether new cards were present in any given snapshot, the adequate model was used. For snapshots where IID seemed to hold (no new cards present), a fine-tuned stacked model was used for predicting. For observations where data was non-IID, a conservative model was run to provide predictions.

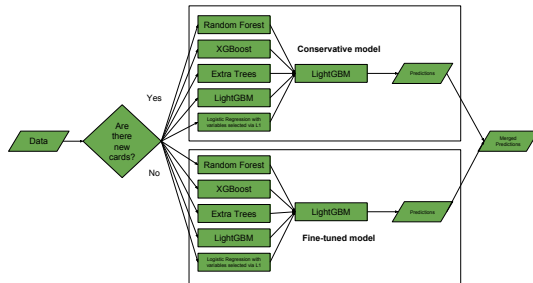

Fig. 4. Final Model

The internal test set obtained 0.967 AUC. The test set managed to obtain a stable 0.795 AUC score (the best solution obtained was 0.802 AUC).

### D. Additional Possibilities

Thankfully, each data science contest has a deadline. Without one, there would be always a new hypothesis to test. Here as well, a number of things can be tried:

- Instead of using minion hp only, doubling (or tripling) the number of columns to add information on attack and count
- Using deep neural networks
- Adding information on what cards an opponent probably has at hand
- Adding more features based on player/opponent possible decisions
- Checking the lot's logic - why some games where a player can win in one turn are not won
- Further optimization of the models' parameters
- Defining and constructing a card space where each card has its representation so that one does not have to rely on actual cards

## IV. CONCLUSION

Even five years ago, many scientists predicted that we are still a decade from constructing an AI capable of winning a Go game with an average professional. Yet, in March 2016 *AlphaGo*, an AI developed by *Google DeepMind* beat Lee Sedol, one of the best players worldwide, 4:1 [6].

Since then, and due to the renaissance of deep neural networks, AI research got a second breath. Currently, the effort is to create a bot capable of playing more human-like games (usually in real time) with imperfect information (at the time of this article being published, games like *Doom* [7] are probably already conquered, therefore *Starcraft* would be a good example of AI researchers' next target).

As part of this ongoing effort, this article helps to sort out what the most practical approach is to structuring non-relational data into a form usable for machine learning, and how to cope with non-IID data (or when a shift in feature distributions is expected to happen).

# Helping AI to Play Hearthstone using Neural Networks

Łukasz Grad

University of Warsaw

Email: lg334481@students.mimuw.edu.pl

**Abstract**—This paper presents a winning solution to the AAIA'17 Data Mining Challenge. The challenge focused on creating an efficient prediction model for digital card game *Hearthstone*. Our final solution is an ensemble of various neural network models, including convolutional neural networks.

## I. INTRODUCTION

**H**EARTHSTONE: *Heroes of Warcraft* is a digital collectible card game that gained huge interest from players and AI researchers over the last couple of years. Although the rules of the game are simple, creating an AI model that would successfully challenge an experienced human opponent is a difficult task, mainly due to inherent stochasticity and partial information. The goal of AAIA'17 Data Mining Challenge: Helping AI to Play *Hearthstone* was to design a model that can accurately evaluate arbitrary intra-game states, by predicting likelihood of winning the game by the first player.

In this paper, we present a winning solution that utilizes both neural network and convolutional neural network architectures. The proposed method requires only minimal domain knowledge and relies on basic feature preprocessing with no feature selection.

The rest of the paper is organized as follows. In section II we describe the details of the AAIA'17 challenge. Section III provides the description of features extracted from the data. Finally in section IV we present the details and results of our solution.

## II. THE CHALLENGE

### A. Game description

*Hearthstone* [1] is a turn based game between two players with custom built decks of thirty cards. Each player starts with thirty health points and zero mana crystals. At the start of each turn, player gains an additional mana crystal, draws a random card and his mana crystals are refreshed. Each card costs mana to play. Some cards are creatures, also called minions, that stay on the game board as long as their health is above 0. Players can make arbitrary number of actions during their turns, limited only by the mana crystals left. The goal of a game is to reduce the opponent's health to zero.

### B. Problem statement

The given problem is an instance of binary classification task. Given a detailed representation of an arbitrary intra-game state, the goal is to predict the likelihood of winning the game by the first player, assuming it is his turn to play. The game

state need not be a beginning state of a current turn. The predicted values do not need to be in particular range, however higher values should indicate a higher chance of winning. The accuracy of a model is defined as an *area under the ROC curve* (AUC). AUC can be interpreted as a probability that a classifier will rank a randomly chosen winning state higher than a randomly chosen losing state.

### C. Data

Data sets provided in competition were extracted from large collection of play outs between weak AI players. Play outs were generated using all available nine classes and decks assembled from basic set of cards. The data was split into seven training sets and three test sets. In total, the training set consisted of 3 250 000 observations for which the correct decision label was provided. The test set had 750 000 game states in total and was missing the true labels. Game states contained in the test set were extracted from different play outs. Competitors were asked to submit their predictions on the whole test set.

Furthermore, data sets were provided in two different formats. The main set is a collection of JSON records containing a detailed description of each game state. Each record in JSON file contained:

- information about player and opponent heroes
- detailed description of all played creatures for both player and opponent
- detailed description of cards in player's hand
- current turn number

However, there was no information about previously played cards neither by player nor the opponent. The remaining cards in the player's deck were also unknown. The second data set was available in a simpler, tabular format. It contained the most important features extracted from JSON format and a handful of additional columns that aggregated information from several JSON fields.

### D. Evaluation

Preliminary leaderboard was available for all competitors, based on a randomly chosen 5% subset of the test data set. This subset was the same for all participants and was known only to the organizers. There was no hard limit on the number of submissions available. Each team could select only one submission as their final solution that was evaluated on the remaining 95% of the data set.

### III. FEATURE ENGINEERING

Since the main data sets were given in a raw JSON format, a crucial first step in the competition was to extract meaningful features. Moreover, usage of external knowledge bases about cards was allowed, as long as it was publically available. In general, we can divide created features into three groups:

- played minion features
- hero features
- aggregating features

The following features were extracted from JSON data for each creature:

- `attack` - attack value
- `health` - current health value
- `can_attack` - whether minion can attack this turn
- `forgetful` - whether minion has 50% chance to miss a target
- `taunt` - whether minion has taunt
- `hp_max` - maximum health value

Other features extracted from JSON data:

- all player and opponent hero information
- all aggregating features from tabular data
- hero and opponent class in one-hot encoding

In addition, the following variables were added to the set:

- for each minion played: `aura` - whether a creature provides an active bonus for other minions
- `effective_health` - difference between total health of hero and total attack value of enemy minions
- `hand_power` - sum of marginal player hand card values based on *Heartharena Tierlist* [2]
- `hand_aoe` - total damage of 'area of effect' spells in hand
- `hand_answers` - number of 'hard removal' spells (that neutralize arbitrarily strong minions)

### IV. SOLUTION

#### A. Preprocessing

In all models, we normalize the data using Min-Max scaling. All features are scaled down to a fixed range from 0 to 1. Min-Max scaling proved to give slightly better results on holdout test sets than standarization with regard to mean and standard deviation.

In both neural network and convolutional neural network models, we also decided to include square and logarithm transformed features for all variables, excluding minion features and one-hot encoded hero class. This increased the total number of features to 260. In terms of bias-variance tradeoff, we want to decrease the bias even at the cost of increased variance of a single model.

#### B. Evaluation

Given a very large dataset we decided to evaluate our models using standard random train and test split, with 70% and 30% size respectively.

#### C. Initial models

To better understand the difficulty of the problem, we decided to train several standard linear and non-linear classifiers. We utilized Python's **scikit-learn** machine learning package (ver. 0.18.1) [3], [4]. For all models, if not explicitly stated, we used default parameters. Optimal hyperparameters were found using basic grid search approach on a small, random subsample of data.

- **Logistic Regression** fitted using Stochastic Average Gradient [5] solver with penalty parameter  $C = 2.0$  and L2 regularization which resulted in 0.79321 score on local test set.
- **Support Vector Machine (SVM)** with RBF kernel and penalty parameter  $C = 35.0$  trained on a random sample of size 50000 achieved a score of 0.78835 on local test set subsample of size 25000.
- **Random Forest** with 500 trees, minimum number of samples to split a node equal to 5 and maximal depth of 30 which resulted in 0.83494 score on local test set, around 0.784 on online preliminary test set.

We can see from the above results that a decent result can be achieved with a simple Logistic Regression model. However, an SVM trained on a very small data sample achieved only a slightly worse result. This tells us that the problem is highly non-linear and more complex models should perform better. On the other hand, the discrepancy between local and preliminary results for a Random Forest model is a clear sign of overfitting. The final test set has different characteristics and a good generalization is the key to win the competition.

#### D. Neural network

Feedforward neural network satisfies all requirements stated in section IV-C. The model can have arbitrary complexity, depending on the number of neurons and hidden layers, is very flexible and provides many techniques to reduce overfitting. Neural networks can also successfully be trained on very large datasets, as opposed to SVMs with non-linear kernels. On the downside, neural network training is highly sensitive to parameter initialization and can be hard to reproduce.

Both neural networks and convolutional networks were implemented in **Tensorflow** (ver. 1.1.0) [6] framework, a library for numerical computations using data flow graphs.

Network architecture consists of two hidden layers with dense connections and ReLU as an activation function [7]. Each hidden layer is followed by a Batch Normalization layer. Batch Normalization can speed up learning and reduce the *exploding gradient* problem [8]. We use L2 regularization of weights with  $\lambda = 0.0002$ .  $\lambda$  was set to a maximal value that did not hinder the network learning performance on local test set.

We trained many models with different number of hidden layer neurons. Best single network consisted of 100 neurons in first hidden layer and 50 neurons in second. It scored 0.7980 on the preliminary leaderboard.

### E. Convolution layer rationale

From bayesian perspective, we can think of convolutional layer as a fully connected layer with an infinitely strong prior over some of its weights [9]. An infinitely strong prior places zero probability on parameters, making them forbidden, regardless of how much support the data assigns to those parameters. In case of convolution, this prior states that the layer should only learn local interactions and be equivariant to translation. Such prior results in sparse connections and parameter sharing, that significantly reduces the parameter space, when compared to fully connected layer of the same size.

The overall performance of convolutional network depends on whether our prior beliefs are reasonably accurate. If we are not correct, the network will likely underfit. On the other hand, if our prior is acceptable, we can expect the convolutional model to perform similarly, or even better then the original fully connected network, while having much less parameters.

### F. Convolution layer in detail

Recall from section III that for each played minion we extracted 7 features. Each player can have up to 7 minions in play, giving a total of 98 variables. Since we already included features that describe the overall state of the game board, from the detailed minion features we want to extract information about how well they perform against each other. We state our belief that such performance should be measured independently of the position of a minion. Let  $p_i$  be the  $i$ 'th player minion feature vector and  $o_i$  be the  $i$ 'th opponent minion feature vector. We have  $p_i, o_i \in \mathbb{R}^7$ , and  $p_i, o_i = \vec{0}$  whenever there is no minion at the position  $i$ .

We can reshape the input vector as a  $[7, 2, 7]$  tensor (multidimensional array), see Fig. 1a. We now introduce a *partial cyclic shift* (PCS) operation on such tensor, that applies a row-wise shift of player minion features, while leaving opponent minion features intact, Fig. 1b. We apply PCS 7 times with shift from 0 to 6. We then reshape each resulting tensor to  $[7, 14]$ , so that  $i$ 'th row contains features of both  $i$ 'th player and  $i$ 'th opponent minions. Finally the tensors are stacked along third dimension, Fig. 1c shows a single row of final tensor (indices modulo 7). We want a convolution kernel to process the effectiveness of *all player minions against a single opponent minion*.

$p_0$	$o_0$	$p_1$	$o_1$	$p_i$	$o_i$
$p_1$	$o_1$	$p_2$	$o_2$	$p_{i+1}$	$o_i$
$p_2$	$o_2$	$p_3$	$o_3$	$p_{i+2}$	$o_i$
$p_3$	$o_3$	$p_4$	$o_4$	$p_{i+3}$	$o_i$
$p_4$	$o_4$	$p_5$	$o_5$	$p_{i+4}$	$o_i$
$p_5$	$o_5$	$p_6$	$o_6$	$p_{i+5}$	$o_i$
$p_6$	$o_6$	$p_0$	$o_6$	$p_{i+6}$	$o_i$

(a) Minion features (b) PCS with shift 1 (c) Final  $i$ 'th row

Fig. 1

Fig. 2: Test set AUC scores during learning using **minion features only**. FC - fully connected layer, BN - batch normalization, CNN( $d_1$ ) - single convolution with depth  $d_1$ , CNN( $d_1, d_2$ ) - double convolution with depths  $d_1, d_2$ .

We introduce new hyperparameter  $d_1$  - the depth of convolution result. After the preprocessing we run two convolutions in parallel creating a layer similar to inception layer [10]. First one, with kernel shape  $[1, 14, 7, d_1]$ , measures performance of player minions against a single opponent minion. Second one with kernel shape  $[2, 14, 7, d_1]$  that can take into account cooperation against 2 adjacent opponent minions. All convolutions are without padding, resulting in tensors with shapes  $[7, 1, d_1]$  and  $[6, 1, d_1]$  for first and second convolutions. We again use ReLU as activation function.

We also tested running additional convolutions with kernel  $[1, 1, d_1, d_2]$  on top of the resulting tensors described above. Applying such operation creates the same  $d_2$  linear combinations from  $d_1$  features for each spatial location, see Fig. 3.

We then tested the performance of our convolution layer on **minion features only** with different  $d_1, d_2$  hyperparameters, merging and flattening the resulting tensors and using a double layer fully connected network. We compared the results with double layer dense networks with raw minion features as input. Results are presented in Fig. 2.

We see that there is a lot of information contained only in minion features about the depending variable. Also, the convolutional layers can extract features that lead to similar classification performance as the raw inputs, despite the im-

Fig. 3: Overview of the convolutional layer architecture. Node vectors represent tensor shapes at each step of computation. Edge vectors represent convolution kernel shapes.

posed prior. We believe that those features will allow a network achieve better generalization performance.

### G. Convolutional network

We create a convolutional network by flattening the output from the convolutional layer and concatenating it with the original features, including raw minion features. We then use 3-layer feedforward network with ReLU activation and batch normalization after each hidden layer, without scaling factors. We did not include batch normalization in convolutional layer. We again use L2 regularization with  $\lambda = 0.0002$ . In some models, we substituted L2 regularization with dropout [11] with 0.5 probability, applied only to the last hidden layer. We present two best convolutional architectures in Table I.

### H. Training

All networks were trained using Adam [12] optimizer with initial learning rate of 0.0001 or 0.0002, without learning rate decay and with cross entropy loss function. Network weights were initialized by sampling from truncated normal distribution with 0 mean and 0.1 standard deviation. Larger convolutional networks were also initialized using lower standard deviation of 0.05. Biases were initialized with 0.1 constants.

TABLE I: CNN with L2 regularization on the left and with dropout regularization on the right

[7x14x1] MINION INPUT		[7x14x1] MINION INPUT

[60] FULLY CONNECTED		[120] FULLY CONNECTED	
[60] BATCH NORM		[120] BATCH NORM + DROPOUT	
[1] FULLY CONNECTED		[1] FULLY CONNECTED	

We used stochastic batch gradient descent with batch size of 320 and trained final models for around 16000 iterations on

whole dataset, roughly 1.5 epochs. Such early stopping method was chosen empirically, basing on preliminary test results, since the holdout test scores proved to be highly unreliable.

### I. Ensembling

We retrained each model a couple of times and selected top networks, based on preliminary results. Choosing models solely on preliminary results certainly could lead to overfitting, thus we created ensembles of top scoring predictors, with manually adjusted weights. All submitted ensembles scored far better than single models, see Table II. Final submission contained 11 models and won the competition with 0.80185 AUC score.

TABLE II: Excerpts of preliminary results

Model	Best model AUC
CNN L2	0.8012
CNN Dropout	0.8005
NN Ensemble	0.80
<b>CNN Ensemble</b>	<b>0.8041</b>
Final Ensemble	0.8037

# Evaluation of Hearthstone Game States With Neural Networks and Sparse Autoencoding

Jan Jakubik

Wrocław University of Science and Technology  
Department of Computational Intelligence  
Wrocław, Poland  
Email: jan.jakubik@pwr.edu.pl

**Abstract**—In this paper, an approach to evaluating game states of a collectible card game *Hearthstone* is described. A deep neural network is employed to predict the probability of winning associated with a given game state. Encoding the game state as an input vector is based on another neural network, an autoencoder with a sparsity-inducing loss. The autoencoder encodes minion information in a sparse-like fashion so that it can be efficiently aggregated. Additionally, the model is regularized by decorrelation of hidden layer neuron activations, a concept derived from an existing regularizing method DeCov. The approach was developed for AAIA'17 data mining competition "Helping AI to play *Hearthstone*" and achieved 5th place out of 188 submissions.

## I. INTRODUCTION

VIDEOGAME AI is one of the most well-known applications of Artificial Intelligence methods in software development. Designing challenging, smart and believable opponents has always been an important goal for videogame developers. Implementation of intelligent actors in games requires development of efficient methods for searching large state spaces and designing game-specific heuristics for state evaluation.

Recently, a breakthrough in the domain of board games achieved by the AlphaGo [1] project has demonstrated the potential of machine learning methods, specifically deep neural networks [2], in game AI. Coupled with a Monte Carlo tree search approach [3], a combination of neural networks for move policy and game state evaluation has achieved results previously thought to be at least a decade of research away and was shown capable to defeat top-level human players. The results are promising for multiple types of games, as Monte Carlo tree search approach is general enough to cover varying types of gameplay, including card games.

This paper describes a solution to the data mining challenge competition organized within the framework of the 12th International Symposium on Advances in Artificial Intelligence and Applications. The goal of the challenge was to evaluate game states of the collectible card game *Hearthstone*, using machine learning algorithms, given a training sample of contextless game states with a single win/loss variable to predict. Our solution is based on a combination of autoencoder neural network for game state encoding and a deep neural network for the actual game result prediction.

## II. CHALLENGE DESCRIPTION

*Hearthstone* is a collectible card game developed by Blizzard Entertainment in which two players, represented by heroes chosen from a pool of 9 character classes, fight each other using minion, spell and weapon cards. Additionally, each hero has access to a "hero power" which can be used once per turn. Possible plays are limited by crystals called "mana". A player starts the game with a single mana crystal, gains one mana crystal per turn and can use their mana crystals once per turn to pay the cost associated with playing a card.

Minions persist on the game board until destroyed, can attack the opposing player or other minions once per turn, and can have various special properties. Minions are positioned on the game board in a single line for the player and another for the opponent; up to 7 minions can be played on each side and adjacency can be relevant to the functioning of certain cards.

Spells are cast by the player, affect the game state in a particular way, and leave the game afterward. Most of spells do not persist on the game board after resolving their effect.

Weapons can be equipped by the player's hero, are persistent, and allow the hero to attack, similarly to the way minions do. However, weapons have a limited durability, which goes down by 1 with each attack, effectively limiting the number of times they can be used. Moreover, only one weapon can be equipped at a time.

The goal of the game is to bring down the opposing player's health points (HP) to 0 or below, with both players starting at 30 HP. Minions are particularly important for this purpose due to their persistence on the game board and the ability to attack every turn.

The challenge data consists of contextless snapshots of game states during the player turn. For training data, a single variable indicating whether the game was won or lost by the player is provided. The data was created using simulations of games between two AI, driven by a Monte Carlo tree search approach. The simulations only use cards from the original card set of *Hearthstone*, released in 2014. Provided datasets are divided as follows:

- initial training set: 4 data chunks of 500000 game states each
- initial test set: 1250000 game states; later became available as training set

TABLE I  
PROPERTIES OF THE PLAYER AND THE OPPONENT

Property	Meaning
deck_count	Number of cards in deck
played_minions_count	Number of minions in play
fatigue_damage	Takes this much damage with next draw
hand_count	Number of cards in hand
crystals_all	Number of mana crystals
spell_dmg_bonus	Damage added to damaging spells
crystals_current	Mana crystals still available this turn
weapon_durability	Uses of equipped weapon left
armor	Additional HP which can go above 30
hp	Health points, maximum 30
attack	Deals this much damage on attack
hero_card_id	One of 9 hero classes
special_skill_used	Hero power was used this turn

- final test set: 750000 game states

The goal of the challenge was to provide real number evaluations of game states present in the final test set, quality of which would be measured by area under the ROC curve (AUC).

### III. GAME STATE ENCODING

In the following section, the term "player" will be used in reference to the player from whose perspective the games are observed, and the term "opponent" will refer to the second player.

The key properties of a single game state consists of turn number, player stats, opponent stats, up to 7 player minions, up to 7 opponent minions and up to 10 cards in player's hand.

Representing these variables so that they can serve as an input to a neural network is non-trivial due to the varying number of minions. Basic information about a single minion can be expressed as a numerical vector. However, a concatenation of seven vectors into a single "board vector" representing one side poses multiple problems. Firstly, this representation does not guarantee equivalent or even similar results for equivalent board states (i.e., shuffling minion positions). Secondly, samples with minions present on all positions are rare in the training set. Usually, only the first few positions are occupied.

Proposed solution is based on using a sparse autoencoder to encode minion data. While autoencoders are typically a dimensionality reduction method, sparse coding aims to detect patterns and improve aggregation of data. E.g., given a set of objects which form clusters in the data space, the simplest form of sparse coding is a dictionary approach in which each object is encoded as a one-hot vector that contains the object's cluster assignment. A sum of such sparse vectors contains information of how much objects of each type there are in the dataset. More complex dictionary encoding methods exist [4], and neural network encoding with sparsity constraints can be viewed as a non-linear extension of them [5].

In our approach, we encode information about each player's minion sparsely and then sum them into a single vector

TABLE II  
PROPERTIES OF A MINION

Property	Meaning
hp_max	Initial HP, cannot be healed above this value
charge	Can attack on the turn it is played
frozen	Cannot attack until next turn
taunt	Allies (without taunt) cannot be attacked
poisonous	Kills any minion it damages
freezing	Attacked enemies become frozen
forgetful	50% chance to attack wrong enemy
crystals_cost	Cost to play in mana
shield	Negates first instance of damage dealt to it
attack	Deals this much damage on attack
hp_current	Current HP
windfury	Can attack twice per turn
stealth	Cannot be targeted by spells and attacks
id	Unique ID number of a card
can_attack	Can still attack this turn

representing player minions. The same is done to opponent minions. The input vector is a concatenation of these minion vectors and the remaining information about the game state.

The training vector takes a form shown below (1):

$$turn|player|opponent|\sum_{i=1}^7 p_i|\sum_{i=1}^7 o_i|hand \quad (1)$$

where  $x|y$  denotes concatenation of vectors.  $turn$  is the turn number,  $player$  is all of the available player information and  $opponent$  is all of the available opponent information.  $p_i$  is a vector of information about  $i$ -th player minion encoded by the autoencoder network described in Section IV, and  $o_i$  is a vector of information about  $i$ -th enemy minion encoded using the same network.

In order to build  $player$  and  $opponent$  vectors, hero class information is encoded in a 9 element one-hot vector. All remaining binary and numerical properties (Table I) are treated as real numbers. Numerical properties are normalized to have values in  $[0,1]$  range.

The input to the autoencoder network is a 17-element vector, where first 14 elements are all numerical and binary properties of a minion (Table II), with the exception of the "id" property (unique identification number). The remaining elements of the vector are used for information about certain unique abilities. 15-th is a unique board-buffing ability (set to 1 for Stormwind Champion, 0.5 for Raid Leader, 0 for other minions), 16-th is a unique adjacent minion buffing ability (set to 1 for Flametongue Totem, 0.33 for Dire Wolf Alpha, 0 for other minions) and 17th element is set to 1 only for Healing Totem to represent its unique healing ability.

Vector  $hand$  contains information about player's hand and uses dictionary encoding. Its dimensionality is equivalent to the number of unique cards in the training set, and  $i$ -th element indicates the number of times  $i$ -th card occurs in player's hand.

Cards which appear in the player's hand in the test set, but not the training set are ignored.

#### IV. SPARSE AUTOENCODER

Autoencoder [7] is a network that attempts to recover input data from a hidden layer representation, as seen in equations (2-4):

$$h_i = \sigma_e(W_e x_i + b_e) \quad (2)$$

$$x'_i = W_d h_i + b_d \quad (3)$$

$$RE(X) = \sum_{i=1}^n \|x_i - x'_i\|_2^2 \quad (4)$$

where  $x_i$  is the  $i$ th input vector,  $h_i$  is its encoded hidden layer representation, and  $x'$  is the input reconstruction.  $\|\dots\|_2$  denotes L2 norm.  $\sigma_e$  is a log-sigmoid activation function. Weight matrices  $W_e$ ,  $W_d$  and bias vectors  $b_e$ ,  $b_d$  of the model are trained to minimize reconstruction error  $RE(X)$  using stochastic gradient descent.

It is possible to encourage a sparse representation within an autoencoding network adjusting the loss function, as seen in equation (5):

$$SparsePenalty(X) = \sum_{i=1}^m \left( \rho \log \frac{\rho}{\hat{\rho}_i} + (1-\rho) \log \frac{1-\rho}{1-\hat{\rho}_i} \right) \quad (5)$$

where  $\hat{\rho}_i$  is the average activation of  $i$ -th output in the encoding layer ( $m$  is the number of neurons in the layer). Parameter  $\rho$  is a low positive value, which encourages low average activations. In practice, this causes the network to encode information in a sparse-like way, i.e., some "active" neurons have significantly higher activations than others. The "inactive" neurons do not have zero activations if rectified linear units are not used, so the representation is not sparse in the strict sense.

Overall loss function of a sparse autoencoder can be defined as (6):

$$L(X) = RE(X) + \lambda_0 SparsePenalty(X) \quad (6)$$

where  $\lambda_0$  is a hyperparameter.

#### V. REGULARIZATION OF THE PREDICTION MODEL

The prediction model is a deep neural network with four hidden layers. The detailed network parameters and the learning process are described in Section VI. In this section, regularization of the model is described in detail. As training set contains data from a set of simulations disjoint from the set of simulations used to create the test data, it is easy to overfit any model by learning to identify specific games, so regularization becomes a key issue.

For regularization, standard L2 norm penalty is applied to weight matrices. In addition, the correlation between outputs in hidden layers is explicitly punished. This is inspired by DeCov

[6], a recently proposed regularization method that adds a loss based on the covariance between outputs in a hidden layer (7):

$$DeCov(H_i) = \|Cov(H_i) - \text{diag}(Cov(H_i))\|_F^2 \quad (7)$$

where  $\|\dots\|_F$  is the Frobenius norm and  $Cov(H_i)$  denotes the covariance matrix of outputs in  $i$ -th layer, i.e., element in  $j$ -th row,  $k$ -th column is the covariance (7) between activations of  $j$ -th and  $k$ -th hidden unit in that layer. Diagonal of the covariance matrix is subtracted from it since the diagonal elements correspond to standard deviations of particular units.

Covariance between outputs  $h_i$ ,  $h_j$  with means  $\mu_i$ ,  $\mu_j$  and standard deviations  $\sigma_i$ ,  $\sigma_j$  is given by equation (8):

$$\text{cov}(h_j, h_k) = (h_j - \mu_j)(h_k - \mu_k) \quad (8)$$

And the relation between correlation and covariance is (9):

$$\text{cov}(h_j, h_k) = \sigma_j \sigma_k \text{corr}(h_j, h_k) \quad (9)$$

This means DeCov punishes both correlation and high standard deviation in activations for any neuron that has a non-zero correlation with another neuron. The authors of DeCov mention this issue and remark the effects of a loss dependent on standard deviations are similar to L2 regularization. However, a similar regularization penalty term which does not punish standard deviations can be used (10):

$$DeCorr(H_i) = \|Corr(H_i)\|_F^2 \quad (10)$$

where  $Corr(H_i)$  denotes a correlation matrix of  $H_i$ , analogous to  $Cov(H_i)$ . Full loss function (11) is then formulated as:

$$L(X, Y) = MSE(X, Y) + \lambda_1 \sum_i DeCorr(H_i) + \lambda_2 \sum_i \|W_i\|_F^2 \quad (11)$$

where  $MSE(X, Y)$  denotes mean square error given inputs  $X$  and target outputs  $Y$ ,  $H_i$  denotes outputs of the  $i$ -th hidden layer,  $W_i$  is the weight matrix of the  $i$ -th hidden layer. Unlike the original formulation of DeCov, this loss function allows us to control respective regularizing effects of the L2 weight penalty and decorrelation through the hyperparameters  $\lambda_1$  and  $\lambda_2$ .

#### VI. EXPERIMENTAL SETUP AND RESULTS

The neural network was implemented using Theano [8] python library which handles both gradient calculation and GPU computation.

The tuning process which led to choosing parameters reported below was based on four original chunks of training data. We trained on three chunks and evaluated on the fourth, repeating the process four times with a different chunk for evaluation. In preliminary tests, we noticed this approach achieved worse performance (measured by AUC) compared to a setup in which all chunks are mixed together and then 75% of data is selected for training. This led us to hypothesize that contents of a single chunk may be sharing similarities which

Fig. 1. Observed performance during training on the initial training set (one chunk used for verification, three remaining for training).

TABLE III  
RESULTS OF THE COMPETITION - TOP 10 SUBMISSIONS

Team	AUC
iwannabetheverybest	0.80185414
hieuvq	0.799223
johnpatcha	0.79895085
vz	0.79733467
<b>jj</b>	<b>0.79706854</b>
karek	0.79684963
podludek	0.79657371
akumpan	0.79653594
iran-amin	0.79636944
basakesin	0.79617152

would not be present between training and test data and the better result achieved with mixed chunks may be artificially inflated. Therefore, we decided to avoid mixing chunks during the parameter tuning. The results of training the tuned network on the initial training set can be seen in Fig. 1.

The size of the minion representation returned by the autoencoder network was set to 20, which resulted in overall size of the vector representing a game state equal to 182. Autoencoder was trained with hyperparameters  $\lambda_0 = 10$ ,  $\rho = 0.01$ , for 100 epochs on all minion data from both training and test sets.

The neural network used for result prediction was 5 layers deep, with hidden layers of size 128, 64, 32, 16 and a single output neuron. Hyperbolic tangent activation was used in hidden layers and logistic sigmoid in the output layer. The weight of L2 penalty term  $\lambda_2$  was set to 0.5, while the weight of DeCorr penalty term  $\lambda_1$  was 0.1.

The network was trained using adaptive gradient [9] (initial learning rate 0.05) for 100 epochs, although the results were saved for 20-th, 40-th, 60-th and 80-th epoch. All results were

uploaded and the one with the best performance on the test set (60 epochs) was chosen as the final submission. The final results of the competition are shown in Table III.

## VII. CONCLUSIONS

As a submission to AAIA '17 data mining competition, we proposed a neural network approach to evaluation of game states for the collectible card game Hearthstone. Sparse autoencoder was used to encode minion data, and a deep neural network was employed to obtain the evaluation of a game state. Additionally, we regularized the network with a novel approach, based on adjusting an existing regularization method DeCov to allow more control over the training process through parametrization. The solution placed 5th on the final leaderboard of the challenge.

The main weakness of our method was not accounting for unique effects which are not expressed through numerical properties and appear in the test, but not training data. An example of such effect is the Northshire Cleric card, a minion which allows its owner to draw a card whenever a minion is healed. It is a complex interaction which is not expressed in any way in a contextless game state description. Evaluation of such special abilities and their effect on gameplay cannot be easily achieved through a machine learning model alone. It would require either an extended set of training data or employing additional Monte Carlo simulations in the process of training and evaluation of the neural network.

## ACKNOWLEDGEMENTS

We would like to thank Silver Bullet Solutions and Knowledge Pit for providing the simulation data and a platform for the competition.

# Multi-model approach for predicting the value function in the game of Hearthstone: Heroes of Warcraft.

Alexander Morgun

Email: alexander.morgun.usu@gmail.com

**Abstract**—This document describes the problem presented at AAIA'17 Data Mining Challenge and my approach to solving it. In terms of reinforcement learning the task was to build an algorithm that predicts a value function for the game of Hearthstone: Heroes of Warcraft. I used an ensemble of 85 models trained on different features to build the final solution which scored the 36th place on the final leaderboard.

**Index Terms**—data mining competition; classification; ranking; feature engineering; algorithm composition; hearthstone;

## I. INTRODUCTION

IN THE RECENT time, there are many pieces of research about applying machine learning algorithms to video games. The most famous of them led to the creation of a learning model for playing Atari 2600 games [1]. This work was followed by many others, including the ones about Starcraft [2] [3] [4] and DotA [5] [6]. In summary, the main point of these works is developing new machine learning approaches which can be applied to other areas such as algorithm trading [7] or robotic manipulation [8] later. Following this trend the task of AAIA'17 Data Mining Challenge was to create an efficient prediction model which would help in building an agent capable of playing the game of Hearthstone: Heroes of Warcraft.

### A. Game description

Hearthstone: Heroes of Warcraft is a turn-based card video game. It is played by two players. Each player uses his own deck of 30 cards. The final goal of each player is to destroy the opponent's hero by setting his health points to zero. To do so each turn players can play cards limited by fixed amount of mana crystals. There are three types of cards:

- Minions - creatures that can be placed on the game board. Minions can attack enemy minions and the hero.
- Spells - single-use cards that cause various effects.
- Weapons - cards that allow the player's hero to attack enemy minions trading health for board advantage.

In addition, minions can have different abilities. The most notable of them is *taunt*. Players minions cannot attack enemy hero until there are enemy minions with taunt on the board.

Complete rules can be found on the official site [11].

### B. Problem statement

The task of AAIA'17 Data Mining Challenge was to predict the probability of player's victory. The metric used for the

TABLE I

COMPARISON OF THE LOCAL CROSS-VALIDATION TO THE PUBLIC LEADERBOARD RESULTS. WE CAN SEE THAT AN IMPROVEMENT IN THE CROSS-VALIDATION RESULTS DOES NOT RESULT IN A BETTER SCORE ON THE PUBLIC LEADERBOARD AND CANNOT BE USED AS A RELIABLE WAY OF VALIDATION.

Local validation	Public leaderboard
0.883	0.788
0.837	0.7926
0.877	0.7924
0.810	0.7842
0.816	0.7754
0.824	0.7646
0.8125	0.7819

evaluation was the ROC-AUC metric [9]. We can see that this probability can be used as a value function for building an agent capable of playing the game [10]. Each provided game state got data about minions played by player and opponent, cards in player's hand and state both of the heroes. Information about active secrets and the history of played cards was unavailable.

### C. Related Work

Hearthstone: Heroes of Warcraft is not a well-studied environment. There are very little scientific publication about applying machine learning methods to this game [16]. This could be explained by the fact that the game's license agreement [17] explicitly prohibits the use of bots and modification of the game files. Regardless of this fact bots exist in the game but there is no publicly available description of their algorithms.

## II. THE PROPOSED SOLUTION

### A. Local validation

I used 5-fold cross-validation stratified by target labels. This method helped me in choosing hyperparameters for each algorithm but it was not very correlated with the public leaderboard. Because of that, I choose my final solution based on its public leaderboard score. My validation scheme was flawed because of the information leakage between train and test folds. This leakage was caused by states from the same game appearing in the train and test folds.

### B. Bagging

Because of the technical limitations, I could not train models on all provided data so I used a technique similar to the bagging [14]. First, I created multiple different subsets of the training data by sampling randomly the examples, trained separate instances of the same model on this subsets and got a number of finally different models which predictions could be combined afterwards. Random subsampling allowed the final composition to use information from the whole dataset.

### C. Composition methods

Due to unreliable local validation results, I decided to use a simple averaging instead of more complex techniques like stacking and blending. The idea was that I did not want to favor any algorithm because I did not know its true quality so I averaged highly correlated answers before final averaging to avoid higher weights of them in the final result. I used two methods of averaging [13]:

1) *Averaging of probabilities*: I calculated the arithmetic mean of probabilities returned by all models.

2) *Rank averaging*: ROC-AUC is a ranking metric and correct ordering of test states is more important than predicting precise probabilities. Averaging ranks instead of probabilities helps with different calibration of classifier probabilities.

### D. Models

1) *Tree-based models*: Most of the used models were XGBoost tree ensembles [15]. I also used one random forest.

2) *Linear models*: I used two kinds of linear models: linear classifier trained by stochastic gradient descent with log loss and multilayer perceptrons with different numbers of hidden layers and neurons.

### E. Features

1) *Baseline features*: Features provided by competition hosts was used to train baseline models and measure the quality of other features I tried. My first model was the XGBoost model trained on these features. Leaderboard scores showed that rank averaging of a few XGBoost models with different maximum tree depth performs better than the single best one (0.7926 vs. 0.788) and rank average performs exactly the same way on the public leaderboard but slightly worse on the local validation. Bagging improved result of this modest even further so I decided to use such composition of bagging plus rank averaging of three XGBoosts with a different maximum depth of the trees. I ended up using three instances of such blocks trained on different features.

2) *Additional handcrafted features*: I extracted a few more features from the provided game states based on my knowledge of the game and intuition.

- player.hand.hp calculated as sum of minion health only. For some reason in baseline features this sum included durability of weapons in hand.
- opponent.played.taunts
- opponent.played.total\_taunts\_hp
- opponent.played.max\_taunts\_hp

- opponent.played.poisonous
- player.played.taunts
- player.played.total\_taunts\_hp
- player.played.max\_taunts\_hp
- player.played.poisonous
- opponent.played.possible\_attack - sum of attack for minions with flag "can\_attack"
- player.played.possible\_attack
- player.card\_advantage as difference between number of cards left in player deck and in opponent deck.
- player.hand.nOfPlayableSpells
- player.hand.nOfPlayableMinions
- player.hand.nOfPlayableWeapons
- opponent.total\_weapon\_damage

$$\begin{aligned} \text{opponent.total\_weapon\_damage} = \\ \text{opponent.hero.attack} \\ \cdot \text{opponent.hero.weapon\_durability} \end{aligned}$$

- player.total\_weapon\_damage

Minions with taunt ability basically serve as additional hero health so the next group of features is linear combinations of hero health, total attack of enemy minions and total health of player minions with taunts. These features were supposed to help tree-based and we can see that their importance is quite high.

- player.max\_hp\_danger

$$\begin{aligned} \text{player.max\_hp\_danger} = \\ \text{player.hp} \\ + \text{player.armor} \\ + \text{player.played.total\_taunts\_hp} \\ - \text{opponent.played.attack} \end{aligned}$$

- player.current\_hp\_danger

$$\begin{aligned} \text{player.current\_hp\_danger} = \\ \text{player.hp} \\ + \text{player.armor} \\ + \text{player.played.total\_taunts\_hp} \\ - \text{opponent.played.possible\_attack} \end{aligned}$$

- opponent.max\_hp\_danger

$$\begin{aligned} \text{opponent.max\_hp\_danger} = \\ \text{opponent.hp} \\ + \text{opponent.armor} \\ + \text{opponent.played.total\_taunts\_hp} \\ - \text{player.played.attack} \end{aligned}$$

- `opponent.current_hp_danger`

$$\begin{aligned} \text{opponent.current\_hp\_danger} = & \\ & \text{opponent.hp} + \text{opponent.armor} \\ & + \text{opponent.played.total\_taunts\_hp} \\ & - \text{player.played.possible\_attack} \end{aligned}$$

I also calculated WOE (Weight of Evidence) for hero classes. For categorical feature  $f$ , object  $x$  and target label  $y$

$$WOE(f)(x) = P(y(x) = 1 | f(x)).$$

WOE can be calculated for a set of categorical variables by considering all their combinations as separate categories. Basically  $WOE(\text{player.hero\_card\_id})$  is a win rate of player class,  $WOE(\text{opponent.hero\_card\_id})$  is a loss rate of opponent class and  $WOE(\text{opponent.hero\_card\_id}, \text{player.hero\_card\_id})$  is a probability that player class will win against opponent class. WOE can be estimated from dataset  $X$  using the formula

$$WOE(f)(x) = \frac{K \cdot \text{mean} + \alpha \cdot \text{global\_mean}}{\alpha + K}$$

where

$$\begin{aligned} K &= |\{i | i \in X \& y(i) = 1 \& f(x) = f(i)\}| \\ \text{mean} &= \frac{K}{|\{i | i \in X \& f(x) = f(i)\}|} \\ \text{global\_mean} &= \frac{|\{i | i \in X \& y(i) = 1\}|}{|X|} \end{aligned}$$

and  $\alpha$  is a regularization parameter. I used  $\alpha = 50$ . In the result for each category we obtain a single WOE feature in contrast with multiple features produced by one hot encoding. This single feature is highly informative and tree-based models can utilize it effectively. This technique is well known among Kaggle [12] participants and was popularized in the Russian data science community by Stanislav Semenov.

- $\text{player.class\_score} = WOE(\text{player.hero\_card\_id})$
- $\text{opponent.class\_score} = WOE(\text{opponent.hero\_card\_id})$
- $\text{class\_pair\_score} = WOE(\text{opponent.hero\_card\_id}, \text{player.hero\_card\_id})$

With addition of this features, I trained three groups of models. First of all the second ensemble of XGBoost described above. Then a group of linear models was added. Due to data size, I used stochastic gradient descent for training and bagging with result averaging to diminish randomness of the final prediction. Lastly, I added a random forest because it is usually a safe bet to try it.

Fig. 1. The 20 most important features from one of XGBoost models. We can see many handcrafted features at the top.

3) *WOE features*: All features listed above can be treated as categorical and I calculated WOE for all of them. For example  $\text{player.hp}$  is an integer feature with values between 1 and 30 so we naturally get at most 30 categories. Using this features I trained the third block of XGBoosts.

4) *Logarithmed features*: Sometimes linear models perform better on logarithmed data. So I calculated  $\log(1 + x)$  for positive-valued features and replaced each of other features with two new ones:  $\log(\max(x, 0) + 1)$  and  $\log(\max(-x, 0) + 1)$ . Using these new features I trained a group of linear models in the way described earlier. Because of the good result of these models on the leaderboard, I also trained a number of multilayer perceptrons with a different structure using the same features. There is no point in training separate XGBoost using this features because logarithm cannot change the ordering of feature values.

#### F. Final composition

At the end, I averaged ranks of all models from the previous steps. I also added two particular groups of XGBoost models directly to the final average because of the low correlation between their predictions and results of the corresponding XGBoost blocks.

### III. CONCLUSION

During this work I constructed a number of features, used them for training multiple models and combined predictions of these models in order to improve quality of prediction over a single model. Almost all described methods can be applied to an arbitrary classification problem. Averaging method is simple enough to be safe from overfitting but requires manual selection of uncorrelated classifiers. It allowed to build model

Fig. 2. Histograms of the feature "opponent.played.hp\_max" before and after the logarithm transformation.

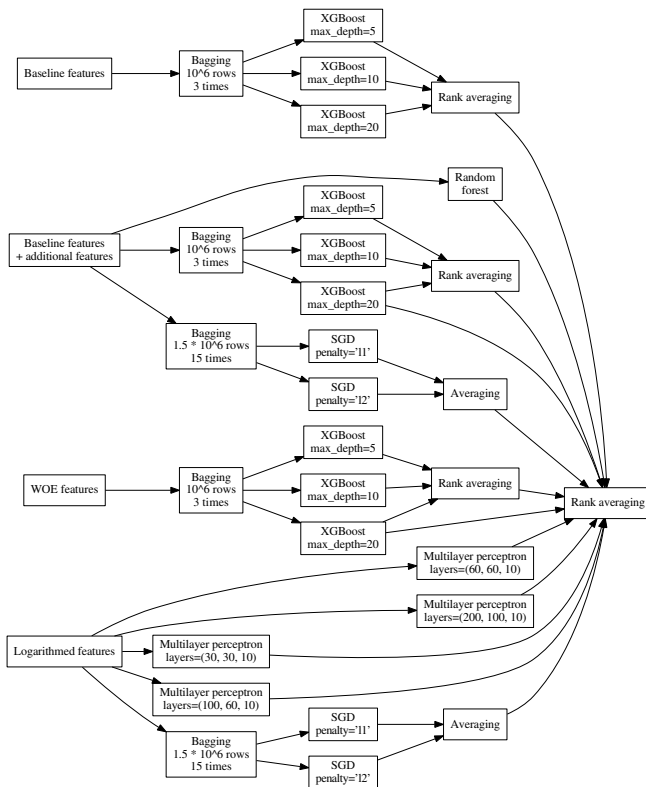

Fig. 3. Final composition scheme

that performs well even without reliable way of local validation. Problem-specific feature engineering also improved final score.

**Abstract**—This paper describes two approaches to the AAIA’17 Data Mining Challenge. Both approaches are making extensive use of domain/background knowledge about the game to build better representation of classification problem by engineering new features. With newly constructed attributes both approaches resort to Artificial Neural Networks (ANN) to construct classification model. The resulting solutions are effective and meaningful.

## I. INTRODUCTION

The past three years saw an increased interest in online collectible card games. One of the most popular games of this type is Hearthstone® created by Blizzard Entertainment [1]. Because of its popularity and simplicity the game has gained attention in the streaming and e-sport community. Although the most popular game modes involve competition between two human players, it’s possible to play against AI. Unfortunately, the AI is no match for a skilled player. Hence the question of improving computer players arose. In order to achieve the best results, players have to be able to judge possible outcomes, predict consequences of their actions, take into account random factors (after all, it’s a card game and the randomness is embedded into its core), and much more. The decisions can be reduced to classifying possible plays or game states as good or bad and these predictions may then guide the player to choose the best possible play. In connection with the International Symposium on Advances in Artificial Intelligence and Applications (AAIA’17) a competition was organised with use of KnowledgePit platform [2]. The goal of this competition – called AAIA’17 Data Mining Challenge – was to estimate the state of the game and decide which player has a higher chance of winning.

Hearthstone is a turn based card game where the goal is to reduce opponent hero’s health to zero. Players may play *spells*, which have an instant effect or *minions* that remain on the *battlefield*. Cards are played from hand and a new card is drawn from deck at the beginning of each turn. The deck consists of 30 cards (see Figure 1) and each card may be present in at most two copies. Hand size is limited to 10 and board size (number of minions present at any point) is limited to 7 for each player. The enemy hero may be damaged using minions and some spells. Minions have certain *attack* and *health*. All cards have cost which is paid in *mana crystals*. At the beginning of each turn the current player refreshes all their previous mana crystals (thus regaining mana they spend

in the previous turn) and gets a new one with the upper limit of 10 mana crystals per player.

The input data represented various states from a large collection of games played between AI players. Game states consist of both players’ health, armour, spell damage bonus, remaining deck size, number of mana crystals, hero class and a brief description of each card on hand (current player only) and on the battlefield (both players). This description contained card’s name, cost, and its attack, health, and some special traits, if applicable. Because some card effects weren’t described, we had to resort to card databases and our knowledge of the game to ensure that all aspects are covered.

The overall goal in the competition was to predict which of two players has a higher chance of winning in the given state of the game. The problem was an example of a binary classification. Solutions were compared by measuring the Area Under Curve (AUC) for the Receiver Operating Characteristic (ROC) curve [3]. This metric allows for interpretation of classification model results in terms of trade-off between true positive and false positive rates. The metric was chosen so that false positives would be eliminated as they have a potentially disastrous effect on the outcome - incorrectly classifying a bad play as a good one may result in choosing that play and losing in the final outcome.

This article describes some of the features used by the authors in their submissions to the competition. Two different approaches are outlined - one employed by team consisting of Szymon Dziewiątkowski, Sebastian Jaszczur, and Mateusz Śmiech (team “jaszczur”) and the other created by Przemysław Przybyszewski (team “pp332493”). Both teams independently developed interesting features and the end product - the classifier - was somewhat alike in both cases as it was based on an Artificial Neural Network (ANN). The similarities may be seen in utilisation of domain knowledge to estimate card value (or usefulness) to allow for more precise classification. The final score for team “jaszczur” was AUC of 0.7930 which placed them 35<sup>th</sup> place and AUC of 0.7950 for team “pp332493” which came 18<sup>th</sup>.

This paper describes solutions developed by both teams. First, the data processing and feature engineering on which both teams put a particular emphasis in their work is described (Section II). Then there is a description of models used in final solutions along with other tested approaches (Section III) and the most interesting findings and conclusions (Section IV).

Fig. 1. Three examples of Hearthstone® cards. Left to right: Acidic Swamp Ooze, Flamestrike and Core Hound. The information contained in each card: **Acidic Swamp Ooze** - the lower left corner contains Attack (3) and the lower right corner contains Health (2). Presence of these two traits indicate that it's a minion. The 2 in the blue hexagon in the upper left corner indicates mana cost of the card. The Battlecry is an effect that takes place immediately before the minions enters the battlefield after being played from hand. **Flamestrike** - lack of Attack and Health indicate that it's a spell. Its devastating effect takes place immediately after casting it. The blue edge indicates that it's a class card, available only to Mages, as opposed to grey-bordered cards which are neutral and available to all classes. **Core Hound** - 7 mana, 9 Attack, 5 Health minion that is additionally a Beast - a minion subtype. Cards belonging to the same subtype usually synergise well with each other. Hearthstone® card designs are property of Blizzard Entertainment.

## II. FEATURE ENGINEERING

The contestants were given two distinct forms of data. The first and more basic one was raw data in JSON format, where an entry was a single game state of a particular game. The organisers processed and aggregated this data in tabular Comma Separated Value (CSV) format. The CSV set consisted of 45 attributes, which are shown in the Table I below (their names are rather self-explanatory).

The training dataset contained 3,150,000 labeled samples. Organisers also provided 750,000 unlabeled samples, of which 5% was used for validation visible to participants during the competition and the remaining 95% was used for final evaluation

Although the CSV dataset contained several useful attributes, the JSON format proved to be much more informative, a quality that was exploited by both teams in their solutions. When connected with domain knowledge, that raw data was especially helpful in gaining an advantage in the competition.

The following subsections show the two approaches to construction of new, meaningful features as applied by the respective teams.

### A. Approach of the team "jaszczur"

The majority of work was devoted to the feature engineering based on raw JSON data. The aim was to use those features later on in an Artificial Neural Network (ANN), therefore only numeric features were investigated. From the input data 796

input columns were extracted, corresponding to 29 different features. A single column represents a single value of a feature.

The major limitation of this approach is the number of columns which had to be constant for every sample. Unfortunately, this doesn't reflect the structure of game states, as those can have a variable number of cards on the table or in hand. To take care of that a maximal possible number of columns per feature was introduced. For example there were 14 columns created for a feature describing minions' attack on the battlefield, as there is an in-game limit of 14 minions on the table, 7 for each player.

Some values were undefined. This happened mostly in cases when a feature was applied to multiple cards (e.g. attack of each minion on the battlefield). In such cases an additional column was added for every possible undefined column. This new column took binary values and represented whether the corresponding value was defined. All undefined values were then replaced with zeroes.

There are cases with multiple possible options with no obvious numeric interpretation, like Hero Class. In such cases an adequate number of binary features was defined, e.g., 18 columns for Hero Classes, one for each player/class pair, with two corresponding features set as 1.

**Tiers and values:** One of Hearthstone's game modes is Arena. It differs from Constructed mode profoundly, mostly in terms of strategies and decks that yield best possible outcomes. These two modes share the card set, of which Standard (cards

TABLE I  
ATTRIBUTE NAMES IN THE TABULAR PART OF DATA SETS.

gamestate_id	decision	turn	opponent.armor	opponent.attack
opponent.hero_card_id	opponent.weapon_durability	opponent.special_skill_used	opponent.hp	opponent.crystals_all
opponent.crystals_current	opponent.deck_count	opponent.fatigue_damage	opponent.hand_count	player.crystals_all
player.armor	player.attack	player.hero_card_id	player.hp	player.special_skill_used
player.weapon_durability	opponent.played_minions_count	player.crystals_current	player.deck_count	player.fatigue_damage
player.hand_count	player.played_minions_count	opponent.played.nOfCards	opponent.played.attack	player.hand.nOfPlayable
opponent.played.hp_current	opponent.played.hp_max	player.played.nOfCards	player.played.attack	player.played.crystals_cost
player.played.hp_current	player.played.hp_max	player.hand.nOfMinions	player.hand.nOfSpells	player.hand.nOfWeapons
player.hand.nOfCards	opponent.played.crystals_cost	player.hand.attack	player.hand.crystals_cost	player.hand.hp

used in the competition) is a small (ca. 16%) subset. In Arena instead of creating the deck from all available cards, players draft cards, i.e., the system chooses three random cards, of which the player selects one that will be added to the final deck. This process is repeated 30 times, resulting in the same deck size as in Constructed. Because of this deck-making scheme, Arena is generally considered less synergy-oriented and more value-oriented than Constructed.

Although this is very situation-specific, some cards are generally considered superior (see Figure I). There are numerous tools that help players gauge the value of cards in Arena, one of which is Lightforge [4]. The fundamental differences between Arena and Constructed wane in the light of AI's weak style of play. Having analysed Lightforge's tier juxtaposition, it was decided to utilise it as it is - without adapting it to Constructed.

Lightforge divides the cards into the following tiers: *Great*, *Good*, *Above Average*, *Average*, *Below Average*, *Bad*, and *Terrible*. They are referred to as tier categories. Furthermore, it also assigns numerical values to cards so that they can be compared within tiers. They are referred to as *tier values*.

For example, for the cards presented in Figure I:

- Acidic Swamp Ooze – tier *Good*. Base stats are standard for its cost but on entering the battlefield it irrevocably destroys the opponent's weapon which costs anywhere from 1 to 5 mana.
- Flamestrike – tier *Great*. It is a costly spell available only for Mages. Serves as an Area of Effect (AoE) card capable of clearing the board. If used properly it is very likely to turn the tide for the player who uses it.
- Core Hound – tier *Bad*. Despite the high Attack, this minion's value is considerably low because of its minute Health.

*Description of attributes used by "jaszczur"*: The 29 constructed attributes were put on the list and ordered with respect to accuracy achieved by Logistic Regression that learned only on that attribute on 750,000 samples with test to validation ratio of 80:20. All features except those annotated with an asterisk (\*) were computed for both players. The annotated ones were created only for the current player because of the limited information available (i.e. we don't know the opponent's hand). There is also a brief explanation of choosing specific features based on authors' Hearthstone experience. The final list of constructed attributes is as follows:

- 1) 0.6569 - Number of cards on the battlefield that with certain cost. Basic set consists of cards of cost between 0 and 8 and 10 (there aren't any cards costing 9 or more than 10). Usually the higher the cost, the better and more impactful the card is, and the more substantial threat it poses.
- 2) 0.6558 - Battlefield state - a single column for every possible card (133 uncollectible and 17 collectible) containing number of copies of this minion on the battlefield. Some cards, like Stormwind Champion or Healing Totem have an additional effect that was not included in the short description the input data provided but have a veritable influence on the game. It was tried to create features tailored to single cards (e.g., Stormwind Champion has greater impact if the board consists of more minions), but initial results were disappointing - the accuracy of 5 of those features combined together was negligibly higher than random guessing.
- 3) 0.6558 - Sum of costs of all minions on the battlefield.
- 4) 0.6512 - Sum of attack of all minions on the battlefield.
- 5) 0.6508 - Attack of every single minion on the battlefield, along with information whether or not it is present.
- 6) 0.6453 - Tier value of each card on the battlefield.
- 7) 0.6432 - Tier category of each card on the battlefield.
- 8) 0.6403 - Number of minions present on the battlefield.
- 9) 0.6396 - Health of each minion on the battlefield. Because minions with 0 health die instantly, there was no need to create additional columns to indicate their presence or absence.
- 10) 0.6307 - Sum and average number of received damage of all minions on the battlefield.
- 11) 0.6227 - Health points of heroes with added armour.
- 12) 0.6193 - Health points of heroes after using hero power.
- 13) 0.6153\* - Tier category of each card on hand.
- 14) 0.5828 - Number of cards in deck, on hand and on the battlefield. For prolonged games this number often represents the advantage a player has. Generally, forcing the opponent to trade multiple cards for your one card gives you an advantage later on. This feature quantifies this advantage in a simple manner but only in the context of opponent's total number of cards.
- 15) 0.5385 - Number of special traits (Windfury, Taunt, Divine Shield etc.) that minions on the battlefield have. These traits help guard the hero and valuable minions

(Taunt), make favourable trades (Divine Shield) or put more pressure on the enemy hero (Windfury). Aggregating them yielded better results because of their rarity - it's uncommon for multiple Divine Shield minions to be present on the board at the same time whereas any two traits are much more likely to occur.

- 16) 0.5359\* - Hand state - a single column for every possible card containing number of copies of this card on hand. It is similar to board state but also includes spells. Some Area of Effect spells (Holy Nova, Flamestrike, Consecration) or so-called hard removal spells may turn the tide for the casting player.
- 17) 0.5252\* - Number of cards costing  $X$  on hand, for every possible value of  $X$  existing in the data.
- 18) 0.5251 - Number of cards on hand.
- 19) 0.5207\* - Tier value of each card on hand.
- 20) 0.5124\* - Sum of costs of all cards on hand.
- 21) 0.5094\* - Sum of damage from spells that can affect the enemy hero (Fireball, Holy Nova, Kill Command etc.) and bonus spell damage (Dalaran Mage, Kobold Geomancer etc.).
- 22) 0.5066 - Fatigue damage.
- 23) 0.5062 - Number of special traits minions on hand have - Charge and Battlecry in addition to those considered by similar feature regarding the battlefield.
- 24) 0.5062\* - The approximate number of possible plays in the current turn, depending on cost of all cards, available mana crystals and number of possible targets. Usually the more choices a player has, the more likely there is a good (or even an outstanding) one.
- 25) 0.5049 - Attack and durability of the currently equipped weapon.
- 26) 0.5017 - Hero class (Mage, Warlock, Shaman etc.).

The remaining three (out of 29) constructed attributes were irrelevant and therefore omitted. Logistic regression ran on the features mentioned above gave a result of 0.7830 AUC.

#### B. Approach of the team "pp332493"

The majority of work of "pp332493" was also spent on the feature engineering part. Apart from the data provided by competition organisers external data from the website HearthPwn [5] was also used. On this website a ranking of decks can be found. Each entry in this ranking consists of deck name, deck type, mana, class, rating, viewcount, comments, and cost. The higher the evaluation score for a deck the higher its chance to win. By knowing the deck name, one could find all the cards it consists of and their respective attributes. Of the deck-related information gained this way only part of the card features, such as mana cost and deck rating, were actually utilised. They were used to generate the 'average card strength' attribute. Only records having rating higher or equal than 60 were taken into account. This value was chosen because decks with this rating were among the 0.5% best decks ever evaluated on this site. As there is no full information about the whole deck of the player and the opponent the approach was to estimate the value of 'strength' attribute for

each minion. These estimates were further summed up in order to get the average strength of the player's and the opponent's played cards as well as the player's hand. Computing the 'strength' attribute for a single minion card was conducted in the following manner:

- 1) Iterate over all decks and retrieve all minions that were present in those decks.
- 2) Iterate over all minions. For each minion create temporary variables 'power\_sum' and 'power\_count' and iterate over all decks. If this minion is in the given deck, then compute its share in a given deck. This share can be represented by the ratio of crystal cost of the minion to the sum of crystals costs of all cards multiplied by the number of appearances of this minion in the deck. Then add the number of occurrences of this minion in the deck to 'power\_count' variable and its percentage share multiplied by the deck evaluation to the 'power\_sum' variable.
- 3) The power of a single minion is computed by dividing 'power\_sum' by 'power\_count'.
- 4) In cases of minions in the training data set, that were not found on the ranking page [5], the median of all computed strengths was taken instead.

Other features that were used in the classification were derived from the data provided for the competition (both tabular and JSON).

*Description of attributes used by "pp332493":* Both provided datasets were used to generate the training data for chosen models. In the feature selection phase attributes first the identifiers that carry no specific information were removed. Those are: 'gamestate\_id', 'opponent.hero\_card\_id', 'player.hero\_card\_id'. The rest of the variables, apart from the decision, is used to create the training data set, as all of them seem to have an influence on the decision value. In the end 41 variables are chosen from this the original 45 in tabular part of data (see Table I).

After checking the part of the data in the JSON format it was noticed, that there are some influential variables that are not present in the tabular data. Those are the special features of a single minion card, such as: Taunt, Charge, Stealth, Freezing, Shield, Poisonous, and Windfury. Sum of each special ability for player's hand and cards played by both player and the opponent are also added to the training data. Additionally, a dedicated variable called 'special' was created. 'special' is derived as a sum of all aggregated special traits. Value of this attribute can be understood as an expression of interaction between the features. Moreover, pair of attributes called 'able\_to\_perform' are generated for both the player and the opponent. Those are binary variables indicating whether a player (or opponent) is able to perform at least one move using the cards that are already on the table. The aforementioned 'average strength' attribute is added to training sample for player's hand and cards played by both adversaries. Features taken both directly from the original data and engineered make the final data set that contains 70 attributes.

### III. CLASSIFICATION MODELS

Both teams experimented with various classification models and at the end selected the one giving the best results on their engineered attributes. Chosen models are described below, followed by a brief description of alternative approaches that were investigated for the purpose.

#### A. Final model of the team “jaszczur”

The best model for constructed attributes turned out to be an Artificial Neural Network [6]. It had 796 inputs nodes, all of which were corresponding to numeric variables that were normalised to have mean of zero and standard deviation of 1. The network consisted of four fully-connected, hidden layers - with 100 neurons in the first and 50 neurons in each of the subsequent hidden layers. The output layer had a single neuron with sigmoid activation.

Neurons in hidden layers used Rectified Linear Unit(ReLU) [7] as the activation function. There was also batch normalisation (see [8]) between each pair of adjacent layers. The overall network error (loss) was calculated as cross-entropy, with batch size of 100 and Adam optimiser [9].

Contestants were provided with 3,150,000 labelled samples, but some of those were from the same games (but different turns). Unfortunately, there was no information about which samples were coming from which game. Because of this, after splitting labelled data randomly into training and validation set, the samples from the same game could go into both sets, what caused the model to recognise specific games instead of general patterns. Because test data was extracted from a completely different set of games, model's result on the validation data turned out to be a really bad predictor of result on test data. The authors were unable to mitigate this problem with training/validation split, so it was decided to use each labelled sample in training only once (that is, there was a single training epoch) to prevent overfitting (recognising specific games). This approach also yielded the best result on 5% of test data available during competition.

Neither L1 nor L2 regularisation yielded better results. That is probably because each sample was shown only once and because batch normalisation already regularises the network.

The model was implemented in Python/Keras [10] with TensorFlow backend [11]. First prototypes and some of data processing were done using scikit-learn module [12].

Training this model took about 20-30 min. to train, out of which at least 15 were devoted to loading the data. It was run on GPUs and total RAM used was about 40GB. The final score for neural network based on constructed attributes (see Subsection II-A) on the test set was AUC of 0.7930 which placed this solution on 35<sup>th</sup> position.

#### B. Final model of the team “pp332493”

The chosen model belongs to the class of ensemble-based classifiers, which is a soft voting classifier consisting of three other classifiers. First of them is logistic regression with the default value for the inverse of the regularisation strength. Second one is an ANN with ReLU activation function and

three hidden layers with 25,15, and 5 neurons, respectively. Last but not least is an ANN with logistic activation function and three hidden layers arranged as previously (25,15,5 neurons). Both ANN models used the Adam optimiser, the L2 regularisation term 0.0001, and the initial learning rate of 0.001. The attempt to run an exhaustive search over a range of possible values for the regularisation terms for those three models was made but finally abandoned due to excessive computational cost. Additionally, to better suit ANN training, the data was normalised by removing the mean and scaling to unit variance which is recommended as a measure to better fit the network model.

The model selection was based on the principle of getting the AUC score as high as possible at the same time minimising its standard deviation. The estimation of the score were derived using the 10-fold cross-validation on the training data set. The score for the finally chosen model was AUC of 0.79652 with deviation of 0.01283. The final model was trained on the training data set, which consisted of two million observations. Predictions made on the test set, which consisted of 750,000 observations, allowed to achieve the AUC score of 0.79508952, which is a bit below the validation result. The discrepancy between validation and actual testing result may suggest that the chosen model was also a bit overfitted.

Model construction and data processing were done in Python using the scikit-learn module [12]. Training of this model took up to 30 min., two-thirds of which was spent on loading the data. It was run on the quad-core CPU and total RAM used was about 16GB. The final score for this classifier based on constructed attributes (see Subsection II-B) on the test set was AUC of 0.7950 which placed this solution on 18<sup>th</sup> position.

#### C. Other classification models tested

Both teams have tested several classification algorithms before arriving at the final solution presented above. The alternative classifiers checked were mostly drawn from the tool box of the scikit-learn [12] library for Python and associated tools.

Team “jaszczur” has tried to use scikit-learn methods such as: K Nearest Neighbours (k-NN), Support Vector Machines (SVM), Decision Trees, Random Forest, and Extra Trees. Unfortunately, k-NN and SVM models could not compare with ANN and tree-based classifiers in this case.

The majority of testing was related to scikit-learn's methods RandomForestClassifier and ExtraTreesClassifier. Both of them resulted in overfitting in addition to excessive memory (RAM) consumption. The best Random Forest solution trained on 1,500,000 examples with maximal tree depth of 23 consisted of 20 trees and achieved AUC = 0.7589. Higher depths show an increase in accuracy and AUC on our validation data, but with a simultaneous decrease in AUC on organisers' test data. Members of the “jaszczur” team were unable to tweak parameters of scikit-learn's DecisionTreeRegressor to yield result above 0.71 AUC.

Alternative models that were investigated and tested by “pp332493” team included Logistic Regression, AdaBoost, Extra Trees, and Artificial Neural Networks with higher number of hidden neurons in each layer than the finally chosen one. Additionally, a Voting Classifier – which consisted of a mixture of previously mentioned ones – was trained and validated. Most of these alternative models were not classifying the data well enough compared to the finally chosen solution, often not reaching 0.79 for AUC in the cross-validation phase. Only the ANN with more hidden neurons yielded the value of AUC metrics nearing 0.8 on 10-fold cross-validation. Unfortunately, checking this model on the provided test set clearly demonstrated that it was significantly overfitted.

#### IV. INTERESTING FINDINGS AND CONCLUSIONS

Some results from the previous section (Section III) are non-trivial and may indicate interesting aspects of the game. Below are the most probable consequences and authors’ explanations of the aforementioned results.

- Features derived from hand state have on average 0.12 less accuracy than their equivalents derived from battle-field state. This is due to the fact that the cards that have been played and are unaffected by summoning sickness (inability to attack in turn they are played) have more measurable impact on the game than cards that are yet to be played because of mana limitations.
- It’s widely recognised that some classes have favourable, neutral, and unfavourable matchups. For example Hunters are more likely to lose to Priests and Warriors (due to their healing ability) – unfavourable matchup, but more likely to win with Warlocks (due to their utilising life as a resource) – favourable matchup. Using just class options for both heroes yielded 0.5017 accuracy – negligibly more than random guessing. This shows that either Basic set is well-balanced or that the AI didn’t utilise the class they played to its full potential.
- Features revolving around card tier or value yielded scored on average 0.01 worse than those based solely on mana cost. Given that a lot of experienced players agree that the tiers and values we employed are a good estimate of card usefulness, this indicates that cost of cards is well-balanced and reflects their strength.
- Minions’ attack is slightly more significant than their health. Experienced Hearthstone players disagree with this result. Health is a little bit more important as it potentially allows for multiple trades and card advantage. This result shows that the AI played too aggressively and could probably be improved by making more trades instead of prioritising damaging the enemy hero.
- Spells have considerably lower impact on game than minions. There are two possible explanations for this result. Although the total number of spells is similar to the total number of minions, all spells are class-dependent. Because there are nine classes, the number of spells to choose from after a class has been selected is an order of magnitude lower than the number of available minions.

Additionally the variance in usefulness of spells is higher, resulting in very few good spells for each class. This, in turn, affects their participation in deck (spell to minion ratio) meaning high number of samples with features corresponding to those spells set to zero (no such spell drawn). Another explanation is that the provided AI didn’t learn how to utilise these spells to their full potential.

Given the final assessment of models on test dataset it can be said that they generalise quite well. The difference between the cross-validated AUC score and that computed on the test dataset was almost negligible. It is apparent that feature engineering and domain knowledge played a major role in the final outcome and that they greatly improved the solutions. Although the differences were profound, the non-obvious affinity led to similar conclusions and results. Leaving implementation details aside, resorting to the opinion of the game community which was shared between the teams led to significantly better outcome and some interesting findings. Thus, it appears mandatory for designers of AI in games, Hearthstone® being just a good example, to factor-in the knowledge accumulated by gamers’ communities.

**Abstract**—This paper introduces an ensemble model that solves the binary classification problem by incorporating the basic Logistic Regression with the two recent advanced paradigms: extreme gradient boosted decision trees (xgboost) and deep learning. To obtain the best result when integrating sub-models, we introduce a solution to split and select sets of features for the sub-model training. In addition to the ensemble model, we propose a flexible robust and highly scalable new scheme for building a composite classifier that tries to simultaneously implement multiple layers of model decomposition and outputs aggregation to maximally reduce both bias and variance (spread) components of classification errors. We demonstrate the power of our ensemble model to solve the problem of predicting the outcome of Hearthstone, a turn-based computer game, based on game state information. Excellent predictive performance of our model has been acknowledged by the second place scored in the final ranking among 188 competing teams.

## I. INTRODUCTION

RECENT Internet of Thing revolution coupled with the emergence of big data technologies present new opportunities to the process of automated data-driven decision making, especially in the presence of multiple sources and different types of data that normally require professional human skills and experience to process. As more and more data becomes available, further gains in classification performance are becoming possible but depend on the ability of the model algorithm to better reconstruct the relationship function between the inputs and outputs (targets) while dealing with typically noisier and more conflicting evidence and much larger computational overhead.

Many existing state-of-the-art Machine Learning models successfully take advantage of this extra evidence to reduce either bias (Deep Learning) or variance (Extreme Gradient Boosted Decision Trees) component of classification error, but fail to reduce both to the extent that would offer significant boost in predictive performance and its confidence. Besides, these models, typically implementing  $\geq O(n^2)$  learning algorithms simply lack scalability and often are intractable when faced with big data sizes that limit their utility down to small samples and typically exclude them from real-time apps.

The model we introduce in this work aims to address above-mentioned gaps and tries to significantly reduce both bias and variance at manageable and scalable computational footprint.

We start our model introduction from a proposition of ensemble model along with rules that govern feature selection and model decomposition. Then, we introduce a simple classification training structure that uses robust but simple linear base classifier to leverage decomposed and ensemble based training to achieve the trade-off between bias and variance reduction with virtually no impact on the computational complexity of the original model. Both of our proposed methods can be used either independently or complementary to each other. To evaluate the performance of our proposed solutions, they were applied in a competition to predict the likelihood of winning a turn-based computer game: Hearthstone [1], given intra-game states for both players of the game [2]. The second place our model scored in this competition has objectively proven its excellent design and predictive performance capabilities which surpassed other academic state-of-the-art solutions and off-the-shelf commercial tools proposed by 188 competing teams from all over the world. In summary, our paper brings the following two main contributions.

- An ensemble model that incorporates Logistic Regression, XGBoost and DL to solve the binary classification problem, along with the capability to decompose the model training along specially selected feature subsets.
- A hierarchical decomposition and aggregation scheme for highly scalable and robust classification and a discussion of how to use it in the case of logistic regression model.

The remainder of the paper is organized as follows. In Section II, we introduce related work. In Sections III and IV, we present our proposed ensemble model and the training scheme, respectively. In Section V, we demonstrate an application in a objectively evaluated competition setup as a case study for our proposed solutions. Finally, we draw some concluding remarks in Section VI.

## II. RELATED WORK

In this section, the machine learning approaches used in our model, specifically, Logistic Regression, XGBoost and Deep Learning, are briefly introduced.

### A. Logistic Regression

Logistic regression is a statistical method for regression analysis to describe the relationship between one dichotomous

dependent variable (outcome) and one or more independent variables (predictors or features). Binary logistic model can be used for estimating the probability of a binary response based on predictors and gain insights on the factors that increase the probability of a given outcome. Logistic regression has been widely used in various areas, e.g., assessing injury mortality or severity for patients [4], predicting votes based on their characteristics such as age, income, sex, race, state of residence, previous votes, etc. [5], estimating probability of failure in various processes, systems or products [6], predicting customers' propensity to purchase a product or cease a subscription in marketing applications [7], etc..

### B. Bagging and Boosting Methods

Bagging and Boosting are powerful meta-algorithms used in machine learning to improve prediction accuracy of classification models by combining a set of weak classifiers with poor performance, unstable predictions, and high rate of misclassification error, into a strong and robust "wide margin" predictive model. Bagging can decrease the variance of unstable procedures and prediction outcomes, while boosting is an effective way to reduce prediction bias [8], [9]. Gradient boosting (GB) is a version of boosting method, which like in standard boosting uses an ensemble of weak prediction models, typically decision trees, yet manages to achieve deeper performance gains beating many other state-of-the-art predictors in a wide range of commercial and academic applications [10]. XGBoost, based on Extreme Gradient Boosting model [11], is an implementation of the gradient boosted decision trees algorithm with a goal to push the limit of computations resources for boosted tree algorithms [12], which recently has been used by many winning teams of a number of machine learning competitions, e.g. [13], due to its advantages of fast processing speed and high prediction accuracy.

### C. Deep Learning

Deep Learning refers to a class of machine learning techniques and architectures, where many layers of non-linear information processing stages in hierarchical architectures are exploited for pattern classification and for feature or representation learning [14]. Unlike the conventional classification algorithms which heavily rely on feature extracting techniques, deep learning techniques could characterize the high-order correlation properties of the observed or visible data for pattern analysis or synthesis purposes, and/or characterize the joint statistical distributions of the visible data and their associated classes, which learn feature representations without the need of labeled data referring to unsupervised feature learning, and thus avoid substantial effort on hand-designing features [14]. In recent years, DL techniques have gain increasing attention and popularity due to drastically increased chip processing abilities (e.g. GPU units), significantly lowered cost of computing hardware and recent advances in research of machine learning and signal/information processing. They have been successfully applied in various areas, e.g. visual object recognition, image processing, speech recognition, hand-

writing recognition, natural language processing, information retrieval, etc. [14].

In the subsequent sections, we will introduce the proposed ensemble model that combines the advantages of Logistic Regression, XGBoost and Deep Learning. We will then demonstrate how it is able to reduce both variance and bias components of the classification error that enables to achieve improved and consistent prediction accuracy when solving binary classification problems.

## III. ENSEMBLE MODEL

Even though ensemble model is not a new concept since it has been extensively used and reported to win top prizes in many recent data mining competitions, there is no clear instruction of how to build a reliable ensemble model that would consistently outperform other predictors. In this part, we propose a general approach that tries to addresses this gap. However, before going into details of our proposal, we would like to emphasize a couple of important points for building an ensemble model as follows.

- Different sub-models in the ensemble model could be trained with different sets of features and examples to leverage the maximum benefits of the ensemble. Predictive performance improvements achieved by different models trained on the same features are possible although limited by the inability of the predictive model to match the evidence it is most compatible to work with.
- The sub-models can be aggregated in a number of ways, of which the most popular ones are averaging and stacking. By averaging, the final result is simply generated by getting the average from sub-model results. Stacking requires a more comprehensive train in the next layer using the results of sub-models.

Our proposed ensemble model in this paper focuses on how to split the feature set into sub-sets for training with different sub-models. As a result, it works with any method for combining results from sub-models. In our approach, we first perform feature selection to obtain a set of useful features for training models. Assuming that a total number of  $f$  features are selected and an ensemble model is built with  $n$  sub-models, two basic rules to select features for training the sub-model are described as follows.

- The set of  $f$  features are split into subsets, each of which contains  $f'$  number of features, defined as  $f' = k \times \frac{f}{n} \pm t$  where  $k$  and  $t$  can be any value between 1 and  $n$  and decided on the course of cross-validation performance evaluation. Feature selection is applied to choose features for each subset.
- Each set of features should be used in at least two sub-models to increase the accuracy of the ensemble output.

It is interesting to note that our proposed approach for splitting feature set in training sub-models is actually similar to the cross-validation method when we leave a subset of data for validation. By splitting the feature set and training data in this way, we can leverage the maximum benefits of training

sub-model separately and obtain the best ensemble result from the combination of sub-models' results.

#### IV. HIERARCHICAL DECOMPOSITION AND AGGREGATION

The model introduces hierarchical training structure  $S$  involving decomposition and/or aggregation of the training data into exclusive sets of examples either along distinct values of one or more feature combinations or randomly along  $k$ -exclusive subsets of examples. The training structure upon the dataset  $X$   $S_D^P(X)$  is defined by two parameters: partitioning criterion  $P$  and the degree of partitioning  $D$ . Partitioning  $P$  can proceed either independently of the feature values ( $P = 0$ ) or along all unique values of the feature  $F_P$ . For data independent partitioning ( $P = 0$ ), the degree of partitioning  $D$  determines the number of exclusive equal-sized parts the training set will be split and trained following  $D$ -fold cross-validation for positive  $D$  or otherwise inverse  $|D|$ -fold cross-validation that we define simply by training on exclusive  $|D|$  subsets of the training data. In case of feature value-based decomposition ( $P > 0$ ), the partitioning degree  $D$  informs whether the unique sorted values of  $F_P$  feature should be grouped in exclusive set of subsequent  $|D|$ -sized groups. Then for each such grouped subset the training follows on either actual subset if  $D$  is negative or on the complement of such subset if  $D$  is positive. In both cases the degree of partition have similar effect of training on multiple overlapping subsets for positive  $D$ , or on exclusive subsets for negative  $D$ , thereby controlling the level of aggregation or decomposition in the training process.

Please note that such defined training structure operator  $S_D^P$  can be combined into sequential expressions defining open hierarchical training structure with virtually infinite number of variants left to be designed for skilled data scientist. Note also that the enumerated parameterized representation of the structure parameters allows for easy iteration procedure to traverse through the structure parameters in a search that maximizes the expected predictive performance that can be carried by an automated ML model designer.

Finally having defined the expression mechanism for creating training structures what is left to define a full classification model  $M$  is to pair it with the base classifier  $C$  such that the fully defined classification model becomes:  $M = (C, S)$ .

#### V. A CASE STUDY

To demonstrate the performance of our proposed model as well as the training scheme, we apply it to build a model that predicts the result (the winner) of a computer game, Hearthstone [1], given the input data of various intra-game states [2].

##### A. Feature Engineering

Before building the prediction model, it is important to analyze the data and perform feature engineering to extract maximum predictive power from the raw data. In this case study, we had over three million records that store data about different intra-game states of Hearthstone. The data is recorded at each game state represented by the turn number of the game

and cover three sets of basic features with a total number of 40 features as follows.

- Opponent properties: hold information about different properties of the opponent at the current state as well as statistical data about played cards of the opponent.
- Player properties: keep similar information about different properties of the player at the current state and statistical data about played cards of the player.
- Player holding card information: this type of data is only available for the player.

These basic features are then complemented with an additional of 121 features generated in the following ways:

- Difference features: the different values of common numerical features between the opponent and the player.
- Player holding card features: the statistics of different types of cards in hand of the player. For these features, we simply count the number of holding cards in each type of the player.

All of the 161 features presented above were then exposed to various feature selection techniques. Different subset of features were selected for different sub-models that are vital unlock maximum predictive power from every model as well as inject diversity that is reported to be quite beneficial when combining multiple classifiers as discussed in Section III. Specifically, for each of the three sub-models we used the following different set of features:

- The set of 53 features - approximately equal to one third of the total number of features.
- The set of 107 features - approximately equal to two third of the total number of features.
- The set of all 161 features that include both basic features and extra features.

It is important to note that for the first two incomplete feature sets, the features were selected based on a combination (union) of feature selection for the top  $K_1$  (KBest) and recursive feature elimination for the bottom  $K_2$  (RFE). In particular, we selected 53 features for the first set from the top  $K_1 = 50$  and the bottom  $K_2 = 50$  in the KBest and RFE selection methods. On the other hand, the 107 features selected for the second set come from the top  $K_1 = 100$  and the bottom  $K_2 = 100$  in the KBest and RFE selection methods.

##### B. Evaluation of the ensemble model

Our ensemble model in this case study was built from 6 separate prediction models built on Logistic Regression, XGBoost and Deep Neural Network.

- Logistic regression: this approach is used for two prediction models. The first model is trained on a set of selected 53 features, decomposed along the *player.hero\_card\_id* feature. The second model is trained on a set of selected 107 features, decomposed along the *opponent.hero\_card\_id* feature. These models respectively receive a score of 0.7963 and 0.7967 from the public leader board.

- XGBoost (eXtreme Gradient Boosting): this approach is used for the next two predictions models, which are trained respectively on a set of 53 original features and all 161 features with scores 0.7964 and 0.7956 in the public leader board.
- Deep neural network: this approach is use for the last two prediction models. The first model is trained on a set of 53 features with three layers: an input layer using relu activation, an hidden layer of 20 nodes using relu activation and an output layer using sigmoid activation. This model scores 0.7957 in the public leader board. The second model is trained on a set of selected 107 features. Since there are more features, this model has an extra hidden layer with 60 nodes using relu activation in between the input layer and the hidden layer of 20 nodes. This model scores 0.7968 from the public leader board.

### C. Evaluation of the hierarchical decomposition and aggregation scheme

We have tested such hierarchical architecture for a classification model build with logistic regression as a base classifier and obtained the best results for the following design:

$$M = (\text{LogReg}, S_{-30}^0(S_1^4(X), S_1^{16}(X))) \quad (1)$$

Deciphering the structure expression of Logistic Regression  $S_{-30}^0(S_1^4(X), S_1^{16}(X))$  in plan words means that the predictor is constructed by an aggregation of the two double-decomposed models: first along the unique values of feature *opponent.hero\_card\_id* and feature *player.hero\_card\_id* and then further into 30 unique random subsets trained exclusively in an inverse cross-validation fashion. These models generated trained classifiers that back-tested with the highest cross-validation accuracy and have been applied to classify the testing set yielding a score of 0.797. What is intriguing is that such deep decomposition as in the presented design leads to decomposition of over 3m data points into over 270 chunks of the size around 10000. Such large model fragmentation is perfect for extremely fast processing on the parallelized infrastructure and delivered very competitive prediction results literally in seconds. Note that it is interesting to have the following observations from the results

- There is no surprise that the decomposition along unique values of feature *player.hero\_card\_id* and *opponent.hero\_card\_id* improves the model performance. It simply means that playing as a different hero character with all its specific characteristic requires distinct set of model parameters that appear to improve the predictive performance of the game outcome if applied only to the same cases of games played with the same character. This type of decomposition is a clear proof of the bias classification error reduction through improved specificity of the models trained on significantly distinct subsets (clusters) of data.
- It appears surprising that further training set decomposition into 30 smaller subsets of around 10000 each leads

to the improvement of predictive performance rather than training on most or all of the available training set. Indeed the experiments confirmed an optimal decomposition and aggregation level obtained for the training sets at around 10000 game states examples. Both, building and aggregating fewer models with larger training sets and more models trained on smaller training subsets results in apparent degradation of predictive performance.

- The identified structure parameters appear to achieve the optimal trade-off between the bias and variance error components reduction subject to logistic regression classifier abilities

## VI. CONCLUSION

In this paper, we have introduced an ensemble model for binary classification with a clear solution of how to split and select features for sub-model training. In addition to the ensemble model, we present an approach for hierarchical decomposition and aggregation model to address the issue of slow and computationally intractable in model training. These proposed solutions have been proved to be good with the second prize in a recent competition, which predicts the likelihood of winning a game given intra-game states of players. Even though our proposed solutions were proved to be good, they are not fully automated. Thus, in our future work, we plan to extend this current work for the automated feature selection of the ensemble model as well as efficient search for the best possible training structure with respect to the hierarchical decomposition and aggregation model.

# 7<sup>th</sup> International Workshop on Artificial Intelligence in Medical Applications

**T**HE workshop on Artificial Intelligence in Medical Applications – AIMA'2017—provides an interdisciplinary forum for researchers and developers to present and discuss latest advances in research work as well as prototyped or fielded systems of applications of Artificial Intelligence in the wide and heterogeneous field of medicine, health care and surgery. The workshop covers the whole range of theoretical and practical aspects, technologies and systems based on Artificial Intelligence in the medical domain and aims to bring together specialists for exchanging ideas and promote fruitful discussions.

## TOPICS

- Artificial Intelligence Techniques in Health Sciences
- Knowledge Management of Medical Data
- Data Mining and Knowledge Discovery in Medicine

**Abstract**—The heart disease describes a range of conditions affecting our heart. It can include blood vessel diseases such as coronary artery disease, heart rhythm problems or and heart defects. This term is often used for cardiovascular disease, i.e. narrowed or blocked blood vessels leading to a heart attack, chest pain or stroke. In our work, we analysed three available data sets: Heart Disease Database, South African Heart Disease and Z-Alizadeh Sani Dataset. For this purpose, we focused on two directions: a predictive analysis based on Decision Trees, Naive Bayes, Support Vector Machine and Neural Networks; descriptive analysis based on association and decision rules. Our results are plausible, in some cases comparable or better as in other related works

## I. INTRODUCTION

THE availability of various medical data leads to a reflection if we have some effective and powerful methods to process this data and extract potential new and useful knowledge. A diagnostics of different diseases represents one of the most important challenges for data analytics. The researchers focus their activities in several directions, e.g. to generate prediction models with high accuracy, to extract IF-THEN rules or to investigate new cut-off values for relevant input variables [30]. All directions are important and can contribute to improving the effectiveness of the medical diagnostics.

Heart disease (HD) is a general name for a variety of diseases, conditions, and disorders that affect the heart and the blood vessels. The symptoms depend on the specific type of this disease such coronary artery diseases, stroke, heart failure, hypertensive heart disease, cardiomyopathy, heart arrhythmia, congenital heart disease, etc. HD is the leading global cause of death based on a statistics of American Heart Association. The World Health Organization estimated that in 2012 more than 17.5 million people died from HD (31% of all global deaths). This growing trend can be reversed by an effective prevention, i.e. early identification of warning symptoms or typical patient's behavior leads to HD. It is a task for data analytics to support the diagnostic process with results in simple understandable form for doctors or general practitioners without deeper knowledge about algorithms and their applications.

The paper consists of three main sections. At first, we introduce the motivation and possible approaches to support the effective diagnostics of HD. The second section describes six phases of the CRISP-DM methodology and related experiments. The last section concludes the paper and proposes some improvements for our future work.

### A. Related Work

As HD is a very serious disease, many researchers tried to predict it or to extract crucial risk factors. The relatively known data sets are Cleveland, Hungarian, and Long Beach VA freely available on UCI machine learning repository.

El-Bialy et al. used all these datasets in their study [18]. At first, authors selected five common variables for each dataset (Cleveland, Hungarian, Long Beach VA and Statlog project) and applied two data mining techniques: decision tree C4.5 and Fast Decision Tree (improved C4.5 by Jiang SU and Harry Zhang). These operations resulted in accuracy from 69.5% (FDT, Long Beach VA data) to 78.54% (C4.5, Cleveland). Next, authors merged all datasets into one containing variables like cp, age, ca, thal, or thalach. The merging resulted in 77.5% accuracy by the C4.5 algorithm and 78.06% by FDT.

Verma, Srivastava, and Negi in their work [19] designed a hybrid model for diagnosing of coronary artery disease (one type of HD). For this purpose, authors used data from the Department of Cardiology at Indira Gandhi Medical College in Shimla in India, which contained 335 records describing by 26 attributes. The authors pre-processed data via correlation and features selection by particle swarm optimization (PSO) method. For modelling authors used four analytical methods: Multi-layer perceptron (MLP), Multinomial logistic regression model (MLR), Fuzzy unordered rule induction algorithm (FURIA) and Decision Tree C4.5. As first, they applied the MLP to the whole dataset. The obtained accuracy 77% was not satisfactory, so they tried to improve it by MLR. This step resulted in 83.5% accuracy. The methods FURIA and C4.5 did not offer higher value. In the next step, authors tried to optimize data

pre-processing and tried to identify the prime risk factors using correlation based feature subset (CFS), selection with PSO, k-means clustering and classification or a combination all of these. Finally, they achieved 88.4% accuracy using MLR and they applied proposed hybrid model on Cleveland dataset. This model improved the accuracy of classification algorithms from 8.3 % to 11.4 %.

Cleveland dataset is only one of several datasets typically used by researchers for analytical support of HD diagnostics. The second is Z-Alizadeh Sani dataset collected at Tehran's Shaheed Rajaei Cardiovascular, Medical and Research Centre. This dataset contains 303 records with 54 features. Alizadehsani et al. aimed to classify patients into two target classes: suffered by coronary artery disease or normal [20]. They divided the original set of variables into four groups: demographic, symptoms and examination, ECG, laboratory, and echo. They focused on pre-processing phase, mainly on features selection by Ginni index or Support Vector Machine. They also created several new variables like LAD (Left Anterior Descending), LCX (Left Circumflex) and RCA (Right Coronary Artery). For classification, authors used four methods: Naive Bayes, Sequential Minimal Optimization (SMO), SMO with bagging and Neural network. They applied these algorithms to different pre-processed data sets: all original variables without three new, all original variables with three new, only selected variables from the original set without three new and the selected variables from the original set with three new. The best-obtained results were 93.4% for SMO with bagging, 75.51% for Naive Bayes, 94.08 for SMO and 88.11 for the Neural network. All results were verified by 10-cross validation. The authors extracted Typical Chest Pain, Region RWMA2, age, Q-Wave and ST Elevation as the most important variables.

The same dataset was used by Yadav's team [21] focusing on an optimization of Apriori algorithm by Transaction Reduction Method (TRM). The new algorithm decreased a size of the candidate's set and a number of transactional records in the database. The authors compared it with some traditional methods and obtained accuracy 93.75%; SMO (92.09%), SVM (89.11%), C4.5 (83.85%), Naïve Bayes (80.15%).

All mentioned works focused mainly on predictive analysis within traditional methods like Decision Trees, Naive Bayes, Support Vector Machine or Neural networks. Next, authors tried to improve these results by suitable operations in pre-processing phase or by other analytical methods like SMO. We selected these works to set a baseline for our research activities.

### B. Methods

The CRISP-DM represents the most popular methodology for data mining and data science. This methodology defines six main phases from business understanding to the deployment [1], [2]. The first phase deals with a

specification of business goal and its transformation to the data mining context. The second phase focus on detailed data understanding through various graphical and statistical methods. Data preparation is usually the most complex and most time-consuming phase including data aggregation, cleaning, reduction or transformation. In modeling, different machine learning algorithms are applied to the preprocessed datasets. Traditionally, this dataset is divided into training and testing sample, or analysts use 10-cross validation. The obtained results are evaluated by traditional metrics like accuracy, ROC, precision, or recall. Next, the analysts verify accomplish of the specified business goals. The last phase is devoted to the deployment of the best results in real usage and identification of the best or worst practices for the next analytical processes.

The decision tree is a flowchart-like tree structure, where each non-leaf node represents a test on an attribute, each branch represents an outcome of the test, and leaf nodes represent target classes or class distributions [3]. We decided to use this method because we were able to visualize the tree or to extract the decision rules. The C4.5 algorithm used normalized information gain for splitting [4]. The C5.0 algorithm represents an improved version of the C4.5 that offers a faster generation of the model, less memory usage, smaller trees with similar information value, weighting, and support for the boosting [5]. CTree is a non-parametric class of regression trees embedding tree-structured regression models into a well-defined theory of conditional inference procedures. This algorithm does not use the traditional variable selection based on information gain or Ginni coefficient but selects the variables with many possible splits or many missing values [6]. It uses a significance test procedure. The CART (Classification and Regression Trees) algorithm builds a model by recursively partitioning the data space and fitting a simple prediction model within each partition [7]. The result is a binary tree using a greedy algorithm to select a variable and related cut-off value for splitting with the aim to minimize a given cost function.

Naive Bayes is a simple technique for constructing classifiers that require a small number of training data to estimate the parameters necessary for classification [8]. It uses the probabilities of each attribute belonging to each class to make a prediction. Naive Bayes simplifies the calculation of probabilities by assuming that the probability of each attribute belonging to a given class value is independent of all other attributes. To make a prediction, it calculates the probabilities of the instance belonging to each class and selects the class value with the highest probability.

Support Vector Machine (SVM) is a supervised machine-learning algorithm, mostly used for classification. SVM plots each record as a point in n-dimensional space (where n is a number of input variables). The value of each variable represents a particular ordinate [9]. Then, SVM performs classification by finding a hyperplane distinguishing the two target classes very well. New examples are mapped into

same space and predicted to a category based on which side of the gap they fall.

Neural networks are a computational model, which is based on a large collection of connected simple units called artificial neurons. We will use this method if we don't want to know the decision mechanism. They work like a black box, i.e. we know the model is some non-linear combination of some neurons, each of which is some non-linear combination of some other neurons, but it is near impossible to say what each neuron is doing. This approach is opposite to the Decision trees or SVM. We used a feedforward neural network, in which the information moves in only one direction – forward [10].

Association rules are a popular and well-researched method for discovery of interesting relations between variables in (large) databases [11], [12]. The most often used algorithm to mine association rules is Apriori [13]. Association rules analysis is a technique to uncover how items are associated with each other. The Apriori principle can reduce the number of item sets we need to examine.

We used some statistical methods to investigate possible relations between input variables themselves or between them and target diagnostics [14]. For this purpose, we applied Shapiro-Wilks normality test (null hypothesis: sample  $x_i$  came from a normally distributed population [22]); 2-sample Welch's t-test (the population means from the two unrelated groups are equal [23]); Mann-Whitney-Wilcoxon Test [29] (the two populations are equal); Pearson chi-square independence test (two categorical variables are independent [24]); Fisher's Exact test (the relative proportions of one variable are independent of the second variable [25]) and logistic regression [28]. Next, we used k-Nearest Neighbour and multiple linear regression to replace the missing values in a dataset by some plausible values [26], [27].

For experiments, we used a language and environment for statistical computing and graphics called R. It provides a wide variety of statistical (linear and nonlinear modelling, classical statistical tests, time-series analysis, classification, clustering, etc.) and graphical techniques, and is highly extensible<sup>1</sup>.

## II. CRISP-DM

### A. Business Understanding

As we mentioned before, the HD diagnostics is complicated process containing many different input variables that need to be considered. In this case, data mining can help to process and analyze available data from a different point of views. The business goal is to provide an application decision support for doctors and general practitioners. From data mining point of view, we can transform this goal into two possible directions: predictive and descriptive analysis. The first one was represented by

binary classification and the second one by extraction of association or decision rules. In data preparation phase we aimed to investigate possible relations between different combinations of variables within some statistical tests. We determined a minimal 85% accuracy based on performed state of the art. For this evaluation, we used a traditional confusion matrix (Table I.)

TABLE I.  
CONFUSION MATRIX

Predicted value	True values	
	TP	FP
	FN	TN

TP (true positive) – healthy people were classified correctly as healthy.

FP (false positive) – healthy people were classified incorrectly as patients with the positive diagnosis.

FN (false negative) – patients with positive diagnosis were classified incorrectly as healthy people.

TN (true negative) – patients with positive diagnosis were classified correctly as sick.

The overall accuracy was calculated within following formula:

$$accuracy = \frac{TP + TN}{TP + FP + FN + TN} \times 100 \quad (1)$$

For evaluating the association rules, we used two traditional metrics: support as the proportion of health records in the dataset, which contains a combination of relevant antecedents; and confidence representing the proportion of health records containing antecedents and consequent two. If we define association rules as  $X \Rightarrow Y$ , then antecedents represent the left part of the rule (X) and the consequent the right part (Y).

### B. Data Understanding and Preparation

We selected three available data sets devoted to the heart diseases. The first dataset dates from 1988 and consists of four databases: Cleveland (303 records), Hungary (294), Switzerland (123), and Long Beach VA (200). Each record is described by 14 variables (Table II.).

The distribution of target attribute in each dataset is following: 139 patients with positive diagnostics/164 healthy people, 106/188, 115/8, 149/51.

This dataset contained nearly 2 thousand missing values, mainly in variable *ca*. For nominal attributes, we used the k-NN method, for numerical multiple linear regression to solve this problem. In the case of k-NN, we normalized all variables to interval  $< -1, 1 >$  and set up the k-value as 5. This cleaning operation changed the original distributions very slightly.

Fig. 1 visualizes a relation between *resting blood pressure* and target attribute. We can say that many patients with ideal

<sup>1</sup> <https://www.r-project.org/about.html>

blood pressure (around 120) have a positive diagnosis of heart disease.

TABLE II.  
VARIABLES – DATASET 1

Name	Description
age	age in years (28 - 77)
sex	0-female 1-male
cp	chest pain type 1-typical angina 2-atypical angina 3-non-anginal pain 4-asymptomatic
trestbps	resting blood pressure (mm/Hg) (0 - 200)
chol	serum cholesterol (mg/dl) (0 - 603)
fbs	fasting blood sugar 0-false(< 120 mg/dl) 1-true (> 120 mg/dl)
restecg	resting electrocardiographic results 0-normal 1-having ST-T wave abnormality 2-showing probable or definite left ventricular hypertrophy by Estes' criteria
thalach	maximum heart rate achieved (60 - 202)
exang	exercise induced angina 0-no 1-yes
oldpeak	ST depression induced by exercise relative to rest (mm) (-2.6 – 6.2)
slope	the slope of the peak exercise ST segment 1-upsloping 2-flat 3-downsloping
ca	number of major vessels colored by fluoroscopy (0-3)
thal	3-normal 6-fixed defect 7-reversable defect
num	diagnosis of heart disease (angiographic disease status) – target attribute 0 - negative diagnosis (absence) 1 - 4 (from least serious most serious - presence)

Fig.2 visualizes a relation between *maximal achieved heart rate* and target attribute. We expect that the higher value covers people with regular exercise. Fig. 3 visualizes a relation between *sex* and target attribute. The first finding was that in the integrated dataset we had significantly more male than female. The second was a ratio between healthy people and patients with positive diagnosis in both groups.

Fig. 1 Histogram (x- trestbps, y-multiplicity, green color – healthy person, orange color – positive diagnosis)

Fig. 2 Histogram (x- thalach, y-multiplicity, green color – healthy person, orange color – positive diagnosis)

Fig. 3 Histogram (x- sex, y-multiplicity, green color – healthy person, orange color – positive diagnosis)

For a better understanding of variables describing the EKG results, we present an example of ST segments (Fig. 4). The normal ST segment has a slight upward concavity. Flat, downsloping or depressed ST segments may indicate coronary ischemia. ST elevation may indicate transmural myocardial infarction.

Fig. 4 An example of ST segment from electrocardiography [16]

Next, we investigated a possibility to reduce the input set of variables. Three variables described the ECG: *Restecg*, *Oldpeak*, and *Slope*. If we visualized their distributions, the first two had a low distinguish ability for target classes. We have omitted these two attributes from next experiments.

Next, we investigated a relationship between nominal variables and target attribute. For this purpose, we tried to use Pearson's Chi-squared Test and we obtained following p-values: *sex* ( $< 2.2e-16$ ), *exang* ( $< 2.2e-16$ ), *cp* ( $< 2.2e-16$ ), *fbs* ( $5.972e-05$ ), *slope* ( $< 2.2e-16$ ), *ca* ( $8.806e-16$ ) and *thal* ( $< 2.2e-16$ ). These results rejected the null hypothesis and confirmed the expected relationship.

In the case of numerical variables, we started with Shapiro-Wilks normality test: *age* (p-value =  $2.268e-05$ ), *trestbps* ( $3.052e-15$ ), *chol* ( $< 2.2e-16$ ), *thalach* ( $1.906e-05$ ). Based on this result, we choose a non-parametric Mann-Whitney-Wilcoxon Test: *age* (p-value =  $2.2e-16$ ), *treshbps* ( $0.001596$ ), *chol* ( $4.941e-05$ ), *thalach* ( $2.2e-16$ ). If we set up the 0.05 as significance level, we rejected the null hypothesis for all numeric variables, i.e. existing dependency between them and target attribute.

Finally, we applied a logistic regression on this data. If we set a level for statistical significance to 0.005, the most significant variables were *sex* = *male* (p-value = 0.000602), *slope* = 2 (0.000355), *ca* = 1 ( $1.04e-05$ ), *ca* = 2 ( $3.01e-06$ ), *ca* = 3 (0.008745), *cp* = 4 (0.001302) and *treshbps* (0.007671). Based on relevant z-values, all these variables increase the chance for classification into positive target class.

Fig.5 visualizes a distribution of target attribute after its transformation to binary one (1-4 were aggregated in 1).

Fig. 5 Histogram (x- target attribute (absence, presence), y- multiplicity)

Since in previous dataset we investigated the higher occurrence of HD in male sample, as second dataset we selected a sample of males in a heart-disease high-risk region of the Western Cape, South Africa. It contains 462 records described by 10 variables without missing values (Table III.). This data sample is part of a larger dataset, described in [15]. The target attribute contained 302 records of healthy persons and 160 positive diagnoses of HD.

TABLE III.  
VARIABLES – DATASET 2

Name	Description
age	age in years (15 - 54)
sbp	systolic blood pressure (101 - 218)
chd	coronary heart disease – target attribute 0 – negative diagnosis 1 – positive diagnosis
tobacco	cumulative tobacco (kg) (0 - 31.2)
LDL	low density lipoprotein cholesterol (0.98 - 15.33)
adiposity	measure of % body fat (6.74 - 42.49)
obesity	measure weight-to-height ratios (BMI). (14.70 – 46.58)
famhist	family history of heart disease (present, absent)
typea	type-A behavior is characterized by an excessive competitive drive, impatience and anger/hostility
alcohol	current alcohol consumption (0.00 – 147.19)

We performed similar operations to understand the data. Figure 5 visualizes a relation between family history of heart disease (*famhist*) and target attribute. We can say that a

chance to be positive diagnosed is around 50% if some heart disease occurred in the family history.

We solved an unbalanced distribution of the target attribute with an oversampling method, i.e. we re-sampled the minority class in the training set. The result was 302 records for absent and 256 for the present.

Fig. 6 Histogram (x- famhist, y-multiplicity, green color – healthy person, orange color – positive diagnosis)

Next, we investigated potentially existing relationships between input variables and target attributes. Since we had mainly numeric variables, at first we tested if they had a normal distribution. For this purpose, we used Shapiro-Wilks test with following results: *age* (p-value = 4.595e-13), *sbp* (1.253e-14), *tobacco* (< 2.2e-16), *LDL* (7.148e-15), *adiposity* (4.245e-05), *obesity* (9.228e-10), *typea* (0.008604) and *alcohol* (< 2.2e-16). In all cases, the distribution deviated from normality based on cut-off p-value 0.05. Based on this result, we choose a non-parametric Mann-Whitney-Wilcoxon Test. We obtained following p-values: *age* (3.364e-15), *sbp* (0.000214), *tobacco* (4.31e-12), *LDL* (6.058e-09), *adiposity* (1.385e-07), *obesity* (0.02073), *typea* (0.05219) and *alcohol* (0.1708). If we set up the 0.05 as significance level again, we confirmed the null hypothesis for the two last variables, i.e. they were independent and we omitted them.

Finally, we generated a logistic regression model based on data with a reduced set of input variables. This model has confirmed the importance of *famhist* = present (p-value = 2.68e-05), *age* (0.000572), *tobacco* (0.001847) and *LDL* (0.002109). All four variables increase a chance for the positive diagnosis of the HD.

The last dataset was Z-Alizadeh Sani Dataset containing 303 records about patients from Tehran's Shaheed Rajaei Cardiovascular, Medical and Research Centre [17]. Each patient was characterized by 54 variables. These variables were arranged in four groups: demographic, symptom and examination, ECG, laboratory and echo features. The target classes were a positive diagnosis of coronary artery disease

(CAD) and normal health status. The patient is categorized as CAD, if his/her diameter narrowing is greater than or equal to 50%, and otherwise as Normal. The dataset did not contain any missing values. In Table IV, we present only selected set of input variables as an example.

TABLE IV.  
VARIABLES – DATASET 3

Name	Description
age	age in years (30 - 86)
Diabetes Mellitus	0 - No 1 - Yes
Fasting Blood Sugar (mg/dl)	62 - 400
Pulse Rate	50 - 100
ST Elevation	0 - No 1 - Yes
ST Depression	0 - No 1 - Yes
Low-Density Lipoprotein (mg/dl)	18- 232
White Blood Cell	3 700 – 18 000
Obesity	0 - No (BMI<25) 1 - Yes (BMI >25)
Creatine (mg/dl)	0.5 - 2.2
Ex-Smoker	0 - No 1 - Yes
Hemoglobin (g/dL)	8.9 - 17.6
Non-anginal CP	0 - No 1 - Yes
<b>Heart disease</b> (target attribute)	0 - Normal 1 - CAD

We performed similar data understanding, Fig. 7 visualizes a relation between typical chest pain and target attribute. If the patient felt chest pain, then change for heart disease is very high. If the patient did not feel the chest pain, the chance for HD is still 50/50.

Fig. 7 Histogram (x- typical chest pain, y-multiplicity, green color – healthy person, orange color – positive diagnosis (CAD))

We have proceeded in the same way as in the two previous cases. We omitted the variables with only one values as e.g. Exertional CP. We started with an investigation of the possible normal distribution of numerical variables. We confirmed it for three variables through histograms (Fig. 8) and Shapiro-Wilks normality test: HB (p-value = 0.1301), Lymph (0.08769) and Neut (0.2627).

Fig. 8 Histogram (x- number of Neutrophil , y-multiplicity)

For these variables, we performed two-sample Welch's t-test with following results: *HB* (p-value < 2.2e-16), *Lymph* (< 2.2e-16) and *Neut* (< 2.2e-16). We rejected the null hypothesis and accepted the alternative one (the population means are not equal), i.e. variables and target attribute were dependent.

For other numerical variables, we performed the non-parametric Mann-Whitney-Wilcoxon Test. Based on significance level 0.05 we were able to reject the null hypothesis for following variables: *Weight* (0.2137), *Length* (0.9428), *BMI* (0.2537), *Edema* (0.3485), *CR* (0.3251), *LDL* (0.6088), *HDL* (0.5036), *BUN* (0.1293), *Na* (0.09188), *WBC* (0.3672) and *PLT* (0.2292). It means that these variables and target attribute were independent and we excluded them from our experiments.

For nominal variables, we had to use two methods: at first Pearson chi-square independence test and if more than 20% of the contingency table's cells are less than five, we used Fisher's Exact test. We omitted following variables with significance level 0.05: *sex* (p-value = 0.2991), *Current Smoker* (0.2614), *FH* (0.6557), *Obesity* (0.8003), *DLP* (0.9284), *Systolic Murmur* (1.0), *LVH* (0.5251); *Ex-Smoker* (0.7297), *CRF* (0.1875), *CVA* (1.0), *Airway disease* (0.1875), *Thyroid Disease* (0.4138), *Weak Peripheral Pulse* (0.3263), *Lung Rales* (0.7349), *Function Class* (0.1405), *LowTH Ang* (1.0), *BBB* (0.307) and *Poor R Progression* (0.064).

The mentioned operations reduced an original set of input variables from 53 to 27. Finally, we generated a logistic regression model that confirmed the importance of variables *Typical Chest Pain = 1* (3.63e-05), *Age* (4.06e-05), *Diabetes Mellitus* (0.00321), *T inversion* (0.00140), *Valvular heart*

*disease = normal* (0.00605) and *Regional wall motion abnormality* (0.0057).

This dataset was also unbalanced from the target attribute point of view. Therefore, we used the oversampling method again, i.e. we re-sampled the minority class in the training set. The result was 216 records for CAD and 174 for normal.

### C. Modelling and Evaluation

We applied selected data mining methods to predict the HD and to extract relevant rules. For the prediction models, we verified experimentally three data division to training and testing sets (80/20, 70/30, 60/40). For each division, we repeated the experiment for 10 times with different sampling and in respect to the original ratio of target classes. We also performed a stratified 10-cross validation, i.e. each fold contained roughly the same proportions of the two types of class labels. Finally, we applied these methods on original datasets and with reduced sets of variables mentioned above.

Table V. presents the best-achieved results for all three datasets.

TABLE V.  
THE BEST ACHIEVED PREDICTIONS

Name	Method	Accuracy (%)
Cleveland, Hungary, Switzerland and Long Beach VA	Decision trees	88.09
	Naive Bayes	86.76
	SVM	88.53
	Neural networks	89.93
South Africa Heart Disease	Decision trees	73.87
	Naïve Bayes	71.17
	SVM	73.70
	Neural networks	68.48
Z-Alizadeh Sani Dataset	Decision trees	85.38
	Naïve Bayes	83.33
	SVM	86.67
	Neural networks	86.32

The first group of experiments resulted in the best model generated by neural network visualized in Fig. 9. This model contained only reduced set of input variables. The best decision tree model was generated by CART, 10-stratified cross-validation, and all original variables. The reduced set of variables provided the same accuracy.

For the second dataset, we obtained less accurate models. The proposed reduction of the variables did not bring any significant improvement. Based on relevant confusion matrices, we found out a relatively high number of records predicted as negative, but in fact, they were positive. This is an important finding for future improvement.

In the last case, we obtained the best model within SVM, which for all datasets provided one of the most accurate predictions. Since it is complicated to visualize the whole SVM model; we present an only 2-dimensional example based on attributes *age* and *tresbps* (Fig. 10).

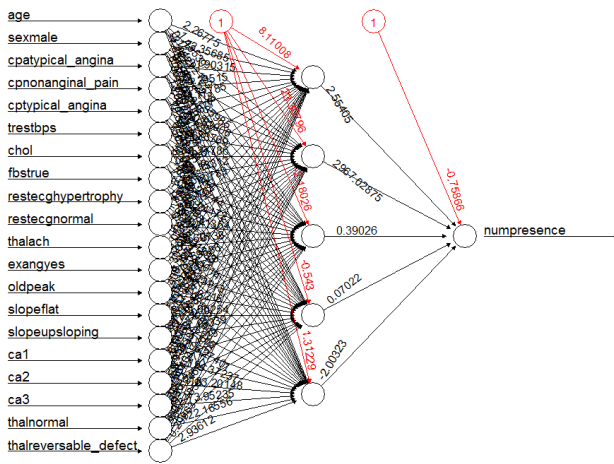

Fig. 9 The structure of the created neural network with the best prediction ability (input layer = 20 neurons, hidden layer = 5 neurons, red numbers - bias)

Fig. 10 The example of SVM prediction model (x – tresbps, y – age, purple – positive diagnosis, cyan – negative diagnosis)

Finally, we discretized all numerical attributes in accordance with the typical categories defined by existing medical literature. Next, we applied the Apriori algorithm to generate association rules. These rules were very similar to those we extracted from the decision trees models:

IF *thal* = reversible defect/ fixed defect AND *ca* = 1/2/3 THEN HD = positive diagnosis (dataset1 – decision rules)

IF *sex* = male AND *exang* = yes AND *oldpeak* > 0.8 THEN HD = positive (dataset1 – association rules)

IF *age* < 50.05 AND *tobacco* > 0.46 AND *typea* > 68.5 THEN HD = positive (dataset2)

IF *famhist* = 1 and *LDL* = high THEN HD = positive (dataset2)

IF *Typical Chest Pain* = 0 AND *Age* < 61 and *Region RWMA* = 0/1 THEN HD = positive (dataset3)

IF *Typical Chest Pain* = 1 AND *VHD* = mild THEN HD = positive (dataset3)

We can conclude that the content of the generated prediction models is in accordance with the results of the relevant statistical tests about attributes dependency.

## D. Deployment

The last phase is devoted to the deployment of the evaluated and verified models into practice. We focused on simple understandable and interpretable application to support the diagnostic process of the heart diseases. We used an open source R package Shiny that provides an elegant and powerful web framework for building web applications using R. Fig. 11 visualizes our prototype offering all analytical features described in this paper, e.g. data understanding, statistical tests, classification models generation and diagnosis of a new patient.

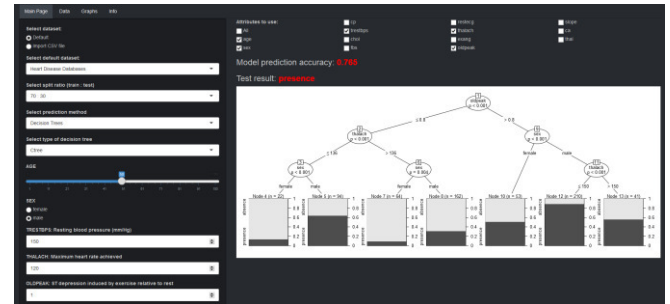

Fig. 11 An example of supporting application

## III. CONCLUSION

This paper presents the application of various statistical and data mining methods to understand three different medical data sets, to generate some prediction models or to extract rules suitable for decision support during the diagnostic process. We used some statistical tests to find out possible existing relationships between input variables and target attribute. Based on relevant results, we prepared the datasets for modeling phase, in which we applied some selected methods as decision trees, Naive Bayes, Support Vector Machine or Apriori algorithm. In comparison with existing studies, our results are plausible, in some cases comparable or better. In our future work, we will focus on several directions: transformation and creation of the new derived variables to improve the data information value; investigation of the new cut-off values for selected variables, boosting for prediction models and e.g. cost matrix for unbalanced distribution

# Subvocal Speech Recognition via Close-Talk Microphone and Surface Electromyogram Using Deep Learning

Mohamed S. Elmahdy and Ahmed A. Morsy

Biomedical Engineering Department, Cairo University, Giza, Egypt  
m.elmahdy@ieee.org, amorsy@ieee.org

**Abstract** - Speech communication is very essential for human-human communication and human machine interaction. Current Automatic Speech Recognition (ASR) may not be suitable for quiet settings like libraries and meetings or for speech handicapped and elderly people. In this study, we present an end-to-end deep learning system for subvocal speech recognition. The proposed system utilizes a single channel surface Electromyogram (sEMG) placed diagonally across the throat alongside a close-talk microphone. The system was tested on a corpus of 20 words. The system was capable of learning the mapping functions from sound and sEMG sequences to letters and then extracting the most probable word formed by these letters. We investigated different input signals and different depth levels for the deep learning model. The proposed system achieved a Word Error Rate (WER) of 9.44, 8.44 and 9.22 for speech, speech combined with single channel sEMG, and speech with two channels of sEMG respectively.

*Index Terms* - Subvocal Speech; Deep Learning; sEMG.

## I. INTRODUCTION

Speech plays an important role, not only in human-human communication but also in human-machine interaction. Often, human speech takes place in harsh acoustic backgrounds with a variety of environmental sound sources, competing voices, and ambient noise. The presence of such noise makes it difficult for human speech to remain robust and clear.

After the wide popularity of smart devices and assistive technologies, Automatic Speech Recognition (ASR) became the most convenient communication tool for humans to interact with these machines [1]. Although ASR systems have achieved reasonably high accuracies compared to human capabilities [2], they still suffer from various limitations. First, they are prone to environmental noise. Second, audible speech can be very disturbing in quiet settings like libraries and meetings. Third, normal speech communication is not suitable for speech handicapped, e.g., stuttering patients. Similar challenges are faced when dealing with elderly people, caused by issues with speech pace and articulation [3].

These limitations motivate the need for the development of another strategy for how ASR works in terms of speech form, acquisition techniques, and processing algorithms. One potential alternative for vocalized speech is subvocalized speech. Subvocalization occurs, for example, when someone whispers while reading a book, talking to one's self, or murmuring. This subvocalization can be acquired using surface Electromyogram (sEMG) signals from the muscles involved in speech production. Articulators involved in speech production are located in the face and neck area [4]. sEMG signals can thus

be used to substitute or at least augment traditional vocalized signals.

While it is already showing great promise, the field of subvocalized speech recognition is fairly recent and not mature compared to vocalized speech recognition. Wand et al. [5] achieved a 34.7% word error rate (WER) on 50 phrases using sEMG signals of 6 facial muscles from 6 subjects. Mendoza et al. [6] obtained a WER of 25% from a single sEMG channel but only for 6 Spanish words. Wand et al. reported a 54.7% WER on 50 phrases using 35 sEMG channels and 6 subjects [7]. Furthermore, Deng et al. achieved an 8.5% WER on 1200 words using 8 channels [8].

Researchers at Nara Institute of Science and Technology, Japan [9], investigated the use of non-audible murmur microphone fabricated in their own lab using hidden markov model for further analysis, reporting a 7.9% WER. However, the NAM microphone they used isn't available, to date, for commercial or academic purposes outside of their premises.

The ability to achieve high recognition accuracies using sEMG only has proven to be very challenging [5]-[8]. The reason can be attributed to the nature of the sEMG signal, which is highly variant from subject to subject depending on the muscle strength and gender. Most of the reported research uses facial muscles to capture speech signals [6]-[8]. While giving better accuracy, this placement isn't user friendly and may not lend itself to practical implementations. Results reported in the literature used hand crafted features, heuristically chosen based on experience and visual inspection of data.

This research introduces preliminary results for a multimodal end-to-end subvocal speech recognition system using a commercially available, low cost close-talk microphone and a single channel of sEMG signal acquired from the throat area. The proposed system uses deep learning algorithms for automatic feature extraction and classification.

## II. MATERIALS AND METHODS

### A. Corpus Design

We built an English corpus of twenty words. These words were selected to match the following criteria: (1) letters comprising the words must represent the English letters in as uniform distribution as possible, as shown in Fig.1; (2) they should be of different lengths; and (3) the similarity between words measured by Levenshtein distance [10] must be qualitatively variable, as demonstrated qualitatively in Fig.2. This limited vocabulary set can be used later for controlling machines or enabling the performance of various daily activities.

Figure 1. Distribution of letters across the corpus words

Figure 2. Levenshtein distance between words

### B. Subjects

Ten healthy subjects participated in this experiment, five males and five females, with average age of  $22 \pm 2$  years. All the subjects are not Native American speakers. The experiment was conducted in a lab controlled environment.

### C. Experiment Protocol and Data Labelling

Each subject was presented with 150 slides, each containing a single phrase. Subjects were asked to subvocalize the phrase within 6 seconds of its appearance on the screen, then relax for swallowing and breathing for 10 seconds, and so on. Fig. 3 illustrates the experimental sequence and timing. The experimental setup and connections are shown in Fig. 5. Each subject gave output of 150 records, out of which 100 records were used for training and 50 records for testing, for both modalities (microphone and sEMG).

### D. Signal Acquisition

As described above, both sEMG, to capture the electrical activities of the muscles responsible for sound production, and

Figure 3. Timing diagram showing the experiment protocol

Figure 4. sEMG electrode placement

Figure 5. Experiment setup

a close-talk microphone, to capture the articulation effect (vibration or sound), were used.

#### 1) Surface Electromyogram (sEMG)

A wireless sEMG from Mega Electronics Ltd was used. The sampling rate was 1 KHz using 16 bit ADC. Two electrodes were placed diagonally around the throat as shown in Fig. 4.

#### 2) Close-Talk Microphone

A Koss CS100 close talk microphone was used. This microphone has a noise reduction filter and has a sensitivity range of  $-36 \text{ dB} \pm 3 \text{ dB per } 1 \text{ V} / 1 \text{ KHz}$ . The microphone is placed 2 cm from the subject mouth to capture the murmurs. For recording this signal, we used freely available software named Audacity [11].

### E. Sound Pressure Level Quantification

In order to make sure that all subjects follow the same level of subvocalization, there was a need to quantify this level numerically. We used an iPhone with an application named SPLnFFT, whose accuracy was proven by [12].

Subjects were asked to subvocalize the sentences appearing on the screen within a range of  $12 \pm 2 \text{ dB}$  and were trained for 10 minutes prior to starting each recording session to help them meet this requirement.

### F. Short Time Fourier Transform (STFT)

Input signals were converted from time domain to frequency domain through Short Time Fourier Transform (STFT) to obtain a spectrogram, which was fed to deep learning model.

### G. Deep Learning

Conventional ASR systems consist of many complex building blocks: pre-processing, feature extraction, and building an acoustic model using Gaussian Mixture Model (GMM) and Hidden Markov Model (HMM) [13]. At the final stage, a language model is used to constrain the predicted subscription in order to follow the context of the speech as shown in Fig. 6.

Using sEMG instead of speech signals means that there is no well-defined building blocks akin to phonemes in traditional audible speech processing. Fig. 7 shows an end-to-end deep learning model as presented in [14].

### H. Spatial Convolutional Layer

Spatial convolution layer performs the traditional convolution operation as shown in Eq. (1). Convolutional operation works to find the most similar pattern to the filter in the underlying image [15].

$$(g*f)(x,y) = \sum_{(a,b) \in A} g(a,b)f(x-a, y-b) \quad (1)$$

### I. Bi-Directional Recurrent Neural Network (BRNN)

RNN was developed to make use of the sequential information. In conventional neural networks, it is assumed that all the inputs and outs are independent, i.e., the input at a certain time is independent of other inputs and the same for the output.

However, for a sequential signal like sEMG and speech, this is not true. That's because each sound or letter in the previous frame affects the prediction of the sound in the next frame [16]. Also, future frames could enhance and fine-tune the prediction of earlier frames. This is the main reason for choosing bidirectional RNN instead of RNN.

### J. Connectionist Temporal Classification (CTC)

The goal from an ASR system is to transfer any sequence of sounds into sequence of letters or phonemes. Traditional

Figure 6. Building blocks for traditional ASR system versus end-to-end ASR

Figure 7. Proposed end-to-end deep learning model

classification algorithms require that both inputs and outputs are aligned, which is not the case in most ASR problems.

The CTC layer generates a probability distribution at each time step of the input sequence instead of generating labels. These probabilities are then decoded into maximum likelihood labels. Finally, an objective function converts these maximum likelihood labels into the corresponding desired labels [17].

All computations were done on a desktop PC with GTX 960 TI and 6 GB GPU ram. Torch platform was used for deep learning implementation.

## III. RESULTS

This section highlights the system performance using different input signals and different number of RNN layers. For acoustic input only from the close-talk microphone, we obtained a WER of 16%, 11.33%, 9.44%, 12.56%, and 10.44% for different numbers of RNN layers as shown in Table 1.

For concatenating acoustic data and sEMG data from channel #1, we achieved a WER of 16.89%, 10.39%, 8.44%, 11.44%, and 9.83% using different RNN layers as illustrated in Table 2.

Combining acoustic data, sEMG from channel #1, and sEMG from channel #2 resulted in WER of 54.17%, 10.61%, 9.22%, 11.33%, and 10.44% as shown in Table 3.

Table 1. Results for speech input

#RNN Layers	WER	CER	Time (minutes)
1	16	2.7	18.26
2	11.33	2.43	24.23
3	9.44	2	32
4	12.56	3.04	58
5	10.44	2.45	68.7

Table 2. Results for speech input + sEMG from channel 1

#RNN Layers	WER	CER	Time (minutes)
1	16.89	2.83	26
2	10.39	2.33	39
3	8.44	1.91	47
4	11.44	2.21	60
5	9.83	1.89	72.5

**Table 3. Results for speech input + sEMG from channel 1 & 2**

#RNN Layers	WER	CER	Time (minutes)
1	54.17	17.4	18.85
2	10.61	2.25	27
3	9.22	2.07	35.9
4	10.11	1.93	64.5
5	11.31	2.14	81.3

## IV. DISCUSSION

In this study, we investigated the performance of an end-to-end subvocal speech recognition system using a wireless sEMG system and a close-talk microphone. The performance criteria were Word Error Rate (WER) and Character Error Rate (CER). We studied the performance of the system for acoustic signal only and acoustic signal combined with sEMG from the throat muscles. The depth of the deep network model was examined in search of the optimum number of bidirectional RNN.

For the input signal being acoustic data only, we found that the performance of the system increases by increasing the number of RNN layers till a peak of 9.44% WER then it decreases by a factor 3.12% then increased by 2.12%. This sudden change in performance is likely to be caused by overfitting. After increasing the number of layers, the model starts to experience an overfitting due to the increase in the number of parameters.

When feeding the network with acoustic data concatenated with sEMG signal from the throat muscle, the performance of the system has been boosted to achieve a WER of 8.44% with an increase of 1% from acoustic signal only. This increase in performance was expected because the microphone is unlikely to catch all the information from the audio in the subvocalization mode while sEMG can capture additional information. We notice that results in Table 2 almost follow the same pattern as Table 1. Three RNN layers is the turning point for the system. After 3 layers the system experiences an overfitting problem.

For the final experiment, we fed the network with a composition of three signals: acoustic, sEMG from channel #1 and sEMG from channel #2. The best WER was 9.22% at 3 RNN layers. The performance drop illustrates that channel #2 is a noisy channel and doesn't add much information.

The timing performance for different model structures and input signals is reported in Tables 1, 2 and 3. The training time was increased when the depth of the network was increased, due to the increase in the number of parameters that need to be optimized and settled.

Comparatively, the proposed algorithm has a better performance compared to Deng et al. [8] and Wand et al. [5] in terms of WER. In contrast with literature of subvocal speech recognition, the system doesn't depend on hand crafted features or traditional building blocks for ASR. In addition, the proposed algorithm demonstrates the efficacy of a single channel sEMG combined with a close-talk microphone.

## V. CONCLUSION

An end-to-end deep learning system for subvocal speech recognition using a close-talk microphone and a single channel wireless sEMG was presented. The proposed system used a mix of convolutional neural layers and bidirectional RNN in addition to a CTC layer as the objective layer. We studied the effect of different input signals and different numbers of RNN layers on system performance. The proposed system achieved a Word Error Rate of 9.44, 8.44 and 9.22 for acoustic, acoustic combined with a single channel sEMG, and acoustic with two channels of sEMG, respectively.

**Abstract**—This article presents a new SVM classifier for the prediction of the extended early-stage (ES) protein structures. The classifier is based on physicochemical features and position-specific scoring matrix (PSSM). Experiments have shown that prediction results for specific classes are significantly better than those already obtained.

## I. INTRODUCTION

THE INTEREST of biologists is to determine the shape of amino acid chains that make up proteins. Accurate measurement methods involving the observation and measurement of real chains are troublesome, so the shape is often predicted basing on the amino acid sequence itself. In addition to methods that simulate the behavior of atoms and larger particles in accordance with known physical laws, methods based on machine learning are used. The shape of an unknown protein is predicted on the basis of the assumption of a similar effect of the amino acid sequence on the shape of the different proteins.

The shape of the chain may be predicted with less details than exact coordinates of atoms in the three-dimensional space. The concept of secondary structure concerns the local shape of the chain, classified as a helix, strand and similar cases, defined by biologists. Predicting the secondary structure consists in assigning individual segments of the chain to one of several classes describing the local shape of the chain. The number of classes may vary in different algorithms. For example, the DSSP algorithm defines eight different classes. Methods operating on the so-called structural code define seven classes. A review of methods used to predict the shape of proteins can be found in the literature. As mentioned in [1], identical sequences of pentapeptides exist with completely different tertiary structures in proteins. On the other hand, different amino acid sequences can have approximately the same three-dimensional structure. However, the patterns of sequence conservation can be used for protein structure prediction. The secondary structure local shape is commonly used for “ab initio” methods as a common starting conformation for precise protein structure prediction. A large number of experiments and theoretical evidence suggests that local structure is frequently encoded in short segments of protein sequence. A definite relation between the amino acid sequences of a region folded into a supersecondary structure has been found. It was also found that they are independent of the remaining

sequence of the molecule. Early studies of local sequence-structure relationships and secondary structure prediction were based on either simple physical principles or statistics. Nearest neighbor methods use a database of proteins with known three-dimensional structures to predict the conformational states of test proteins. Some methods are based on nonlinear algorithms known as neural nets or Hidden Markov Models. In addition to studies of sequence-to-structure relationships focused on determining the propensity of amino acids for predefined local structures, others involve determining patterns of sequence-to-structure correlations. The evolutionary information contained in multiple sequence alignments has been widely used for secondary structure prediction. Prediction of the percentage composition of  $\alpha$ -helix,  $\beta$ -strand and irregular structure based on the percentage of amino acid composition, without regard to sequence, permits proteins to be assigned to groups, as all  $\alpha$ , all  $\beta$ , and mixed  $\alpha/\beta$ . Structure representation is simplified in many models. Side chains are limited to one representative virtual atom; virtual  $C\alpha$ - $C\alpha$  bonds are often introduced to decrease the number of atoms present in the peptide bond. The search for structure representation in other than the  $\phi$ ,  $\psi$  angles conformational space has been continuing. Other models are based on limitation of the conformational space. One of them divided the Ramachandran map into four low-energy basins. In another study, all sterically allowed conformations for short polyalanine chains were enumerated using discrete bins called mesostates. The need to limit the conformational space was also asserted.

The model introduced in [1] is based on limitation of the conformational space to the particular part of the Ramachandran map. This part is represented by an elliptical path which traverses areas corresponding to well defined secondary structural motifs on the Ramachandran plot. The structures created according to this limited conformational subspace are assumed to represent early-stage structural forms of protein folding in silico. In contrast to commonly used base of final native structures of proteins, the early-stage folding conformation of the polypeptide chain is the criterion for structure classification.

This article presents two methods for predicting structural codes and results for selected classes of the structural code. The methods assume the possibility of determining the local protein structure only on the basis of a known sequence of

amino acids, without implementing any physical or chemical relationships between the particles other than precomputed features for specific amino acids. The sequence of amino acids is described by strings of symbols (letters) representing 20 amino acids, while the structural code with a sequence of symbols denoting individual classes of the local shape. For structural code, there are seven classes. Thus, the task of predicting a secondary structure can be defined as a search for a function mapping a set of words over a 20-character alphabet into a set of words over a 7-character alphabet. There is a set of learning data, containing proteins with known shape. Methods for predicting the secondary structure do not usually produce accurate results and are therefore evaluated by quality measures that specify the fraction of correctly-enrolled classes for experiments involving previously examined proteins. For the secondary structure prediction, modern methods achieve accuracy of about 80%. Achieving high accuracy (over 90%) is hampered by the ambiguous classification of the local shape, especially at the ends of the chain fragments belonging to one class. For the structural code, the most commonly method uses contingency tables described later.

## II. METHODS AND ALGORITHMS

### A. The structural code

Predicting the three-dimensional shape of proteins may be implemented as a simulation of atoms and particles, where all known physical forces are involved and influence the dynamics of the whole system. This approach is called “ab initio”. The final shape of the protein is a result of minimizing the energy of the whole system. However, the number of variables to take into account is enormous and the time complexity of algorithms implementing this idea makes it difficult to use this approach for longer chains of amino acids. The “ab initio” method needs a starting point - an initial conformation of the chain. Good starting point results from predicted secondary structure or structural codes. In our experiments we have tried to predict the structural code, which is described in [1], [2]. The local shape of amino acid chain results from the values of the  $\phi$  and  $\psi$  dihedral angles. Observations of angles occurring in chains are presented in the so-called Ramachandran graph. Observations show that in that two-dimensional space ( $\phi$ ,  $\psi$ ) clusters are formed describing possible pairs of angular values. A method used to classify angle pairs ( $\phi$ ,  $\psi$ ) into one of those clusters defines an ellipse in the plane ( $\phi$ ,  $\psi$ ), divides it into seven segments, and determines which segment is the closest to the sample. The structural code does not directly map into classes defined for secondary structures. For certain codes there is a rough mapping: the code C corresponds to an  $\alpha$ -helix, E and F represent  $\beta$ -sheets while other codes correspond to a loop.

### B. The SVM method applied to the structural code

The SVM (support vector machine) ([3]), method is widely used in machine learning and protein shape prediction [4]. This method allows to classify vectors in a multidimensional

feature space. However, the method was mainly applied to the secondary structure of proteins, not to the structural code.

As stated in the paper [4], SVM has shown promising results on several biological pattern classification problems. This method became a standard tool in bioinformatics. SVMs have been successfully applied to the recognition of protein translation-initiation sites in DNA sequences and functional annotation of genes from expression profiles.

### C. Feature extraction

For predicting the shape of proteins, we have tried to used different features, mapped to numbers. Our experiments involve some physicochemical features and features based on statistics.

Physicochemical features have been already used to predict the protein secondary structure, as described in [6]. Following features have been used: hydrophobic values (F1), net charge (F2), side chain mass (F3), probabilities of conformation for the three secondary structures H, E and C (F4, F5, F6). The values have been defined for each of 20 amino acids and are presented in table I.

1) *Hydrophobic values*: For protein folding, polar residues prefer to stay outside of protein to prevent non-polar (hydrophobic) residues from exposing to polar solvent, like water. Therefore, hydrophobic residues appearing periodically can be used to predict protein secondary structure. In general, the residues in  $\alpha$ -helix structure are made up of two segments: hydrophobic and hydrophilic. However,  $\beta$ -sheet structure is usually influenced by the environment, so this phenomenon is not obvious. In other words, hydrophobic residue affects the stability of secondary structure. The hydrophobic values of amino acids can also be obtained from Amino Acid index database (or AAindex, [5]). Higher positive values mean, that the residue is more hydrophobic.

2) *Net charges*: There are five amino acids with charges: R, D, E, H and K. Because residues with similar electric charges repel each other and interrupt the hydrogen bond of the main chain, they are disadvantageous for  $\alpha$ -helix formation. Besides, succeeding residues of  $\beta$ -sheet cannot be with similar charges. This information helps to predict the secondary structure. The net charge of amino acids can be taken from the Amino Acid index database (or AAindex). The value 1 represents positive charge, the value -1 represents a negative charge.

3) *Side chain mass*: Although the basic structure is the same for 20 amino acids, the size of the side chain group still influences protein folding. First, the side chain R group is distributed in the outside of the main chain of  $\alpha$ -helix structure, but the continuous large R groups can make  $\alpha$ -helix structure unstable, thereby disabling amino acids from forming  $\alpha$ -helix structure. Next, the R group with ring structure like proline (P) is not easy to form  $\alpha$ -helix structure. Proline is composed of 5 atoms in a ring, which is difficult to reverse and is also not easy to generate a hydrogen bond. Finally, we observe that the R group of  $\beta$ -sheet structure is smaller than those of other structures, in general.

TABLE I  
FEATURE VALUES FOR INDIVIDUAL AMINO ACIDS

AA	F1	F2	F3	F4	F5	F6
A	1.8	0	15.0347	0.49	0.16	0.35

M	1.9	0	75.1483	0.44	0.23	0.33
F	2.8	0	91.1323	0.35	0.30	0.35
P	-1.6	0	41.0725	0.18	0.09	0.74
S	-0.8	0	31.0341	0.28	0.19	0.54
T	-0.7	0	45.0609	0.25	0.27	0.48
W	-0.9	0	130.1689	0.37	0.29	0.35
Y	-1.3	0	107.1317	0.34	0.30	0.36
V	4.2	0	43.0883	0.30	0.41	0.29

4) *Conformation parameters*: Conformation parameters are the probabilities of creating particular types of the secondary structure by a given amino acid. In general, protein secondary structure is divided into three types:  $\alpha$ -helix (H),  $\beta$ -sheet (E) and coil (C), so that there are three values for each amino acid. In the feature extraction, all the conformation parameters are calculated from a data set. The conformation parameters for each amino acid  $S_{ij}$  are defined as follows:  $S_{ij} = \frac{a_{ij}}{a_i}$ , where  $i = 1, \dots, 20$ ,  $j = 1, 2, 3$ . In that formula,  $i$  indicates one of 20 amino acids,  $j$  indicates the 3 types of secondary structure: H, E and C. Here,  $a_i$  is the amount of the  $i$ -th amino acid in a data set whereas  $a_{ij}$  is the amount of the  $i$ -th amino acids with the  $j$ -th secondary structure. The conformation parameters for each amino acid in a data set are shown in table I as F4, F5 and F6. The reason of using conformation parameters as features is that the folding of each residue has some correlation with forming a specific structure.

5) *PSSM profiles*: The position-specific scoring matrix (PSSM) is a commonly used representation of motifs in biological sequences. The matrix is defined for a given set of proteins and specifies the probability of finding a given amino acid at a given position. There are 20 amino acids, so there are 20 values from the PSSM matrix for each position. When generated for a sliding window of the length 15, we have additionally  $20 \cdot 15 = 300$  features.

To use the SVM method, we need a feature vector for each position of the amino acid chain. The feature vector should include information about the context in which a given amino acid occurs. To get a clear result for a given position in the chain, we choose a window of 15 elements

and describe feature for the element in the middle of it (at the 8th position). Therefore, we construct a feature vector using a sliding window of 15 elements. We slide it through the amino acid chain and for each position, we retrieve six features from the table I. In this approach, we get a vector of 90 features. The window size (15) was chosen arbitrarily after experimenting with shorter and longer windows. With additional PSSM features, we get a vector of 390 features for each position of the chain. Initial values at the ends of the chain, where the windows contains positions outside of the chain, are impossible to compute. So we have decided to cut the analyzed part of all chains by 7 positions from both sides, obtaining full coverage of data and complete feature vectors.

#### D. Contingency tables

The structural code for amino acid chains may be predicted using statistical methods, as described in [1]. The idea of contingency tables described in this article assumes, that the sequence of amino acids determines or at least influences the local shape of the protein chain. To reduce the complexity of computations it was assumed, that a sequence of only four amino acids (so called tetrapeptide) influences the secondary code within this sequence. Unfortunately the tetrapeptide does not strictly determine the shape, because there are cases, where identical tetrapeptides lead to different shapes. The contingency table collects information about tetrapeptides-shape relation in a given set of training data (over 1.5 million of tetrapeptides in the cited paper [1]). There are 7 structural codes and 20 different amino acids, so the table is a matrix of the size  $7^4 \times 20^4 = 2401 \times 160000$  elements. Based on the training set, statistics are generated to describe how many times a given 4-element structural code occurred for a given tetrapeptide (so we have  $2401 \times 160000$  counters). Then, probability values are computed and stored in the array to predict structural codes. After collecting data, regularities may be observed in the contingency table. Results of structural code prediction using contingency tables are presented e.g. in [7] and summarized in table III (in the first row).

### III. TRAINING AND TEST DATA

To test the performance of the SVM classifier, we have taken a set of proteins called CB513 (<http://comp.chem.nottingham.ac.uk/disspred/datasets/CB513>). Training and testing sets in such experiments should contain carefully selected proteins to avoid distortion in results of experiments. If the training set contained proteins similar to proteins selected for testing, results of prediction would be distorted, possibly improved. The presence of training samples similar to testing samples makes the classification task easier for the classifier and thus is avoided in experiments. The CB513 is a set of selected proteins, where no pair of proteins shares more than 25% sequence identity over a length of more than 80 residues. All proteins are available in the PDB protein database (<http://www.rcsb.org/pdb/home/home.do>) with precise three-dimensional shape.

TABLE II  
RESULTS OF STRUCTURAL CODE PREDICTION WITH SVM ON CB513, 9-FOLD EXPERIMENT

S. code	s1	s2	s3	s4	s5	s6	s7	s8	s9	Total

TABLE III  
COMPARISON OF STRUCTURAL CODE PREDICTION WITH CONTINGENCY TABLES AND SVM

S. code	A	B	C	D	E	F	G
Accuracy cont. table	2.26%	1.95%	82.32%	5.95%	38.05%	17.56%	10.95%
Accuracy SVM	17.28%	0.00%	62.45%	16.55%	87.19%	0.79%	17.74%

#### IV. EXPERIMENTS AND EVALUATION OF THE RESULTS

For the secondary structure prediction, the traditional measure of the prediction quality is called  $Q_3$ , which is defined as the number of correctly predicted residues divided by the length of the chain. However, it was shown, that the evaluation should be more specific. For seven codes, a slightly modified version of  $Q_3$  called  $Q_7$  has been used.  $Q_7$  was described in [8]:  $Q_7 = \frac{N_{r7}}{N} \cdot 100$ , where  $N$  expresses the total number of amino acids in the polypeptide under consideration,  $N_{r7}$  expresses the number of correctly predicted amino acids representing the structural form  $r$ .

Experiments have been implemented in the R language with the Machine Learning package (*mlr*). A set of precomputed PSSM matrices was used. The Radial Basis Function kernel (RBF, Gaussian kernel) was used in the SVM classifier - *classif.ksvm* from the *mlr* package, which implements multi-class classification. The RBF kernel for two samples  $y$  and  $y'$  representing feature vectors, is defined as:

$$K(y, y') = \exp\left(-\frac{\|y - y'\|^2}{2\sigma^2}\right).$$

The term  $\|y - y'\|^2$  is a squared Euclidean distance between feature vectors  $y$  and  $y'$ . Values of the RBF kernel are in the range from 0 (for very distant samples, in the limit) to 1 (for equal samples). It is interpreted as a measure of similarity.

Results of experiments on the CB513 set are shown in the table III. As this table shows, the results on some structural

codes differ significantly for two tested methods. Especially, the code A, D and E are predicted better by the SVM method. Code E is usually found at the end of  $\beta$ -twists, which may lead to the conclusion, that SVM is better at borders of motifs. Reasons of differences on other codes need further research.

□

**Abstract**—Medical and healthcare study programmes cover various curricula consisting of many theoretically focused courses and clinical teaching training. Curriculum attributes usually contains thousands of requirements on the form of knowledge and skills which fully define a complete graduate profile. It is not humanly possible to go through the entire curriculum or to imagine how the individual courses, learning units, outcomes and branches of medicine are interrelated. This paper introduces an innovative analytical approach which helps to identify automatically the most frequent topics based on keyword extraction. Moreover, the transparent and clear web-based visualisation of achieved results is shown in practice.

### INTRODUCTION

CONTINUOUS enhancement of quality of medical education is a long-term and extremely challenging issue. Higher education institutions, especially in medical and healthcare domains, require a process of lifelong learning, starting from undergraduate professional education and continuing in graduate study and in clinical practice [1]. Generally, study programmes in medicine cover a set of learning outcomes combining theoretically focused courses and clinical teaching training. These skills and knowledge fully define a complete graduate profile. Unfortunately, such study programmes usually involve hundreds or even thousands elements of unstructured information which need to be understood, evaluated and optimised. As a result, it is very difficult to look at any given programme, to identify the main topics across the curriculum, and to find one's way through it to see what is actually being taught and how is it done [2,3]. From the perspective of human cognition abilities, it is not possible to carefully read and remember every single detail of all learning units and outcomes including their linkages and co-dependencies. The MEDCIN project<sup>1</sup> (Medical Curriculum Innovations) brings a new way of viewing and evaluating medical curricula. We have designed and implemented a web-based platform that makes information about a given curriculum accessible to curriculum designers, teachers and guarantors alike.

This paper addresses the need for an innovative methodology proposal which helps to identify automatically the most frequent topics taught over the six-year study of

medicine and healthcare. The research problem was defined by the following questions: (i) How to apply data mining and analytical methods effectively for a crucial keyword-based exploration of medical curriculum data? (ii) Which visualisation components can be used for a transparent and clear web-based presentation of achieved results?

### METHODS

#### A. Technological background

The MEDCIN platform is a web-based application with a client-server network architecture that consists of several different parts. Some of them are separated on the software layer, but we decided to use more than one physical environment due a more effective performance and manageability. Its three main parts involve an application core, a database server and an OpenCPU server [4]: (i) The application core is based on a Symfony framework<sup>2</sup> written in PHP, Javascript and HTML, which uses the Twig template engine<sup>3</sup>. Currently we work with a Symfony framework in version 3.2 and all developed modules are PHP 7.\* compliant. The platform architecture has been implemented using the Model-View-Controller software architectural pattern [5]. Doctrine<sup>4</sup> was applied for PHP entities mapping in Model part (data access layer). All Twig templates are located in View part. Routing and data passing is covered by Controller part. (ii) The MEDCIN platform database is located on the database server and provides one public scheme where all descriptive curriculum data are stored. PostgreSQL<sup>5</sup> (version 9.5) represents a database system providing extensive data retrieval for this platform. (iii) The OpenCPU server represents the last physically separated part. The R statistical software environment (version 3.3.3) has been installed on this server, and all R scripts are stored and executed here. Every particular script is available on a specific URL thanks to the OpenCPU and its interface. The communication with this component goes on through REST API<sup>6</sup> methods.

A request-response POST method with concrete input data is used for RPC<sup>7</sup>. The OpenCPU either sends output data (in the form of JSON<sup>8</sup> or another format) directly to the web application or stores all outputs of script to a temporary folder structure which is accessible by a token. The R server is used

especially during the text analysis of the curriculum, where the retrieval of results is the most complicated and the most time-consuming issue.

### B. Keyword Extraction

Keyword extraction is an important technique for document retrieval [6]. By extracting appropriate keywords, we are able to show the most frequent and potentially relevant topics occurring in the entire curriculum. Before we describe data processing and analysis phases, data structure of the curriculum needs to be introduced. The MEDCIN platform provide the following building blocks which serve as common parameters for a standardised specification of the curriculum: A sequence block (SQB) contains sub-elements that define an organisational component of the curriculum, such as a course, a module, a learning unit or a learning block (e.g. Anatomy I – Lecture). An event contains information about educational and assessment events that make up the curriculum (e.g. Abdominal Radiology). Competency objects (CO) involve learning outcomes, competencies, learning objectives, professional roles, topics or classifications, which define what students should be able to know or demonstrate in terms of knowledge, skills, and values (e.g. Student analyses benefits and issues of the up-to-date development of the healthcare system).

The MEDCIN platform contains a complete curriculum of the General Medicine master's degree programme at the Faculty of Medicine of the Masaryk University. The database contains more than 140 courses which are described by 1,347 events (learning units) and 6,974 competency objects (learning outcomes); in total, this makes up more than 2,500 pages of text. We have proposed a robust data model which portrays all fundamental attributes as well as relations between the individual items.

#### 1) Data queries

Data for the MEDCIN platform are stored in the PostgreSQL database system running on a database server. The structure of the database is mapped to the Symphony application by a Doctrine 2 ORM<sup>9</sup> framework. First of all, the XML<sup>10</sup> metadata files are generated from the existing database; these files are subsequently transformed to PHP classes. The connection between the stored data and the web application is ensured by DQL<sup>11</sup> and SQL<sup>12</sup>. DQLs are typically used for easier queries such as to return the content of a single table using the `findOneBy` and `findBy` methods. SQLs are more suitable to execute more complex queries, when many tables are joined and several columns selected.

An important application of SQL in the context of this paper is data retrieval for keyword analyses. Two queries are implemented: (i) The first SQL query takes titles, keywords and text descriptions of sequence blocks, events and competency objects, puts it together and returns it as a single text. The keyword analyses are based on selected sequence blocks. All text descriptions of events and its COs related to

selected sequence blocks and all text descriptions of COs related to selected sequence blocks enter the text analyses. A particular event can appear in the final text field multiple times depending on the number of connections to COs. Similarly, competency objects can appear many times because each of them can be linked to both SQB and event. However, text representation of sequence blocks is always distinct. The text field prepared in this way serves as an input for a word cloud and frequency analyses.

(ii) The second SQL query prepares data for a similarity analysis of events. It returns titles, keywords and descriptions of each event and its COs in a single text. Since SQB can be selected by the app user, the SQL query returns only texts relevant to this selection. Descriptions of the events can be included multiple times, depending on the number of linked COs.

#### 2) Data analysis procedures

Data analysis is based on a proven CRISP-DM reference model [7], which provides the life cycle guideline of a data mining project. Special attention was paid to the pre-processing phase, where many unexpected issues appeared. This task includes data collection, description, exploration and verification. In general, we aim to obtain a clean final dataset with meaningful words in their basic forms. It also means reduction of data size and computational time. The input text covers the following metadata, which were subsequently mapped to the designed database structure: courses, learning units, learning outcomes and their descriptive attributes. First of all, non-text expressions – such as HTML characters, punctuation (! " # \$ % & ' ( ) \* + , - . / : ; < = > ? @ [ \ ] ^ \_ ` { | } ~) and numbers (0-9) – were replaced by spaces. Since R is case-sensitive, the next step was to transform the words to lower case, in order to ensure that data are stored in a unified format. In the following step, the so-called stop-words were removed. Finally, data cleaning such as additional white space removing and replacing multiple spaces by a single one was performed. The second challenging part is to get stems from the mined keywords (a stem was considered a form of the word that never changes even when morphologically inflected). We used a procedure called stemming, specifically the Porter's algorithm [8], which is an iterative series of simple rules that chops off the suffix from a word and leaves a stem. A set of stems input to the data analysis itself.

#### 3) Data visualisation

Text analysis of the curriculum requires an input in the JSON format, which is passed into POST method used with RPC. OpenCPU server automatically parses all JSON objects using the `jsonlite` R package afterwards. Therefore, we do not need any additional JSON processing. The keyword extraction R package generates two output sources: (i) A JSON data file (front-end visualisations are made on the basis of this file); we use the `d3.js` library as well as a native

<sup>9</sup> Object-relational mapping

<sup>10</sup> eXtensible Markup Language

<sup>11</sup> Doctrine Query Language

<sup>12</sup> Structured Query Language

HTML5 functionality to create some graphs and data tables. (ii) A SVG<sup>13</sup> file (created completely by the R script and passed to the web application screen).

R package visualisations depend heavily on several R graphics packages (see Fig. 1). In particular, these include *wordcloud* and *ggplot2*. Firstly, the *wordcloud* package creates good-looking word clouds and avoids overplotting of texts in scatter plots. One main drawback is that it uses the base R graphics and therefore cannot be exported into fully responsive and reusable SVG objects. Secondly, the *ggplot2* package is a plotting system for R which provides a powerful model of graphics and makes it easy to produce complex multi-layered outputs. This package plots dendrograms and uses grid graphics, which can be successfully exported into responsive SVG objects. In order to have all visualisations fully responsive, we use a modified version of the *wordcloud* function that computes the necessary coordinates, but plots graphics using the *grid* and *ggplot2* packages afterwards. The entire visualisation process can be represented by the following dependency tree:

**Cairo graphics device ← Rcpp ← gdttools ← svglite ← ggplot2**

Fig. 1 Scheme of R package graphic dependency tree.

After the OpenCPU server performs the keyword extraction analysis, it creates necessary visuals and stores them in temporary folders. All visual results are afterwards accessible by individual tokens for their further use in the website environment.

## RESULTS

The MEDCIN platform is divided into four linked modules providing medical and healthcare curriculum overview from different perspectives: (i) Summary report; (ii) Building blocks' context; (iii) Search by keyword; (iv) Text analysis. The fourth module is completely based on the keyword extraction algorithm, which was described in the Methods section. The user is allowed to select particular sequence blocks for a detailed analytical report (at least one, at most three SQBs). The visual representation of the most frequent keywords covering a wordcloud, a histogram and a data table is then displayed. These three graphical interpretations provide three different points of view on the same dataset.

The wordcloud-producing part of the R frequency analysis procedure is parameterised; namely, image margins, word orientations, font size and word size boundaries are customisable. Therefore, we are able to modify the output for various purposes (web application environment, PowerPoint presentations, printed materials etc.). All R procedures can be called directly from graphic user interface of the OpenCPU server (OpenCPU API Explorer), which is involved in the default server installation.

Moreover, the MEDCIN platform visualises the content similarity between all related SQB subset (events) using

a dendrogram. It draws a tree diagram illustrating hierarchical clusters based on a term-document matrix of keywords frequency vectors representing the occurrence of keywords in particular events. Euclidean distance has been used to compute events dissimilarities (see Fig. 2). The distances between two particular events visualise how similar these events are (based on the keyword occurrence). The achieved results will provide the possibility of an effective evaluation of the curriculum by senior curriculum designers and guarantors of a given medical and healthcare discipline. The final online analytical reports must be assessed in terms of meaning, interpretation and visual transparency.

## DISCUSSION

The main limitation concerning R-based visualisations is the non-availability fully responsive and reusable vector outputs. One of the possibilities to get the required SVG object is to use a graphic output of the *ggplot2* package. We managed to plot the dendrograms using this package. In terms of wordclouds, *ggplot2* does not have any feature for these types of graphs yet. But with the massive package expansion, *ggwordcloud* feature is expected to be developed. In order to keep the wordclouds both informative and good-looking, we decided to use the *wordcloud* package, which limits the SVG output responsiveness due to the usage of the base R graphics. Solving the issue of SVG export might be one of our goals for the future.

Moreover, stemming is not necessarily a user-friendly approach for further visualisations; rather, it is desirable to obtain a meaningful word again. Therefore, our future plans are to add a stem completion function, which will take all words with the same stem, find the equivalent of their original forms and complete the stems to these respective forms.

In future, the main challenge in terms of produced information visualisations will be to create outputs which would combine the standardised MedBiquitous vocabulary with an understandability to wider groups of users. The problem is that some of the defined terms are either too concrete and not well-known or, by contrast, too common and abstract (e.g. sequence block). That is why the visualisations or web page blocks are followed by text with additional information and examples.

## CONCLUSION

We described the main research questions of automatic keyword exploration on medical and healthcare education data. We showed a pilot R package analysis including web-based visualisations in accordance with a proven data-mining methodology, which led to real results in practice. We demonstrated a powerful tool for the visualisation of curriculum data, which makes an overview of comprehensive keywords very simple to be critically evaluated by an expert in a given field. The selected algorithm for keyword exploration was successfully implemented as a module in the MEDCIN platform.

**Abstract**—At the Charles University, Faculty of Medicine, in Hradec Kralove, the *Biophysics and Biostatistics* subject is implemented as a traditional combination, i.e. contact, educational method and e-learning. The e-learning is realized in the LMS Moodle in the “multicourses” called *Biophysics and Biostatistics – General Medicine* and *Biophysics and Biostatistics – Dentistry*. A process of teaching during the whole term is described in this contribution too. One of the important points is the explanation of the evaluation system of the key activities that are realized in the LMS Moodle. As a part of contribution are added the statistical results of the success rate of all the *Online tests to lab and Credit tests*. In the conclusion, the reader gets to know our main aim, which is the completion of the student’s complex evaluation during the whole “multicourse”. This complex evaluation demands the interconnection of the interactive Excel protocols with the LMS Moodle.

## I. INTRODUCTION

AT THE Charles University, Faculty of Medicine, in Hradec Kralove, the *Biophysics and Biostatistics* subject is implemented as a traditional combination, i.e. contact, educational method and e-learning, that is defined in [1]. A number of software tools is used to create e-learning courses as, e.g. WebCT, Blackboard, Adobe Connect, etc. [2]. For about 10 years, e-learning has been implemented using the LMS Moodle software on the *Moodle LFHK* portal ([moodle.lfhk.cuni.cz](http://moodle.lfhk.cuni.cz)). Currently, the system Moodle constitutes more than a half of all the installations of LMS (Learning Management System) systems on the world [3]. Our faculty, especially the *Department of Medical Biophysics*, has many years of experience with e-learning, which is obvious from [4] - [6]. Since the start of this approach, Moodle has been primarily used as a space to upload files to. To a small degree, optional tests for students were implemented; however, they didn’t follow a comprehensive concept. Our goal was to gradually find a comprehensive approach on how to evaluate each student’s activities in Moodle within the *Biophysics and Biostatistics* subject. Another target was to create e-learning lessons

(both mandatory and optional) students could go through without a teacher’s assistance. In this way, an extensive textbook on statistics, available at *Moodle LFHK*, was created, as well as e-learning courses used to support practical laboratory tasks. These workshops include, for example, interactive guides for practical exercises combining the scientific and didactic approach to a specific problem. An example is a laboratory task to measure the firmness of a nitinol stent, where the theory of this task is a result of [7] - [9]. In the academic year 2012/13, two new “multicourses” called *Biophysics and Biostatistics – General Medicine 2012/13* and *Biophysics and Biostatistics – Dentistry 2012/13* were established for both educational programs. In fact, both courses virtually have the same structure, basic controls, and settings. Therefore, we will focus on the course for general medicine.

## II. METHODS AND MATERIALS

General medicine students are divided to 5 study groups during the registration process (within each biophysics group, the students are divided into approx. 10 units of 3 members), thereby, a group reporting process was created. This reporting system enables filtering test results and other activities based on the groups. Simultaneously, it enables submitting seminar tasks as a group. All these activities are the key for further implementation. The basic concept was created to enable copying of the above mentioned course, *Biophysics and Biostatistics – General Medicine 2012/13*, at the end of the year, name the copy during the current year, and move the original course to the archive. To enable this, each mandatory activity and material had to be created as a part of this course.

The course is divided into 9 topics. This structure brings an advantage that only the current year changes in several topics and the rest of the information remains the same. The topics of the course include:

1. Information on the subject
2. Lectures for the current year
3. Self-study
4. Practical lessons – labs
5. Practical lessons – statistics

This work was written with the support of the project of the Ministry of Education MŠMT IP 2016-2018 63 *Creating of multi-platform systems for Education support including tools for user friendly support*

6. Practical lessons – informatics
7. Practical lessons – test seminars
8. Students' projects
9. Continuous testing

Topics 1 and 2 contain general information only. In topics 3, 5, and 6, students can use links to existing courses. These courses were designed as separate units – to enable other students, which we do not want to enroll to the above mentioned “multicourse” for the current year, to access these courses. These courses are optional, and potential course grades are not necessarily included in the overview of “multicourse” grades. Topics 4, 8, and 9 contain required and monitored activities, usually linked to the contact education method, i.e. seminars or lectures. Therefore, grades from these activities are included in the grade overview. This concept ensures that all activities necessary to obtain a credit are available in a single integrated grade overview. Topic 4 is the key topic used to combine the traditional educational method and e-learning.

This topic enables students to use links to guidelines for laboratory measurement, again designed as e-learning courses. This way, students can get ready for both theory and measurement before they actually do it. Laboratory measurements are done using the contact educational method in biophysics laboratories. Interactive protocols are another part of topic 4. Each of 5 laboratory measurements has its own output – an interactive protocol the student uses to record their measured values. The protocol also contains Excel macros, which automatically verify the calculations, including statistical tests. Based on this, the student immediately knows whether their calculations are correct or not. Moreover, metadata from the protocol is uploaded to a server after the student finishes their protocol by clicking on Submit. These interactive protocols advantageously provide students with instant feedback. The main benefit for teachers is that protocols are evaluated automatically. The goal is to try to modify the protocols so that a record of the protocol is automatically uploaded to the students' records in Moodle for the above mentioned “multicourse” and a grade is assigned. The third part of topic 4 are *Online Tests to Labs* (hereinafter only the *Online tests*). These tests are directly attached to the course; therefore, their evaluation is also available in the general grade overview and can be used to verify whether students are ready to perform a measurement task.

Each of 5 online tests contains 5 questions with a time limit of 10 minutes. The tests are mandatory, and each student must complete a specific test corresponding to a measurement task in the computer classroom before they can do the task. The goal of the test is to clarify how well students are prepared to execute laboratory measurement tasks, both in the theoretical and practical manner. As these tests have been used in this form since the 2012/13 academic year, they provide interesting statistical information for overview. Moreover, they are included in comprehensive student evaluation of the subject, and the evaluation process is fully implemented in the above

mentioned “multicourse”. As stated above, this complex model was established in the 2012/13 academic year. For results of the average success rate for each of the 5 online tests, see Fig. 1 and Tab. 1.

TABLE I.  
AVERAGE SUCCESS RATE [%] FOR ONLINE TESTS FOR THE LAST 5 YEARS

	Senses	ECG	Ultra-sound	CT	Micro-scropy
2012/13	96,5	94	84,9	94,5	85,5
2013/14	62	82,6	85,9	91,5	87,3
2014/15	69,1	86,3	71,3	76,1	84,6
2015/16	67,6	87,6	69,1	75,8	84
2016/17	62,8	87,3	63,7	72,9	89,9

Fig. 1 Average success rate [%] for *Online tests* for the last 5 years

The values displayed are always arithmetic means of the success rate in percentage, since this is what Moodle enables. Figure 1 shows that in the first academic year (2012/13), online tests were not successful to the same degree. The main reason was that not all online tests were designed by the same author. In the following academic year, questions in the online tests were supposed to change to make tests more difficult. This manifested mostly in the *Senses* test and *ECG* test. A very small change occurred in the *CT* test, which may not have necessarily been caused by the change of the questions. For the next academic year (2014/15), questions for the *Ultrasound* test and *CT* test were adjusted, based on the protocol in Moodle. This influenced success rates for both tests in that academic year. Based on the attached chart, we can make an observation that the authors succeeded in their attempts to unify difficulty levels of the *Senses*, *Ultrasound*, and *CT* tests from that academic year onwards. The general trend showing success rate dropping for the three tests mentioned above confirms this fact. And as the tests have not been updated since the 2014/15 academic year and the success rate drop is still obvious, we will have to focus on this drop if it manifests in the upcoming years. Last but not least, the chart clearly shows the *Microscopy* test and *ECG* test have been resulting in significantly higher success rates in the last

three years than the remaining 3 tests. However, a lower level of difficulty of both of these topics might be the cause. Since each student has to finish all 5 online tests, it is not necessary to unify levels of all online tests.

From the general didactics point of view, topic 8 in the above described course is interesting. A Moodle database is created within this topic. Presentations on additional topics students choose and process in the work group mentioned above are uploaded in this database. Unlike submitting via email, this method's benefit is that a teacher can filter presentations based on fields created in the database and does not manage their receipt. Additionally, group reporting applies to the entire course; therefore, a teacher can select one of five study groups for verification. Moodle settings enable setting up separate groups, which means that, for example, students from the 2<sup>nd</sup> group cannot see other groups' presentations. Having uploaded their presentations in Moodle within the defined period, each work group (1 through 10) within each of the five study groups delivers its presentation during *Student Project Presentation*. Only then is the student's activity named *Student Project Submission* in Moodle marked as *Satisfactory*.

Two continuous tests, *Continuous Test – Statistics* and *Continuous Test – Biophysics*, are prepared for students in the final course topic. Students complete both tests in the IT room across various days – per each study group, based on the schedule. The test usually includes the *Calculated Question* type. This task type enables the creation of various numerical values in the test instructions. Both tests are also restricted by a password, time lock, and IP address. Therefore, it is virtually impossible for students to complete the test at another time than within the pre-defined time period under an assistant's supervision. This format of continuous tests was established in the 2012/13 academic year; test settings have not changed, even though a new test is created every year. Again, Moodle provides success rate statistics for both tests for the last 5 years, see Fig. 2 and Tab. 2.

TABLE II.  
AVERAGE SUCCESS RATE [%] FOR BOTH CONTINUOUS TESTS

	Test - statistics	Test - biophysics
2012/13	74,06	56,18
2013/14	82,3	73,06
2014/15	77,67	63,15
2015/16	72,37	67,85
2016/17	81,53	67,38

No common trend seems to emerge out of the tests. The main reason lies in a different concept of both tests; the biophysics test almost exclusively uses the *Calculated Question* type. Variability of statistics-test tasks is significantly lower than that of biophysics. Moreover, the task pool used to select tasks is much broader for

Fig. 2 Average success rate [%] for both continuous tests

biophysics. These 2 factors result in the obvious conclusion you can see in Fig. 2: a higher success rate of the statistics test from the long-term perspective. Another factor that influences the rate is that the biophysics test should actually be more difficult, which was our intention, and it is confirmed by Fig. 2. The change of the average success rate of the statistics test where the difference between the minimum and maximum is less than 10 (roughly 1.5 tasks) indicates fairly low fluctuation during 5 years and is no surprise to us. The test contains 15 tasks selected from 16 task categories where one task is selected from each category. Therefore, variability of test options is not very high, unlike the biophysics test where the type variability is significantly higher. Table 3 shows the higher variability.

TABLE III.  
NUMBER OF CATEGORIES AND NUMBER OF TASKS FOR BOTH  
CONTINUOUS TEST

Computer	Number of categories	Number of tasks
Test - Biophysics	20	65
Test - Statistics	16	25

One reason to create the above mentioned “multicourse” was a possibility to provide users with all information on the subject within a single course. At the same time, a course designed in this way provides teachers with a comprehensive overview of student grades. Teachers who create grade overviews can use filters to select grades of a particular study group from all 5 study groups. Most of the activities are graded automatically, except for the student project database, where the teacher has to save a grade named *Student Project - Satisfactory* for each student in the database, after the student has delivered their presentation as described above. Nevertheless, this manually entered grade also appears in the grade overview.

The grade overview of each student contains the following items: *Database – Student Projects* (the grade entered by the teacher), *Senses test*, *ECG test*, *Ultrasound test*, *Microscopy test*, *CT test*, *Test 1 – Statistics*, and *Test 2 – Biophysics* (grades applied automatically). The only item of all graded student activities, which is not included in this “multicourse”, is *Protocol Evaluation*. As indicated above,

the protocols are interactive and are evaluated automatically using Excel macros. When a protocol is submitted, metadata is saved to a student record in the *PC Doctor* system. The protocol and student's record in *PC Doctor* are linked together using the student's ISIC card number the student enters to both the protocol and their record in *PC Doctor*. Therefore, the entire process is fully automated, except for the final verification stage which must be executed manually by the teacher.

### III. CONCLUSION

We came to a conclusion that a targeted complex evaluation method brings benefits for both teachers and students. Students can browse points awarded in each activity throughout the entire term. Moreover, the evaluation is fully unbiased. The main advantage for teachers is in reduction of the time they used to need to correct tests. The main disadvantage of this complex evaluation is that, as of today, it is not possible to automatically evaluate interactive protocols we created and assign them to the Moodle system. Therefore, our current objective remains unchanged – to integrate protocols and *LFHK Moodle* so that the data of a correctly evaluated protocol is loaded to *LFHK Moodle*, assigned to the respective student, and added to the grade overview. This way, the grade overview of each student will be fully automated and complete. It will then make sense to create linked scoring and an overall grade of the course for each point-awarded activity. This method basically enables the award of a credit without being potentially “biased” by the teacher. In the time of publishing this article, this option had not been finished and, therefore, no conclusion from a complex evaluation system we head toward within the course can be presented.

### ACKNOWLEDGMENT

We would like to thank to our IT support staff from the IS/IT Division of our faculty for their invaluable help.

# A Method For Data Classification In Slovak Medical Records

Erik Kučera, Oto Haffner and Erich Stark

Faculty of Electrical Engineering and Information Technology

Slovak University of Technology in Bratislava

Bratislava, Slovakia

Email: erik.kucera@stuba.sk

**Abstract**—The topic of representation, classification, and clustering of text documents and information extraction is currently a very researched area. The area of data mining and text mining has its specific problems in the Slovak language. This paper deals with the methods of pre-processing of medical data, namely Slovak health records written in natural language, and their subsequent analysis, especially classification of their parts into classes.

## I. INTRODUCTION

**D**ATA mining is a process of analyzing large amounts of data from different perspectives, their summarizing and their use in various sectors. It uses methods of statistics, artificial intelligence, machine learning, mathematics, etc. Data mining is very widely used in practice. For example, in scientific research, for spam blocking, in marketing to decide which customers it is appropriate to send a products offer. Knowledge discovery is a process of (semi-) automatic extraction of knowledge. There are different methods of knowledge discovery but in general, it has following key steps: definition and analysis of our task, obtaining relevant data and its comprehension, data pre-processing, data mining, evaluation and identification of patterns and found knowledge [1] [2].

Data mining process begins with an analysis of the particular task and understanding of existing knowledge and definition of an objective. A process of obtaining relevant data follows. Therefore, it is necessary to decide which attributes in the existing databases are relevant to the task. Then we need to understand this data [3]. It is necessary to decide whether there is sufficient sample for extracting relevant applicable knowledge. All these steps were also applied in our project. In the phase of understanding the problem, we studied the current state of the problem of elektronisation of medical records in Slovakia [4]. In the next phase of understanding the data we started studying specific reports, we investigated their quality regarding further processing and subsequent data mining. During the preparation phase, we tried to select a suitable sample of medical records for the next phases of the process. In the phase of modelling the data, we applied various algorithms and tweaked their parameters. Then we evaluated the results achieved by these algorithms.

## II. RESEARCHED METHOD

In this section, we introduce a methodology, which is a contribution to the field of data mining and categorization

of medical records in Slovakia. The result of this procedure is mainly paragraph classification of medical reports and aggregation of data into logical units.

*Division of medical records to individual paragraphs* - Doctors usually divide logical parts of their documentation into paragraphs. A reasonable step is a division of the original text into these physical units (paragraphs). Each paragraph of the report is saved in a separate text file. We used a library named Apache POI which was used for creating of our application. This application was used for division of documents into paragraphs. Using this application, we can easily divide a lot of documents into distinct paragraphs.

*Lemmatization* - The next step is a lemmatization of texts using software tool Morphonary. During the process of lemmatization, we ensure the words with the same word root (i.e. doctors and doctor) are identified as the same term. This is important during paragraph classification process.

*Analysis of the list of the most common words in the records* - Lemmatized texts should be further investigated with the application RapidMiner. Using the list of the most common words in records, we can analyze whether a certain doctor uses its own atypical abbreviations or words. If these words are found, they should be inserted into lemmatizer's dictionary as a new entry. E.g. if the doctor uses an abbreviation 'pcent' instead of a word 'pacient' it is good to add a pair 'pcent - pacient' to lemmatizer to replace all 'pcent' occurrences with 'pacient'.

*Completion of lemmatizer* - It consists of the aforementioned addition of atypical words to the dictionary of lemmatizer.

*Categorization of the paragraphs* - This is one of the most important things on our progress in the researched area. In this step, we try to classify paragraphs of medical records to the correct category like prescribed medicine or patient's subjective complaints. In the practical part of the paper, we try to introduce the procedure using RapidMiner how to classify these paragraphs. Since this is a broader issue, our results and the success of each method is given for clarity in a special chapter.

*Classification of data into logical units* - Using tokenization we divided the text into small pieces, and many of them are related. Therefore, in the last phase, we tried to group each part of the medical reports using logical structures into compact units.

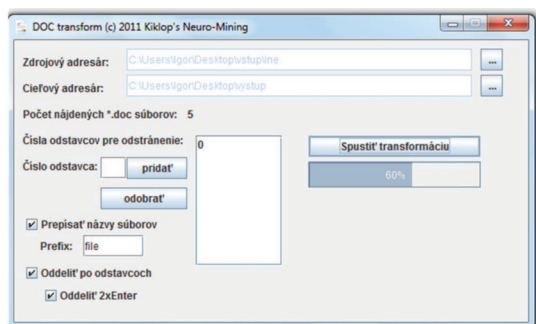

Fig. 1. Application "DOC transform" programmed using Apache POI library

#### A. Division of medical records into paragraphs

We assume that documents produced by doctors are created by Microsoft Office or OpenOffice. We used the library Apache POI [5] for processing these files. Our application can be used for processing of a large amount of files (health records). We can send the input and output folder where processed documents (divided into paragraphs) are stored (Fig. 1).

#### B. Lemmatization

We used software tool Morphonary for lemmatization because of its best ratio 'speed / efficiency / complexity' [6]. This tool was programmed in Java.

Morphonary works with three dictionaries: Dictionary of foreign words (in Slovak language *Slovník cudzích slov - SCS*), Dictionary of Slovak language (in Slovak language *Slovník slovenského jazyka - SSJ*) and declined words dictionary. SCS contains approximately 60 000 words in basic form. SSJ contains approximately 12 000 words.

The very important is 'declined words dictionary'. This dictionary contains 1730 words in basic form and their inflected forms. These 1730 words are selected to represent the variability of inflected forms of words. There are pairs 'basic form / inflected form'. If the algorithm does not find a word (that is going to be lemmatized) in SSJ or SCS, this process occurs. On the basis of these word pairs, the algorithm evaluates the suffixes. In the case of similarity, the algorithm replaces the word to be lemmatized with its predicted pattern - the root word in the basic form found in this dictionary.

#### C. Analysis of the list of the most common words in the records

This step consists of pre-processing (tokenization, stop-words removal, filtering tokens shorter than 2 characters and longer than 99 characters) and further processing by RapidMiner application (Fig. 2).

Now we can use RapidMiner for obtaining of the wordlist and analyze it (Fig. 3).

#### D. Completion of lemmatizer

In health records, there are frequently used foreign words, technical terms or own doctors' abbreviations. By analysis,

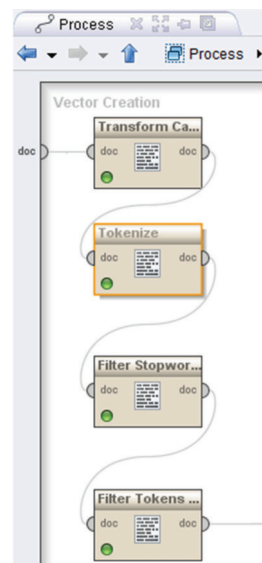

Fig. 2. Pre-processing - RapidMiner application

Word	Attribute Name	Total Occurrences	Document Occurrences
mg	mg	48	12
hrudník	hrudník	26	17
bila	bila	25	11
st	st	25	13
mmnut'	mmnut'	23	3
mudr	mudr	21	9
pacient	pacient	21	16
deň	deň	20	13
vyšetriť	vyšetriť	20	15

lekár	lekár	14	14
min	min	13	11
prijat'	prijat'	13	11
uka	uka	13	3

Fig. 3. Wordlist - RapidMiner application

it was investigated that lemmatizer has the lowest percentage of correctly processed words with this group of tokens. We decided to find a method that does not lemmatize these words. If a word is an abbreviation, it should be transformed into its full form.

This is a brief description of proposed method:

- 1) For several randomly chosen health records of a certain doctor, we obtain a word list that belongs to mentioned word group.
- 2) A list of these words is shown to the physician who translates it into the full form.
- 3) We export these pairs of words ('abbreviation - full form') to CSV file.
- 4) We import this file in the Morphonary and add it to the declined words dictionary.
- 5) After lemmatization process, these abbreviations and special words will be translated into their full forms.

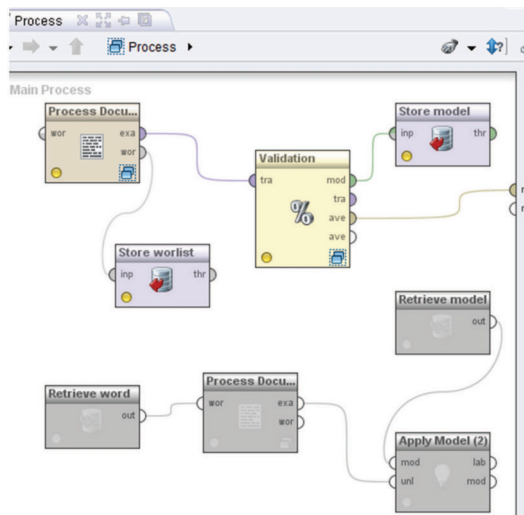

Fig. 5. Report of cross-validation

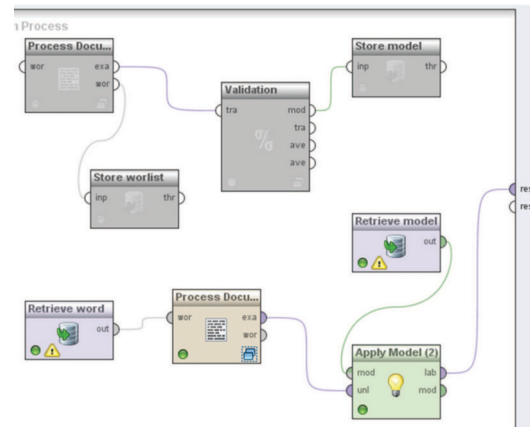

Fig. 6. Classification using trained classifier

### E. Categorization of paragraphs

For categorization of paragraphs, we mainly use classification (supervised learning). That means that we have to classify some sample data manually. Then a classifier is created, and then this classifier is used to classify the other data. We can easily perform this process in Rapidminer. We use mainly three methods of classification - Naive Bayes, k-nearest neighbour (k-NN) and decision tree.

We will briefly show how to use k-NN method in Rapid-Miner (using of Naive Bayes or decision tree is very similar).

The basis is to correctly set the operator named *Process Documents from Files*. We can see the entire process in Fig. 4.

In a window, we have 2 groups of operators (Fig. 4). The lower group is deactivated in the figure. Next, we set input files for operator *Process Documents from Files*. These input files are a training set of data that are manually classified by a supervisor (human). Our categories are epicrisis, code of the medical facility, medicine (or therapy), names (of doctors, etc.), subjective problems, examination, and conclusion.

We need also the operator named *X-Validation* that can be found in operators menu: *Evaluation - Validation - X-Validation*. This operator is used for teaching the classifier and its cross-validation.

When we double-click on the operator *X-Validation* we can see the window of cross-validation subprocess. This window contains two subwindows: *Training* and *Testing*. We insert the operator *k-NN* (or *Naive Bayes* or *Decision tree*) to subwindow *Training*. Then we set *Measure types* to *NumericalMeasures* and *CosineSimilarity*.

Next we insert operators *Apply Model* (*Modeling* - *Model Application* - *Apply Model*) and *Performance* (*Evaluation* - *Performance Management* - *Performance*) to subwindow *Testing*. Finally, we link the operators.

We need to add two operators of type *Store (Repository Access - Store)* to the main process. We link the first one

to the output named *wor* of the operator *Process Documents from Files*. On its settings, we choose the path where the input should be stored. This output is the wordlist from operator *Process Documents from Files*. We will need this output later during classification. The second operator *Store* is linked to the output *mod* of the operator *X-Validation*. By this, we save our trained classifier to a file. We will need it during the classification process.

Then we can run the process. Then we open a results window and the tab *PerformanceVector*.

In Fig. 5 there are results of cross-validation that was performed using training data. A sum of values in a row determines the number of documents that are categorized to the certain class. For example, there are 9 files categorized to the category *epicrisis*. A sum of values in a column determines the number of documents that are actually of a certain type/class (we have this information because training data was manually categorized). For example, 7 files really belong to the category *epicrisis*.

The last column *class precision* determines what ratio of documents classified by the operator as epicrisis actually belongs to this class. The last row *class recall* determines what ratio of documents that are actually of a certain class has been really classified to correct class.

The result of cross-validation gives us information about the precision of classifier. We can further modify our training data or parameters of the operator.

Next, we are going to classify uncategorized data by trained classifier. Operators that were used previously should be deactivated. We add new operator *Process Documents from Files*.

	names	exam.	therapy	concl.	epicrisis	codes	subj.	PREDICTION
	(REAL)	(REAL)	(REAL)	(REAL)	(REAL)	(REAL)	(REAL)	PRECISION
names (PREDICT.)	37	0	1	1	0	0	0	94,87%
exam. (PREDICT.)	2	37	0	0	0	0	2	90,24%
therapy (PREDICT.)	0	0	24	1	0	0	0	96,00%
conclusion (PREDICT.)	0	0	2	10	0	0	0	83,33%
epicrisis (PREDICT.)	0	0	0	3	10	0	0	76,92%
codes (PREDICT.)	0	0	0	0	0	8	0	100,00%
subj. prob. (PREDICT.)	0	2	2	0	0	0	10	71,43%
RECALL	94,87%	94,87%	82,76%	66,67%	100,00%	100,00%	83,33%	

Fig. 8. Results of Naive Bayes classifier

Fig. 7. Describing of group of tokens - blood pressure

In settings windows, we choose the folder with documents to be classified. We need also the operator *Apply Model* and two operators *Retrieve (Repository Access - Retrieve)*. The first one we link to the input *wor* of the operator *Process Documents from Files* and in its settings, we choose a path to the saved wordlist that has been saved during classifier training. The second operator *Retrieve* we link to the input *mod* of the operator *Apply model* and in its setting, we set the path to the model that has been saved during the training process. We can see the entire process in Fig. 6. After execution of the process, we can choose the tab *ExampleSet - Data View* and see the list of classified files.

### F. Classification of data into logical units

In the GATE framework, we used *Annotation schema* to describe groups of tokens, and we would like to ensure that this activity has been gradually automated by rules and grammar JAPE (Fig. 7) [7]. This point will help future generations in their next work.

## III. RESULTS OF CLASSIFICATION

In this section, we briefly describe the results of categorization of paragraphs from health records. We have randomly chosen 25 records that were divided into paragraphs using application created with Apache POI library. We have manually categorized these paragraphs into 7 categories: epicrisis, code of the facility, medicine (or therapy), names (of doctors, etc.), subjective problems, examination, and conclusion.

We describe the results of classification with a supervisor. It was necessary to divide the data (25 health record divided into paragraphs) into training and testing set. The amount of data may seem small, but for the purpose of this project, it is fully sufficient because the goal is to find a suitable methodology and not to test large amounts of data. We afford to say that, despite this, the amount of our data is sufficient also for

practice, since it is not possible to create a versatile classifier for any health facility (at least at this stage of the project). It is, therefore, necessary that a particular health facility should prepare its training data, the quantity of which need not to be much larger than in our case. Consequently, these data will be used for the creation of the classifier for the facility.

Training data / Testing data:

- 1) 13 / 39 paragraphs of class *names (of doctors, etc.)*
- 2) 15 / 39 paragraphs of class *examination*
- 3) 13 / 29 paragraphs of class *medicine (or therapy)*
- 4) 12 / 15 paragraphs of class *conclusion*
- 5) 7 / 10 paragraphs of class *epicrisis*
- 6) 5 / 8 paragraphs of class *code of the medical facility*
- 7) 7 / 12 paragraphs of class *subjective problems*

We achieved the best results with Naive Bayes classifier. The results of Naive Bayes classifier are very good (Fig. 8). There is a certain error in categorizing of paragraphs of type *conclusion* but in practice this class is interchangeable with *epicrisis* or *therapy*. We can see that this is where the classifier categorized the remaining entries so this is not a big error.

## IV. CONCLUSION

This paper deals with the methods of pre-processing of medical data, namely Slovak health records written in natural language, and their subsequent analysis, especially classification of their parts into classes. We tried to achieve progress in the field of text mining in health records. We researched a successful method of paragraphs classification using RapidMiner. The best results were achieved using Naive Bayes classifier. It will be a challenge to try this method for health records from different medical facilities.

**Abstract**—Problem based learning, utilizing simulations and virtual reality tools represents one of the approaches integrated into the education of medicine to prepare medical students for both the bedside teaching and their later clinical praxis. On the other side, implementation of innovative didactic materials may be useful also for veterinary medicine students. Thus, veterinary topics can be introduced and explained in the form of virtual cases, helping students to understand relationships between theory and practical application of their decisions. Simulations and virtual cases are also used to assess students' clinical reasoning skills. Therefore, our work is aimed on integration of modern simulation tools into education process at University of veterinary medicine and pharmacy in Košice, Slovakia. Inspired by our colleagues from Faculty of Medicine in Košice and respecting our requirements we were able to specify appropriate methods and to introduce the first veterinary virtual patient to our students.

## I. INTRODUCTION

THE long history of education brought various attractive teaching and learning approaches. To reach the most effective and modern forms of education it is necessary to revise not only what we teach but also how we teach.

The failures resulting from inadequate competencies of medical and veterinary practitioners may lead to fatal consequences of their patients. To increase the competence of students as well as their clinical reasoning ability the problem based learning (PBL) methods are widely used. Using information and communication technologies (ICT), the former presentation of paper patient cases in PBL was enhanced by using multimedia content. Here, the virtual patients (VPs) were introduced as interactive electronic medical cases that offer advanced support for learning [1]. However, the primary aim of virtual patients is to simulate real patient care [2]. From the technical point of view, it represents an interactive computer based tool simulating medical practice [3, 4].

VPs are usually used to introduce clinical problems to the students, to begin education of medical cases or to evaluate students' medical knowledge. In most cases, the goal of the student is to find the right diagnosis and propose a correct medical treatment based on the presented data [5]. VPs are implemented to substitute appropriate real-life patients, connection between preclinical and clinical information and feedback about performance or decisions realized by

learners. Natural advantage of VPs is a safe educational clinical environment where the students obtain first clinical experience as their decisions affect progress of the case and are equipped by expert's explanations. Using VPs, learners improve their clinical reasoning skills from their mistakes that increase the level of preparation for subsequent real interactions with live patients [6, 7].

Many areas of medical education already implemented certain forms of VPs into the curricula. These areas include surgery [8, 9], nursing care [10, 11], human behaviour [12], psychiatry [13], medical microbiology [14], pharmacy [15] and many others. However, VPs integrated into the curricula of veterinary medicine are rarely reported. One of the positive examples is the project vetVIP (Use of virtual problems/virtual patients in veterinary basic sciences) [16].

Considering the ways how the veterinary medicine curricula is delivered to our students and recent capabilities of modern teaching methods, we decided to integrate simulations of virtual cases into the courses of veterinary medicine. We expected positive impact on our students in the sense of their better preparation for later practical contact with veterinary patients. Our expectations were based on the surveys and results that were obtained by our colleagues from Faculty of Medicine in Košice, Slovakia, in teaching of medical students [17, 18]. Thanks to their activities and cooperation within MEFANET network (Medical Faculties Network), which already brought many effective tools to support medical education in Czech Republic and Slovakia [19], we were able to identify the optimal platform and the ways how to integrate it into our curricula and thus to modernize education process of veterinary medicine.

## II. MATERIALS AND METHODS

Our innovation activities started by the survey and needs analysis results of the CROESUS project [20]. This project brought PBL and VPs into the curricula of medical education at Masaryk University in Brno, Czech Republic and Pavol Jozef Šafárik University in Košice, Slovakia. Survey was oriented to identify requirements on VPs and ICT simulation platforms. The questions covered the topics related to current state of e-learning services used by educators, methods to assess students' knowledge and skills, preferred technologies and architectures, technical skills,

current usage of VP systems (if any) and also the financial capabilities to operate VPs and/or VP platform.

37 (78,7%) of 47 respondents that participated in the survey stated that they do not use any VPs. However, 66% of all respondents want/plane to use VPs in their curricula. Responses in the survey resulted in the list of requirements for VPs and VP platforms. These users' requirements included: a) learning materials for students should be accessible anytime and almost anywhere, b) the system should offer various paths to the solution of the patient case and the user's decision should have an influence on how patient case unfolds, c) multimedia content should be supported by the system and easily integrated and/or modified in VP paths, d) content of VP should be created in the way which allows its reusability and standardization, e) system should offer tools for continuous assessment of students' knowledge, f) the whole system should be easily administered and adaptable to the infrastructure of existing learning courses if needed, g) functions, features and interface of the system should be intuitive and easy to use, and h) based on academic environment and educational purpose it is expected the system will require minimal or no financial resources.

Respecting these teachers' requirements, we concluded the VP platform should support the following main features: a) branched structure, b) multimedia content, c) interoperability to exchange outputs, d) web administrative and web accessible environment, e) national or English localization and f) free/open license.

In the next analysis, we studied and summarized information about several recently available computer-based simulation programs/platforms designed and used in medical education. The list of platforms involved CAMPUS, CASUS, DecisionSim, OpenLabyrinth, RoD, TUSK, UChoose, VIC and WebSP. Comparing all available information, the systems were rated and they obtained one point if they had the required feature, half of the point if the feature was not as expected but acceptable and zero if the feature was not available at all. The final order of the systems was OpenLabyrinth (8.0), Tusk/OpenTusk (7.0), DecisionSim and Web-SP (6.5), UChoose (6.0), CAMPUS and CASUS (5.5), and RoD and VIC (3.5). Respecting results of this analysis, we decided to use OpenLabyrinth as a platform to simulate veterinary VPs.

OpenLabyrinth, used as a VP simulation platform is fully standards compliant and free open source software. It supports authoring and playing VPs in online environment. The principle of VP in Open Labyrinth is based on the map of global properties such as the map type (game, maze, algorithm, etc.), authors, real timers, visual appearance, scores, counters, etc. Within each map there are series of linked pages, named nodes, defining the options available to the user. In general, the node is the webpage presented to the user/student. Although a map may have just one node, typically it will consist of many interconnected nodes.

Individual nodes are interconnected by edges that represent potential decisions of the learner. Completing a case requires choices to be made at key scenario points with

the consequences of these choices affecting the final path through the case. The virtual patients developed using Open Labyrinth are conforming with the MedBiquitous Virtual Patients Specifications.

### III. RESULTS

To create a virtual case of veterinary patient, we have to note that there are essential differences comparing virtual patients developed for human medicine and medical students. Expecting that the VP is based on data of real cases, there is almost no problem to obtain anamnesis from human patients, but the verbal discussion with the veterinary patients is impossible.

To unfold problems or to identify place of pain, the veterinarian can consult only with owners of animals. Consultation between owner and veterinarian can significantly help to reveal diagnosis, because only the owner of animal can see the differences in behaviour of his/her animal. If the owner is not precise in monitoring, it can be a severe problem to obtain correct diagnosis - based on incomplete anamnesis. Then, the veterinarian can obtain exact diagnosis only using differential diagnostic methods and/or results of special diagnostic and clinical tests, for example haematology. Depending on location of the disease, the different diagnostic methods should be used, for example in case of corneal ulcer or in case of haemorrhagic diarrhoea. Special group of veterinary diagnosis is used in cases of infectious diseases, e.g. zoonoses or zoonothropoones. Considering these facts, we prefer to integrate branched structures into VPs to force reasoning skills of our students.

After the OpenLabyrinth (OL) was installed, using common web server running Apache, MySQL, and PHP, the pilot veterinary virtual patient was developed. Figure 1 shows individual nodes of VP as organized in visual editor.

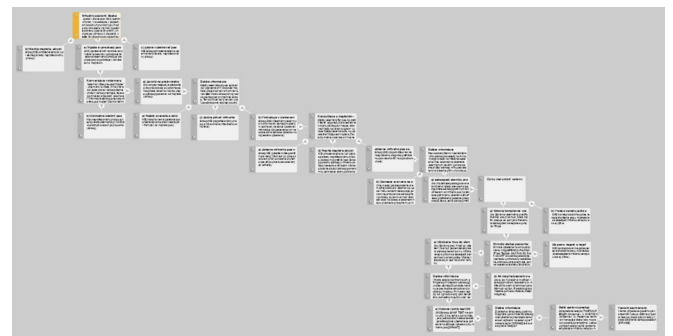

Fig. 1 VP nodes in OpenLabyrinth's Visual Editor.

The idea was to generate a highly representative case that will be used not only by the veterinary medicine students in education process, but also as a template and an exemplary case that will be presented to potential authors with the aim to increase their motivation, to reveal advantages of this approach and to minimize apprehensions that may arise from insufficient technical and ICT skills of veterinarians.

Figure 2 shows the root node of pilot VP case named Apathy. The recent sequence of the case consists of 30 nodes, in which the students are able to choose one of

**Virtuálny pacient: Apatia - Vzorový prípad; (Spolupráca UVLF a UPJŠ LF)**

Apatia v chove psov NO s jedným úhynom. V susedstve, v poslednom období uhynuli štyri psy. Podľa slov chovateľa vraj mali podobné príznaky, údajne ich otrávil. Uhynuté psy už nie sú k dispozícii, keďže ich už podľa slov osadníkov taktiež údajne zakopali. Majiteľ psov, obyvateľ rómskej osady, jednoduchý bez vzdelania má dvoch psov, ktorých chová v nevyhovujúcich podmienkach. Psy sú dehydrované a jeden z nich zomrel. Preto bol privolaný veterinár vykonávajúci kastráciu v rámci kastračného programu, ktorý aktuálne prebieha na území celého Slovenska.

**Čo urobí veterinárny lekár?**

a) Vypýta si preukazy psov  
b) Nechá majiteľa, aby zlikvidoval psa podozrivého z infekčnej choroby na svoje náklady a odíde preč  
c) Začne vyšetřovať psa bez náhubku a ochranných prostriedkov

Fig. 2 First node of final pilot veterinary VP created in OpenLabyrinth.

usually three links to other nodes – decisions. The links are randomly ordered and correct and incorrect decisions are particularly commented. All the nodes have additional explanatory information to allow students to find supplementary study materials and to explain consequences of their decisions.

The pilot VP deals with diagnostics of parvoviruses in animals breeding in inconvenient conditions and in segregated gypsy communities. Such animals often cause the health risks not only for other animals living nearby these communities, but also for people living there. Except of educational background related to the topic, the case should also point out to the long-time problem of unbearable and uncontrolled reproduction of animals in such conditions. VP also highlighted the problems related to cruelty to animals, needs to regulate population of such animals, and considerable risks of infectious diseases occurrence. This topic was purposely selected, as there is a need of special patient care. At the beginning of the case, it is necessary to select the proper procedure of the veterinarian in given conditions. The problem related to anamnesis data and to incomplete documentation needed for breeding of animals, especially vaccination certificates of perished animals (dogs) is presented as well. Whole case is designed in the way, where, based on data from pathological and anatomical dissections of perished animals as well as on fast diagnostic method, the students are able to reveal if there is an infectious disease or not. The Snap test was used as fast diagnostic method. The procedures used to examine the presence of endoparasites in animals are also presented in VP structure. Finally, to make this pilot case the most complex one, the procedures of manipulation with infectious animals, methods to design best therapy depending on diagnosis and the draft of measures to prevent spreading of

infection diseases in given breeding conditions were integrated into the explanatory parts of particular nodes.

The students are able to study the case everywhere as its link was shared for them through university webpage. Also, they are able to use any device as the VPs generated in OL are played using standard web browsers. Educational context is supported by various tools (multimedia, supporting information, comments, path review etc.) integrated directly in VPs. Our first students, that played this pilot VP, also appreciated existence of review pathway feature as it allows them to understand relations between individual decisions when they review their progress.

Fig. 3 Pathways checked by the students.

This first case, developed for veterinary medicine students at University of veterinary medicine and pharmacy in Košice, Slovakia, was accepted very well by the students as well as by the teachers. Both groups were positively surprised by the system and the way how relatively easily it can be created and applied into the pedagogical process. This pilot result convinced us to generate a series of VPs that will be aimed on various diseases and animals. Also, the final versions will be translated from Slovak to English to be able to use them in education of foreign students of veterinary medicine.

#### IV. CONCLUSION

Our effort is aimed to improve experience and intuition, as the most essential factors for clinical reasoning, in veterinary medicine students. Nowadays, majority of students use various devices to access electronic education resources, with no time and space limitation. Therefore, the VPs were recognized as modern and efficient tools that can be used in combination of traditional approaches to modernize our education process.

The first pilot veterinary medicine VP registered positive reactions from the students and they reported that they can feel responsibility for their decision, but everything in a safe environment. Also, they have to combine various clinical information before their decision is done and this is not only about memorizing and understanding of basic knowledge. Teachers were impressed by possibilities of this interactive approach too. They already suggested the topics and base structures of their new veterinary VPs including heavy, small and exotic animals.

Further complex analysis should be performed after new veterinary VPs will be finished and integrated into the education process. Then, the real impact on students' knowledge, skills and competences will be verified in an objective way.

#### ACKNOWLEDGMENT

Results presented in this work were obtained with the support of the national agency's grant KEGA 017UPJS-4/2016 "Visualization of education in human anatomy using video records of dissections and multimedia teaching materials".

**Abstract**—University admission exams belong to so-called high-stakes tests, i. e. tests with important consequences for the exam taker. Given the importance of the admission process for the applicant and the institution, routine evaluation of the admission tests and their items is desirable.

In this work, we introduce a quick and efficient methodology and on-line tool for semi-real-time evaluation of admission exams and their items based on classical test theory (CTT) and item response theory (IRT) models. We generalize some of the traditional item analysis concepts to tailor them for specific purposes of the admission test.

On example of medical school admission test we demonstrate how R-based web application may simplify admissions evaluation work-flow and may guarantee quick accessibility of the psychometric measures. We conclude that the presented tool is convenient for analysis of any admission or educational test in general.

## I. INTRODUCTION

ADEQUATE selection of students to higher education is a crucial point for both the applicant and the institution, because the quality of students influences the school's reputation and vice versa. In some countries, standardized tests have been used for decades in admission process and examination of test and item properties according to field standards [1] is a routine task [2].

In the Czech Republic, medical schools traditionally organize in-house admissions and prepare their own admission tests. Total score achieved in admission tests is usually the main criterion for the admission decision. Yet, at Czech universities, the scope of analyses checking test and item properties varies among individual institutions. While some

schools publish validation studies of their exams [3], [4], [5], [6], [7], others may perform psychometric analyses as internal reports or the test and item analysis is missing. While monographs containing the methodology of test analysis have been published in Czech language [8], [9], [10], the use of robust psychometric measures in test development is still limited.

Test and item analysis can be carried out in a variety of widely available general statistical analysis software, such as R [11], SPSS [12], STATA [13], SAS [14], and others. For item analysis based on CTT, software Iteman [15] or descriptive statistics available in Rogo [16] may be used. For analyses within IRT framework, there are several commercially available packages including Winsteps [17], IRTPRO [18], and ConQuest [19]; for other psychometric software, see also [20]. While commercially available psychometric software provides graphically convenient environment for the end user, its use may be limited due to financial costs. It is usually also impossible to tailor the provided calculations to the needs of the user, for example to adopt the existing methods for multiple true-false format of the items or to take into account the ratio of admitted students.

In this work, we present a web application ShinyItemAnalysis [21] for psychometric analysis of admission tests and their items, available online at

<https://shiny.cs.cas.cz/ShinyItemAnalysis/>,

which covers broad range of psychometric methods and offers training data examples while also allowing the users to upload

and analyse their own data and to generate analysis report. We further focus on generalization of traditional item characteristics and their incorporation into the application to allow for analyses tailored to the needs of specific admission test. We conclude by arguing that psychometric analysis should be a routine part of test development in order to gather proofs of reliability and validity of the measurement. With example of medical school admission test we demonstrate how ShinyItemAnalysis may simplify the workflow of admission tests.

## II. RESEARCH METHODOLOGY

The item analysis and evaluation of its psychometric properties should be a routine part in test development cycle [22], [23]. At First Faculty of Medicine, Charles University, the current test development cycle consists of the following phases:

- (i) item writing;
- (ii) item revision performed by domain experts;
- (iii) test composition based on prespecified knowledge domains;
- (iv) test revision;
- (v) test printing distribution to admission applicants;
- (vi) test administration (written examination);
- (vii) automatic and anonymized test scoring using a scanner (output of which is a vector of student total scores as well as a flat-file dataset consisting of responses of all applicants to each item);
- (viii) automatic evaluation of test and item psychometric properties;
- (ix) feedback to item creators

In case when the evaluation detects a suspicious item e.g. with a very high or low difficulty or with very low discrimination, such item is eliminated and not used in test scoring. The item is sent back to item writer and is further reformulated or eliminated from the item bank.

The methodology of evaluation of admission tests and their items described below is particularly involved in phases (viii) and (ix) of the workflow above. In optimal case, the evaluation should be done during a pretest. This is currently not the case due to security reasons, and it is thus even more important to perform the analysis in a semi-real time.

### A. Psychometric measures used in test and item evaluation

To evaluate the test, we use mix of CTT and IRT measures. Summary statistics are provided for the total score, together with a histogram and standard scores. Correlation heatmap displays dependencies between test items and internal structure of the test. Cronbach's alpha [24] is provided as a measure of internal consistency. Traditional item analysis further displays item difficulty and discrimination as well as properties of each individual distractor: Difficulty is defined as ratio of students who answered correctly to the item. Discrimination is defined as difference of percent correct in upper and lower third of students (Upper-Lower Index, ULI) and by Pearson correlation (R) between item and Total score (index RIT).

By rule of thumb, discrimination should not be lower than 0.2, except for very easy or very difficult items. To analyse properties of individual distractors, respondents are divided into three groups by their total score; having the equinumerous division of students' scores, ULI could be computed after that. Subsequently, we display percentage of students in each group who selected given answer (correct answer or distractor) in Distractor plot. The correct answer should be more often selected by strong students than by students with lower total score. The distractor should work in opposite direction, i. e. the ratio of students who picked distractors should be decreasing with total score. Items with negative or very low discrimination should be revised or discarded [23], ineffective distractors should be reconsidered as well.

Regression models [25] and so called IRT models [26] are used to give more precise description of item properties. Instead of displaying proportions, the regression models fit a smooth line with given parameters. These parameters are then used to describe difficulty and discrimination of the item and probability of guessing. In IRT models, student abilities are estimated simultaneously with item parameters and each item may influence ability estimates differently depending on its discrimination power. As a more detailed analysis, regression and IRT models may be used to detect a situation when item functions differently for different groups, e.g. males vs. females, or majorities vs. minorities. This so called *differential item functioning* [27] is a potential threat to item fairness and test validity and should therefore be tested routinely [28].

### B. Generalized ULI index and Distractors Plot

Because the test used at First Faculty of Medicine is composed of multiple true-false items, as part of the CTT measures, we have developed graphical representation, Distractors plot, allowing quick visual check of item properties (see also [8], [10], [29]). This visualization represents properties of all correct answers and all distractors at once. Since ratio of admitted students is usually around  $1/5$ , we may consider employing quintiles instead of terciles in the above defined index ULI. More generally, any  $q$ -quantiles may be considered. Formalization of this generalization is provided below.

Let's suppose we have a flat-file dataset (created at phase (vii)) for a given exam test, where each row consists of one of applicant's answers and each column corresponds to one of the test item questions. Dimension of the flat-file dataset is thus equal to the number of all the applicants (vertical dimension) times number of all the test items (horizontal dimension). All items included within the test are multiple true-false, thus each cell consists of combination of answers the student selected (item response pattern).

First of all,  $q$ -quantiles are calculated for applicants' total scores (see also [30]), where  $q \in \{2, 3, 4, \dots\}$ ;  $q$ -quantiles are values that partition sorted vector of applicants' total scores into  $q$  subsets of (nearly) equal size. For example, if  $q = 3$  we got terciles dividing the range of the scores vector into three subsets, for  $q = 5$  obtained quintiles split the vector into five nearly equal-size subsets.

Let  $n$  be a number of all the applicants taking the test,  $m$  be a number of all the test items and  $x = (x_1, x_2, \dots, x_n)^T$  be a vector of applicants' total scores, i.e. number of items they answered correctly, where  $0 \leq x_j \leq m$ . Let  $Q_i$  be the  $i$ -th  $q$ -quantile for applicants' total scores, where  $i \in \{1, \dots, q-1\}$ , then<sup>1</sup>

$$Q_i = \lceil (j - (n-1)p)x_{(j)} + ((n-1)p + 1 - j)x_{(j+1)} \rceil,$$

where  $p = i/q$ ,  $j = \lfloor (n-1)p + 1 \rfloor$  and  $x_{(j)}$  is the  $j$ -th smallest value in the vector of applicants' scores  $x = (x_1, x_2, \dots, x_n)^T$ . Formally, let's define  $Q_0 = 0$  and let  $Q_q = m$  be equal to the number of the test items. Then an applicant with a total score equal to  $x_j$  belongs to  $k$ -th subset if and only if

$$Q_{k-1} \leq x_j < Q_k,$$

where  $k \in \{1, \dots, q\}$ .

As a second step, let  $u_{k,t}^{\{q\}}$  be a proportion of applicants belonging to the  $k$ -th subset, who answered the item  $t$  correctly, to all applicants belonging to the  $k$ -th subset, where  $k \in \{1, \dots, q\}$ ,  $t \in \{1, 2, \dots, m\}$  and where  $q \in \{2, 3, 4, \dots\}$  is fixed. Let  $s_{j,t} = 1$ , if the  $j$ -th applicant answered the item  $t$  correctly, and  $s_{j,t} = 0$  otherwise; and let  $\mathcal{M} = \{j : j \in \{1, 2, \dots, n\} \wedge Q_{k-1} \leq x_j < Q_k\}$  be the set of all applicants belonging to the  $k$ -th subset whose boundaries are  $Q_{k-1}$  and  $Q_k$ , i. e.  $k-1$ -th and  $k$ -th  $q$ -quantile. Then,

$$u_{k,t}^{\{q\}} = \frac{\sum_{j \in \mathcal{M}} s_{j,t}}{|\mathcal{M}|}.$$

for each  $k \in \{1, \dots, q\}$  and each  $t \in \{1, \dots, m\}$  and fixed  $q$ .

Furthermore, let's suppose  $u_{k,t,w}^{\{q\}}$  be a proportion of applicants belonging to the  $k$ -th  $q$ -quantile who answered the item  $t$  by checking the option  $w$ , to all applicants belonging to the  $k$ -th quantile, where  $q \in \{2, 3, 4, \dots\}$  is fixed and  $k \in \{1, \dots, q\}$ ,  $t \in \{1, \dots, m\}$  and  $w \in \{A, B, C, D\}$  in our settings. Let  $c_{j,t,w} = 1$ , if the  $j$ -th applicant answered the item  $t$  by checking the option  $w$ , and  $c_{j,t,w} = 0$  otherwise. Then,

$$u_{k,t,w}^{\{q\}} = \frac{\sum_{j \in \mathcal{M}} c_{j,t,w}}{|\mathcal{M}|}$$

for each  $k \in \{1, 2, \dots, q-1, q\}$ , each  $t \in \{1, 2, \dots, m\}$  and each  $w \in \{A, B, C, D\}$  and fixed  $q$ .

In case we fix  $t$  and choose an appropriate  $q$  (common choice is  $q = 3$ ) we are able to get a  $q$ -tuple in the form of  $[u_{k,t}^{\{q\}}]_{k=1}^q$  and exactly  $w$   $q$ -tuples in the form of  $[u_{k,t,w}^{\{q\}}]_{k=1}^q$  which can further be used to illustrate properties of the item  $t$  and all its distractors and correct answers (as an example, see Fig. 1)

To depict attractiveness of individual answers and their combination, proportion of selected item response pattern may

<sup>1</sup>Function  $\lfloor x \rfloor$ , floor of  $x$ , returns the greatest integer less than or equal to  $x$ , and function  $\lceil x \rceil$ , ceiling of  $x$ , returns the least integer greater than or equal to  $x$ .

be depicted as formalised below for a test in which all items are multiple true-false with four options  $A, B, C, D$ . In such a case, there is exactly  $2^{|\{A,B,C,D\}|} = 2^4 = 16$  possible ways how to answer the item question (16 item response patterns). Let

$$\begin{aligned} \mathcal{O} = \{ & \emptyset, \\ & A, B, C, D, \\ & AB, AC, AD, BC, BD, CD, \\ & ABC, ABD, ACD, BCD, \\ & ABCD \} \end{aligned}$$

be the set of all possible item response patterns. For each item  $t$ , we can calculate proportion  $v_{o,t}$  of number of applicants who checked item response pattern  $o$  of item  $t$  such that  $o \in \mathcal{O}$  to number of all applicants<sup>2</sup>. Let  $\mathcal{V} = \{j : j \in \{1, 2, \dots, n\} \wedge j\text{-th applicant who chose item response pattern } o \in \mathcal{O} \text{ of item } t\}$  be the set of all applicants who chose item response pattern  $o \in \mathcal{O}$  when answering item  $t$ . Then,

$$v_{o,t} = \frac{|\mathcal{V}|}{n}$$

for each  $t \in \{1, \dots, m\}$  and each  $o \in \mathcal{O}$ .

In case we fix  $t$ , i. e. if we choose one item  $t$ , we are able depict a 16-tuple in the form of  $[v_{o,t}]_{o \in \mathcal{O}}$  which shows attractiveness of each item response pattern for item  $t$  (for example, see Fig. 2).

Finally, for each item  $t$ , we can calculate *difficulty* and *discrimination* measures. Difficulty  $\text{diffc}_t$  of the item  $t$  is defined using the proportion of applicants who correctly answered the item question  $t$  to all applicants,

$$\text{diffc}_t = 1 - \frac{\sum_{j \in \{1, \dots, n\}} s_{j,t}}{n},$$

for each  $t \in \{1, \dots, m\}$  and where

$$s_{j,t} = \begin{cases} 1, & \text{if } j\text{-th applicant answered item } t \text{ correctly} \\ 0, & \text{otherwise.} \end{cases}$$

Intuitively, difficulty of an item is proportional to number of incorrect answers recorded for the item question. (Note: often, difficulty is defined as proportion of examinees who answered the item correctly, thus describing rather item easiness, see [23].)

Discrimination which is in CTT often described by upper-lower index (ULI, difference in proportion of correct answers in upper and lower third of students, i. e. using 3-quantiles) is here defined using quintiles (5-quantiles).

In general, discrimination  $\text{discr}_t^{\{q\}}(l_1, l_2)$  is a difference between two proportions:

$$\text{discr}_t^{\{q\}}(l_1, l_2) = u_{l_2,t}^{\{q\}} - u_{l_1,t}^{\{q\}},$$

where

<sup>2</sup>No option checked, i. e.  $o = \emptyset$  is also possible item response pattern.

- $u_{l_1,t}^{\{q\}}$  is a proportion of applicants belonging to the  $l_1$ -th group, who answered the item  $t$  correctly, to all applicants belonging to the  $l_1$ -th group, where  $l_1 \in \{1, \dots, q\}$
- a proportion  $u_{l_2,t}^{\{q\}}$  of applicants belonging to the  $l_2$ -th group, who answered the item  $t$  correctly, to all applicants belonging to the  $l_2$ -th group, where  $l_2 \in \{1, \dots, q\}$  and where  $l_1 < l_2$  for a fixed  $q$ .

Intuitively, discrimination of an item describes, how well does the item discriminate between two groups of applicants which are defined by their total scores.

In our particular case, we use discrimination measure depicting differences between first and fifth quintile ( $q = 5$ ) groups as a general discrimination measure analogous to traditional index ULI (where  $q = 3$ ). We are even more interested in item discrimination between fourth and fifth quintile, because we usually admit only upper fifth of the students, thus this (the fourth quintile) is the cut-off where we want to discriminate the best. As an example, see difficulties and discrimination measures depicted in Fig. 3.

### C. R-language web-based application for semi-real-time evaluation of admission exam tests data

Methodology described above was implemented in an online, freely-available application and R package *ShinyItemAnalysis* [21], [31], available online at

<https://shiny.cs.cas.cz/ShinyItemAnalysis/>.

The core of the application is built of source code written in language R which is a *free-as-in-beer* and *free-as-in-speech* programming language and environment for statistical computing and graphics and is widely used among statisticians, econometricians, or biologists. Code chunks written offline in R language were uploaded online using *shiny* package on server dedicated to R calculations; *shiny* package is a library written also in R which provides an online framework for R scripts.

Components of the application consist of `ui.R`, which defines graphical user interface in terms of HTML (HyperText Markup Language), CSS (Cascading Style Sheets) and a little bit of javascript, and of `server.R` covering all workhorse functions and procedures of the application. There are other components beyond the mentioned two, but these are not necessary for application running. Graphical user interface offers multi-tabular layout as each tab displays one of several kinds of plots based on the tuples of important characteristics described in Research methodology passage.

The application is accompanied by training datasets, example R code, model equations and interpretation and is thus well suited for routine test analysis as well as for educational purposes and teaching the methods. Also, the application allows for online typesetting of  $\text{\TeX}$  documents and downloadable .pdf and HTML reports containing tables and figures with estimates described above.

Fig. 1. Distractors plot for item 2014 based on quintiles. Bold lines (A and B) depict correct answers, as expected, percentage of applicants who chose these answers is increasing with total score. Dotted lines (C and D) represent distractors, relative frequency of their selection is decreasing with total score. Combination of correct answers (correct item response pattern) is depicted by bar graph and again is supposed to be increasing.

## III. RESULTS

Here we focus on presentation of Generalized ULI index and Distractors Plot, while we leave it upon the reader to examine the other functionalities of the *ShinyItemAnalysis* application online or in R. We present analyses and plots for medical school admission test in chemistry.

Calculation of Upper-lower index (ULI) as well as of Discrimination Plot (Fig. 1) is based on quintiles (5-quintiles) due to the fact that usually about 1/5 of the applicants is admitted. We are thus mostly interested, how well does the item discriminate between students above and below the fourth quintile.

Detailed distribution of item response patterns is depicted in Fig. 2.

Finally, item difficulties and discrimination indices are displayed in Fig. 3.

## IV. CONCLUSION

In this paper we have introduced *ShinyItemAnalysis* application for psychometric analysis of admission tests and their items. *ShinyItemAnalysis* provides graphical interface and web framework to open source statistical software R and thus opens up its functionality to wide audience. Application covers broad range of methods and offers data examples, model equations, parameter estimates, interpretation of results, together with selected R code, and is thus suitable for teaching psychometric concepts with R, besides, it aspires to be a simple tool for routine analysis by allowing the users to upload and analyse their own data and by generating

Fig. 2. Detailed distribution of item response patterns for item 2014

analysis report. We have demonstrated, how traditional Upper-Lower index may be generalized to tailor this descriptive statistics to the needs of the individual test. We conclude by arguing that psychometric analysis should be a routine part of test development in order to gather proofs of reliability and validity of the measurement. With example of admission test to medical faculty we demonstrate how *ShinyItemAnalysis* provides a simple and free tool to routinely analyse tests.

**Abstract**—The Moodle portal of our faculty is running in a virtualized environment together with other about 50 application servers and 60 virtualized desktops. Increasing traffic on the site (reaching over 400 000 views/posts monthly) forced us to assess its performance impact on the virtualization environment. The performance analysis identified processor cycles and disk operations as the bottlenecks of the system. We are planning to address these issues with increasing of the number of processor cores in our virtualization hosts and with a solid state disk upgrade of the disk array used in our virtualization environment in our next hardware upgrade cycle.

## I. INTRODUCTION

THE FACULTY of Medicine in Hradec Kralove is like most medical faculties massively overburdened with the combination of both research and educational tasks. Just for example, our Department of Medical Biophysics has only 8 full-time staff members, who are currently teaching 16 pre-graduate courses and 2 postgraduate courses, while at the same time they are actively involved in research projects in several different fields, ranging from mathematical statistics and applications of mathematics and statistics in medicine [1]–[3] through mathematical modeling of apheresis procedures [4]–[5], applications of shape memory materials in general medicine [6] and dentistry [7]–[8] up to inclusion of modern teaching method based on applications of information technology in medical education [9]–[11]. The conditions in the other departments are hardly any better.

The only solution of such situation is extensive application of the methods of unsupervised learning [12], which are in our faculty represented mainly by the e-learning courses running in the learning management system (LMS) Moodle.

Unfortunately there is an unavoidable downside of this approach – the ever-increasing demand for the computational and data storage resources. We are therefore currently planning a significant upgrade of our IT infrastructure, which we would like to base on a thorough analysis of the performance requirements and the potential bottlenecks of our current setup.

This work was supported by the program PROGRES Q40-09.

## II. CURRENT STATE OF OUR INFRASTRUCTURE

### A. Virtualization environment

Our faculty is currently using a virtualization environment consisting of a cluster of four identical hosts (DELL PowerEdge R810 servers equipped with two Xeon E7540 processors, each containing six cores running at 2.0 GHz, and 256 GB of RAM), connected through redundant 8 Gbps FibreChannel connections to the IBM DS3512 disk array containing 48x 600 GB and 12x 450 GB 15k rpm SAS drives organized in RAID 10 arrays. The hosts are running the VMware ESXi 6.0 hypervisors and are managed through the VMware vSphere 6 Standard.

Apart from the Moodle portal servers, there are about 50 various application servers (mostly web servers, but also MS Exchange mail servers and MS SQL database servers) and about 60 virtualized desktops running in the cluster.

### B. Moodle portal

The Moodle portal of our faculty is consisting of two virtual machines (VMs), both running a 64-bit version of the Ubuntu 14.04.1 operating system. The front-end server has 4 virtual CPUs, 6 GB RAM, and 150 GB of storage space allocated; this storage space is divided into three separate volumes, located at different physical arrays, and mounted as “root”, “moodledata”, and “logs”. It is currently running Moodle 3.2.2+. The back-end database server is running on a VM with 4 virtual CPUs, 5 GB of RAM, and 95 GB of storage space; it has just two storage volumes – a combined “root” + “logs” volume and a standalone “data” volume. The database server VM is currently running MySQL 5.5.55.

There are 381 active courses within our Moodle portal to the present day (May 2017); most of them are based on text and image information with only very limited use of video materials so far.

Our portal is used by about 1200 students and 400 staff members almost on a daily basis. Its usage pattern is showing strong year-to-year growth with peaks during the examination period of the winter term and periods of limited activity during the summer holidays (see Fig. 1).

Fig 1. Moodle portal usage statistics

### III. PERFORMANCE METRICS USED

Our analysis of the impact of our Moodle portal on the virtualization environment is mostly based on the detailed performance metrics recorded by the tools built into the vSphere management system (CPU, RAM, and disk usage – see Table I and Table II), supplemented with few statistical figures provided by Moodle itself (monthly usage statistics for different user roles – see Fig. 1).

The metrics recorded in the vSphere were chosen according to our preliminary observations of behavior of the whole virtualization system and the analysis of probable performance bottlenecks affecting our Moodle portal. CPU and RAM resources are often considered to be the most critical ones in the virtualized environments; on the other hand disk performance, especially disk I/O operations may be sometimes incorrectly given low priority. [13] We also considered recording of the network performance metrics, but we found them to be unnecessary in this particular application, as the current content of our Moodle portal was not very demanding on network resources (there were just few standard definition videos, no HD neither UHD videos stored). The over-

all utilization of network resources in our virtualized environment was also quite low.

The final set of the metrics therefore included:

- the actual CPU usage and the demand for CPU resources, both measured in MHz and summarized for all virtual cores in the VMs
- the amount of memory granted to the VMs and its actual usage
- the read and write disk operations summarized for all volumes in the VMs
- the highest value of disk latency observed in each time interval, aggregated for all volumes in the VMs

All these metrics were recorded separately for the front-end and the back-end VMs in 30 minute intervals for total duration of one week to accumulate a representative sample of the performance variation. The default aggregation methods provided by the vSphere were used in all metrics: The CPU, memory, and IOPS metrics were calculated as averages for each of the 30 minute intervals; the latency figures represented the highest values observed in each interval.

TABLE I.  
RECORDED PERFORMANCE METRICS – CPU AND MEMORY

	CPU Usage (MHz)	CPU Demand (MHz)	Memory Active (MBytes)	Memory Granted (MBytes)
<b>Moodle front-end (average value)</b>	102.7	156.4	469	6144
<b>Moodle front-end (maximum value)</b>	756	1807	2864	6144
<b>MySQL back-end (average value)</b>	37.8	47.4	162	5120
<b>MySQL back-end (maximum value)</b>	264	421	811	5120

TABLE II.  
RECORDED PERFORMANCE METRICS – DISKS

	Read operations per second	Write operations per second	Disk latency (ms)
Moodle front-end (average value)	5.7	0.2	2.2
Moodle front-end (maximum value)	240	10	101
MySQL back-end (average value)	0.1	7.4	1.0
MySQL back-end (maximum value)	10	144	41

#### IV. PERFORMANCE ANALYSIS

##### A. CPU resources

Even though the demand for CPU resources was relatively modest in both front-end and back-end VMs, it was consistently outstripping the available resources of the hosts where these VMs were running by a large margin. Both VMs were therefore CPU-limited not only in the peak load conditions but also during regular operation. The uneven character of the demand for the CPU resources can be nicely demonstrated in the chart plotting these metrics recorded for the Moodle front-end over time (see Fig. 2):

Fig 2. Moodle front-end – CPU usage and demand

##### B. Memory resources

Unlike the CPUs, the memory resources were not strained in any of the VMs even at the peak load, when the more demanding front-end VM consumed just close to 50% of its allocated memory, and the back-end VM managed to be even more prudent, consuming just up to about 16% of its allocated memory. This result should be attributed to the choice of the OS, which was installed without any memory intensive graphical user interface (GUI), as well as to the memory conserving features of the hypervisor.

##### C. Disk resources

Disk usage patterns were significantly different in each of the VMs, which is hardly surprising. The front-end (essentially a web server) was heavily leaning towards the read operations, while the back-end (database) performed mostly write operations. The absolute numbers of disk operations in both VMs were relatively low; but as the latency figures showed, these values were affected by the overall performance limits of the disk array used in our virtualization environment anyway. The coincidence of high IOPS and high latency figures can be illustrated by the chart depicting both of these metrics in the Moodle front-end (see Fig. 3):

Fig 3. Moodle front-end – aggregated disk performance

#### V. CONCLUSION

Our main conclusion should probably be that we were able to demonstrate that even a relatively large Moodle portal (381 courses, about 1600 users, up to 400,000 page views per month) could be running in our virtualized environment on very modest resources. The main reason of such low demands was without any doubt the character of e-learning materials presented in our portal – when we start using the video-based materials on a larger scale, the demands of the portal are undoubtedly going to increase significantly.

We were also able to identify CPU and disk performance as the two main bottlenecks affecting responsiveness of our Moodle portal. When we aligned these metrics to the activity logs in Moodle, we were able to identify the most resource intensive operations: The CPU activity in both front-end and back-end as well as the disk write operations were highly taxed by grading of simultaneously running tests and re-grading operations, while the disk read operations reached their high values in backup sessions (see Fig. 2 – 5):

Fig 4. MySQL back-end – CPU usage and demand

Finally, the results of this performance analysis provide us (and not only us) with the invaluable clues for a proper design of the virtualized environment capable of running of such demanding tasks without annoying lags.

Fig 5. MySQL back-end – aggregated disk performance

Based on these findings we decided to increase number of processor cores in the planned new virtualization hosts, include solid-state disks, able to provide at least  $10^5$  IOPS, in the planned new disk array, and separate virtualized servers and VDI machines to different clusters, if possible.

#### ACKNOWLEDGMENT

We would like to thank to our IT support staff from the Computer Technology Center of our faculty for their invaluable help with collecting of the performance metrics used in this article.

**Abstract**—Brain injuries seem to be one of the most widespread diseases. Hence, the main goal of our research was to investigate feature importance in the severe brain damages dataset according to the Glasgow Outcome Scale. This scale is recognized as one of several measures used to evaluate patients' functional ability as well as their conditions after applying brain damage therapy. The current approach is focused on an identification of a relevant subset of features with a similar influence on quality of classification models. According to the results gathered, about 12 from 42 descriptive features could be treated as important without the decrease of classification results.

## I. INTRODUCTION

ACCORDING to many sources [1-8], brain damages seem to be one of the most widespread civilization illnesses, occurring at different levels of severity, usually described by means of various measures (scales) [9]. It is important to say that there is no single outcome measure which can describe or predict all dimensions of recovery and disability after acute stroke. Several scales have proven reliability and validity in stroke trials [10], including the *National Institutes of Health Stroke Scale* (NIHSS), the *modified Rankin Scale* [8] (mRS, patient's functional agility), the *Barthel Index* (BI), the *Glasgow Outcome Scale* (GOS, assessment of patient's condition after therapy), the *Extended Glasgow Outcome Scale* (GOS-E) [11] and the *Stroke Impact Scale* (SIS). In this domain, several scales have been applied in stroke trials to derive a global statistic for better recognition of the effect of acute interventions, although this composite statistic is not clinically tenable. In practical applications, the NIHSS is efficient for early prognostication and serial assessment. In turn, the BI index is helpful for rehabilitation planning. The mRS and GOS parameters specify cumulative values of outcome and they are appropriate for clinicians and patients considering early intervention, while the SIS scale was created to evaluate the patient's perspective on the effect of stroke. However, the GOS-E extends five original GOS scale categories to eight. It is made to apply wide categories that are insensitive to change and to deal with difficulties with reliability due to lack of a structured interview format. Familiarity with these

different scales could support clinicians' interpretation of stroke research and improve their clinical diagnosis.

The Glasgow Outcome Scale (GOS) is a scale in which patients with brain injuries, such as cerebral traumas, can be divided into groups that allow standardized descriptions of the objective degree of recovery. This scale was very often applied before other scales were introduced. After the improvement of disability recognition, the GOS has been replaced by the *Disability Rating Scale* (DRS) [12]. However, it is still cited occasionally in the literature, often in research investigating early acute medical predictors of gross outcome. In these type of approaches, five classes of the original scale are defined: *dead*, *vegetative*, *severely disabled*, *moderately disabled*, and *good recovery*.

## II. METHODS AND TOOLS

### A. Input data

An investigated data set contains the *Glasgow Outcome Scale* characterization for 161 anonymous patients. For a description of each object, 42 features were defined [7]. Objects were assigned into five different categories, according to the *Glasgow Outcome Scale*: **1** means *death*, **2** means *persistent vegetative state*, **3** means *severe disability*, **4** means *moderate disability* and **5** means *good recovery*.

Additionally, features are divided into six groups according to their context:

**A1-A9** – General data about patient.

**B1-B14** – Patient's specific features.

**C1-C7** – Condition of health.

**D1-D3** – Disorders.

**E1-E6** – Treatment.

**F1-F3** – Rehabilitation.

Detailed information about features and their values is presented in Table I.

### B. Methods

The main focus during the research is to investigate presented data in the context of finding relevant features inside data that provide similar information after reduction of a feature space [13]. For this purpose, four different approaches for ranking measures and algorithms were

applied. Classification quality was computed before and after an application of a feature selection procedure. Firstly, a simple filter method using a ranking measure in a form of *Information gain* was applied to calculate ranking values for each feature [14]. In this step, the dataset was extended by adding contrast variables to define the threshold between informative and non-informative features [15]. It means that each original feature was duplicated and its values were randomly permuted among all objects. In this way, a set of non-informative, by design shadow, features was added to the set of original features. The features, selected as important rather than random, were treated further as an important feature subset. Then, the classification process using five learning algorithms (*CN2 rules*, *Classification Tree*, *kNN*, *SVM*, *RandomForest*) was executed. After that, to extract a relevant feature subset, two other algorithms were applied [16]. The first one is based on the frequency of presence of features contained in the rule model that is created on the basis of the original dataset and additionally takes into account the quality of rules in which an analyzed feature occurs. Thus, the importance value of the  $i^{th}$  attribute (*DRQualityImp*) could be presented as:

$$DRQualityImp_{A_i} = \sum_{j=1}^n Q_{R_j} \cdot Pres(A_i)$$

where  $n$  is a number of rules in the learning model,  $Q_{R_j}$  is the classification quality of the rule  $R_j$  and  $Pres(A_i)$  describes the presence of the  $i^{th}$  attribute, usually either 1 (feature occurred) or 0 (feature did not occur). In turn, the quality of a given rule  $R_j$  is defined as:

$$Q_{R_j} = \frac{E_{corr}}{E_{corr} + E_{incorr}}$$

where  $E_{corr}$  is a number of correctly matched learning objects by the  $j^{th}$  rule and  $E_{incorr}$  is a number of incorrectly classified objects by this rule. In turn, the second algorithm (*DTLevelImp*) is based on the presence of a feature in the decision tree nodes generated from the original dataset and also takes into consideration the product of a weight  $W_j$  assigned to a given level  $j$  of the tree and the number  $Inst(node)$  of cases classified in a given node at this level in which the feature  $A_i$  occurs. Thus, the *DTLevelImp* of the  $i^{th}$  attribute can be presented as:

$$DTLevelImp_{A_i} = \sum_{j=1}^l \sum_{node=1}^x W_j \cdot Inst(node) \cdot Pres(A_i)$$

where  $l$  is a number of levels inside the model,  $x$  is a number of nodes inside at a given level and  $Pres(A_i)$  denotes the presence of the  $i^{th}$  attribute, usually either 1 (feature occurred) or 0 (feature did not occur).

In turn, a weight  $W$  of the level  $j$  is defined as:

$$W_j = \begin{cases} 1 & \text{if } j = 1, j \in N, \\ \frac{W_{j-1}}{2} & \text{if } 1 \leq j \leq l. \end{cases}$$

The last approach to feature selection is based on rough set theory. In rough set theory, feature selection refers to finding

TABLE I.  
FEATURES DEFINED ACCORDING TO THE GLASGOW OUTCOME SCALE

Code	Name	Values
A1	Gender	Male; Female
A2	Admission_diagnosis (Acc. to ICD-10 classification)	Subarachnoid_hemorrhage; Intracerebral_hemorrhage; Cerebral_infarction; Stroke; Other_cerebrovascular_diseases

original set of attributes. Various rough set methods were proposed to calculate decision reducts in decision tables, however calculation of all decision reducts is the *NP*-hard problem (see [20]). Therefore, in the experiments, we have used a more efficient method, called the QUICKREDUCT algorithm proposed in [21] and implemented in the *Rough Sets package* for the R environment. It is an example of a method producing the so-called decision superreduct that is not necessarily a decision reduct (i.e., it is a subset of attributes that may be not minimal).

After subset selection, the classification process was applied. All results of classification, before and after feature selection, are presented in Table II. In this table, results were obtained using a dataset divided into five concepts. However, we also provide results gathered using a modified dataset, where five primary concepts were replaced by two more general categories: *healthy* and *sick*. Healthy concept corresponds to the 5<sup>th</sup> concept, i.e., *good recovery*, in turn, the *sick* concept corresponds to the remaining concepts merged into one.

During the experiments, the Orange data mining tool [17] and the R environment were applied. Our own implementation of algorithms in this environment was also involved. The 10-fold cross validation paradigm was also applied during the classification process.

### III. RESULTS AND CONCLUSIONS

The results of feature selection and calculation of quality of classification are acquired in Table II and Table III. Additionally, the average results are presented in a form of a chart, see Figure 1. It could be observed that each method

caused decreasing a number of features in comparison to the original dataset. Particularly, in case of the five-class problem, application of contrast features led to selection of 12 relevant features from 42 original features, and at the same time classification accuracy (CA) and area under ROC curve (AUC) [18,19] slightly increased. Other three methods also reduced a feature space, from 42 features to 29, 17 and 9 using *DRQualityImp*, *DTLevelImp*, and *Rough Set* approaches respectively. However, in these approaches, CA and AUC parameters slightly decreased. In turn, in case of the two-class problem, there could be observed substantial improvement of classification accuracy.

Fig. 1 Average results of classification accuracy (CA) and area under ROC curve (AUC) using five learning models.

During the experiments, some of the features achieved significant values of ranking measures. In turn, other features were estimated as much less important. In this way, it could be stressed that the most important features should be diagnosed very carefully.

The future research should be focused on simplification of the descriptive parameters, finding the compromise of a low classification error rate according to high efficiency of the Glasgow Outcome Scale. Some constructive induction methods could be applied to find general measures that may simplify diagnosis support for medical specialists.

**Abstract**—The paper describes the study on the problem of applying classification techniques in medical datasets with a class imbalance. The aim of the research is to identify factors that negatively affect classification results and propose actions that may be taken to improve the performance. To alleviate the impact of uneven and complex class distribution, methods of balancing the datasets are proposed and compared. The experiments were conducted on five datasets - three binary and two multiclass. They comprise several data preprocessing methods applied on data and the classification with different techniques. The study shows that for some datasets there exists a combination of a certain preprocessing method and a classification technique which outperforms other approaches. For datasets with complex distribution or too many features the ratio of correctly predicted labels may be low regardless what resampling method and classification technique has been applied.

**Index Terms**—imbalanced datasets, class imbalance, medical data analysis, data preprocessing techniques

## I. INTRODUCTION

CLASSIFICATION is one of the core terms in machine learning. It refers to the process of prediction of class labels for unclassified, new instances basing on the knowledge drawn from historical, classified records [1]. It consists of application of the algorithm of classification technique on the already labeled data to build the classification model and attempt to discover the dependencies lying behind class labels. Afterwards, new instances are examined and assigned to the predicted groups.

Depending on the characteristics and the quality of gathered data it may be impossible to build a perfect model. In many real life cases, especially in medicine, accessing and measuring desired parameters is either costly, cannot be done precisely or at all. Collecting a representative number of samples from each class may be difficult due to above mentioned factors or due to naturally occurring disproportions. When one class is represented by much larger number of samples than the other, we refer to the class imbalance problem. It commonly arises in medical databases - large number of samples concerns patients with frequent observations while records describing special cases that are of particular interest may occur rarely.

Medical data analysis is important due to its meaning for medical decision making and diagnosis [2], [3]. Many studies have been conducted on the topic of classification techniques and how to improve their performance [4]–[6], specifically when it comes to the treatment of imbalanced datasets, but no universal, highly performing solution has been discovered yet.

Applying machine learning on unevenly distributed or incomplete datasets, in particular medical cases and resulting consequences, is discussed in the paper. Uneven class distribution is one of the problems that gains researchers' attention since late 90s [7]. In October 2005 dealing with non-static, imbalanced and cost-sensitive data was announced one of the top 10 challenging problems in data mining research by the International Journal of Information Technology and Decision Making [8].

The aim of the paper is to identify factors that affect classification results and propose actions that may be taken to improve the classification performance in terms of imbalanced datasets. Different combinations of preprocessing methods and classification techniques were used with regard to differences in datasets' characteristics: the number of target classes (two or more), the imbalance ratio, the number of features and the ratio of missing values. Even though classification problems have been studied extensively over the past few years, no universal solution has been discovered. Nowadays, there is still no perfect approach of classification as applied to imbalanced datasets and the paper constitutes an independent contribution to the relevant literature.

The rest of the paper is organized as follows. Section II describes the preprocessing techniques that may be applied to balance uneven distribution in datasets. Section III corresponds to the methods used in the experimental part of the paper and is followed by the description of medical data used in the research (Section IV). Section V is dedicated to the experiments conducted on sample data and the results. Finally, in Section VI, the concluding remarks are discussed.

## II. HANDLING IMBALANCED DATASETS

The imbalanced class distribution may be defined by the ratio of the number of instances from minority class to those from majority class [9]. Such inequality may occur in many medical problems, where the number of patients diagnosed with rare illnesses, requiring special therapy or treatment is much smaller than the number of patients who do not need it. In certain domains, the datasets may be highly imbalanced with the imbalance ratio of, for example, 1:10000 [7].

Classification methods may fail when applied to an imbalanced dataset. Learning algorithms attempt to reduce global quantities such as the error rate and do not take the data distribution into consideration. As a result, samples from the dominant class are well-classified whereas samples from the minority class tend to be misclassified.

Weiss and Provost [10] after performing classification with decision tree in imbalanced two-class problems investigated the correlation between imbalance ratio and classification results. They found out that better results are obtained in a relatively balanced sets. However, the degree of class imbalance that starts to hinder the performance cannot be explicitly defined. 1:1 population ratio may not be always the optimal distribution to learn from.

The main approach of handling data imbalance problem is resampling in order to obtain more even class distribution. It allows classifiers to perform as in standard conditions. It is a flexible, independent of the classifier solution that usually improves classifier performance. Three main techniques of datasets' balancing are described in Sections II-A – II-C.

### A. Undersampling

Undersampling involves a removal of some examples from the majority class. Non-random selection of sample removal is called a focused undersampling and may refer to the samples of the majority class lying further away [11]. Two non-random examples of informed undersampling that proved to give good results are EasyEnsemble and BalanceCascade algorithms [7], [12]. Both of them intend to overcome information loss introduced in the traditional random undersampling method.

One of more interesting approaches that was applied in [14] is Neighbourhood Cleaning Rule (NCR). Given a sample in a training set, three nearest neighbors are found. If all neighbors belong to minority class while a sample belongs to majority class - the sample is removed. In the contrary case - when a sample belongs to the minority class and its three nearest neighbors to opposite class - all three neighbors are removed [23]. In other words NCR is an informed undersampling technique where majority class samples are removed only when they closely surround or are surrounded by minority class samples.

### B. Oversampling

Oversampling consists of generating new examples and adding them to the original dataset. Similarly to undersampling, two approaches can be distinguished: random and focused oversampling. Random oversampling refers to simple

replication of existing samples. Focused oversampling means oversampling only those minority examples that occur on the boundary between the minority and majority classes.

The main advantage of oversampling is no loss of information from original dataset. On the other hand, it increases dataset size and thus computational cost [20] and may result in overfitting due to too many *tied* instances [7]. Random undersampling carries a risk of missing potentially important data, however Drummond and Holte [21] show that random under-sampling yields better minority prediction than random over-sampling.

Garcia et al. [22] applied four resampling algorithms and eight different classifiers on 17 real datasets. Authors' experiment showed that oversampling the minority class outperforms undersampling the majority class when datasets are strongly imbalanced and there are not significant differences for data with a low imbalance. Results also indicated that the classifier had a very poor influence on the effectiveness of the resampling strategies.

A variation of oversampling called Synthetic Minority Oversampling Technique (SMOTE) was proposed in 2002 by N.Chawla et al. [24] which produces synthetic examples. New minority class examples are created along the line segments between each positive class object and any of the *k*-nearest neighbors.

SMOTE shows that a combination of oversampling the minority class and undersampling the majority class can achieve better classifier performance than only undersampling the majority class. It has proven good efficiency in many works but a problem may appear when a dataset is not only imbalanced but also has a complex distribution. In such a case synthetic samples generation may lead to the overlapping between classes.

### C. Hybrid approach

Hybrid approach is a combination of over- and undersampling [24], eliminating some of the examples before or after resampling, in order to reduce overfitting. It allows to balance the dataset and keep the trade-off between decreasing majority class size and replication of minority class samples. Common approach is a combination of random undersampling with SMOTE.

### D. Multiple imbalanced class problems

Datasets with more than two classes imply an additional difficulty for classification algorithms. When multiple labels are present, solutions proposed for binary-class problems may not be directly applicable, or may achieve a lower performance than expected. For example, solutions at data level suffer from the increased search space, and solutions at algorithm level become more complex, as the learning algorithm must consider several small classes [23].

Fernandez and Lopez [23] presented binarization schemes in order to apply standard approaches to solve two-class imbalanced problems as well as several procedures which have been designed for the scenario of imbalanced datasets

with multiple classes. They proposed to transform the original problem into binary subproblems.

Class binarization techniques make it possible to apply the standard classification solutions. Two best known approaches to transform a multiple class classification problem into a set of binary problems are distinguished.

a) *One-versus-one (OVO)*: The approach trains a classifier for each possible pair of classes, ignoring the examples that do not belong to the related classes. When classifying instances, a query is submitted to all binary models, and the predictions of these models are combined into an overall classification. For those algorithms that do not have an associated certainty degree for each class, the most common way to generate the class label is to represent the output of each binary classifier in a code matrix.

b) *One-versus-all (OVA)*: The approach builds a single classifier for each of the classes of the problem, considering the examples of the current class to be positives and the remaining instances negatives. An instance will be assigned to the majority class, or randomly among the majority classes if they have the same amount of examples.

### E. Complex distribution

Additionally to class imbalance two other major factors with regard to class distribution can be distinguished: class overlapping and areas with small disjuncts and noise.

The serious problem that complicates learning of the minority class is a difficulty in separation of two classes. When in some feature space overlapping patterns are present, it is hard to determine rules for separating one class from another. Such a feature may become redundant to help recognize decision boundaries between classes.

Often standard classifiers that tend to maximize accuracy in classification fail while encountering the problem of overlapping, since they classify the overlapping region as belonging to the majority class and assume the minority class is noise [25], [26].

Another issue concerning class distribution is when a class consists of several sub-clusters of different amount of examples, referred to as small disjuncts. Many current approaches to class imbalance mostly aim to solve the between-class imbalance problem and disregard the uneven distribution within the class [27].

## III. METHODOLOGY

The proposed methodology of indicating the best pairwise combination of the preprocessing technique of datasets' balancing and the classification method consists of three steps:

- 1) applying classification methods on the original dataset without preprocessing (NOP),
- 2) performing preprocessing on datasets,
- 3) carrying out classification on datasets modified in the previous step,
- 4) comparing results of classifications.

The datasets were modified with the following methods:

- random undersampling (RU),

- SMOTE (SM) as a variation of oversampling,
- hybrid approach by SMOTE and random undersampling (SM-RU).

Four classification techniques were applied on original and preprocessed datasets:

- decision tree (DT),
- Naïve Bayes (NB),
- k-nearest neighbors with  $k=3$  (3NN) and  $k=5$  (5NN) neighbors,
- support vector machine (SVM).

Due to the fact that the presented approach aims at supporting medical diagnosis, there were chosen simple, comprehensible algorithms, as physicians should understand the tools they use.

For kNN and SVM all string or category features were normalized and mapped to numerical values where necessary. The information for the value mapping was taken from the dictionaries built in a Predictive Model Markup Language files (PMML) and integrated with the experimental environment [13].

Additionally for the sets with incomplete data, the influence of substitution of missing values by mean values was examined (-SUB suffix).

Random undersampling was performed by random row removal from all classes until each class had the same number of samples as in the least numerous minority class. SMOTE used 5 nearest neighbors, which was also consistent with results described in [14].

The approach with random undersampling and SMOTE replicated minority data by 5 times and randomly removed rows from majority class to reach equal number of rows for every class.

Gini index was applied in decision tree classification to evaluate scores, 3 and 5 neighbors were used for kNN classifier and radial basis function (RBF) kernel was employed in SVM.

Experiments for each combination were repeated 10 times. Each original dataset was divided into test and validation sets in proportion 9:1 with 10-fold cross-validation, which is widely accepted in data mining and machine learning community and serves as a standard procedure of validation [15]–[17].

Accuracy and sensitivity were chosen as evaluation metrics. Sensitivity tells how good the technique is in determining the exact class label while accuracy gives an overall ratio of correct predictions to all predictions made. All values presented in the tables are mean values from the scores obtained in 10 runs. Additionally sensitivity score is a mean value from predictions of all classes: minority and majority ones.

## IV. DATA DESCRIPTION

To demonstrate the problems encountered while dealing with medical data, test cases with different characteristics have been chosen. All of them are public datasets dedicated to researchers for machine learning tasks and medical diagnosis improvement:

TABLE I: Characteristics of considered medical datasets

Dataset name	Number of samples	Class labels ratio	Number of attributes	Missing values
Hepatitis	155	123 : 32	19	5.7%
Lung Cancer	96	86 : 10	7129	0.0%
Hypothyroid	3163	3012 : 151	30	3.2%
Thyroid	7200	6666 : 368 : 166	21	0.0%
Lung SCC Cancer	494	467 : 14 : 13	71	8.6%

Fig. 1: Pie charts for class imbalance

- Hepatitis [28],
- Lung Cancer [29],
- Hypothyroid Disease [30],
- Thyroid Disease [31], and
- Lung Squamous Cell Carcinoma [32].

Table I presents a brief characteristics of the datasets. The class imbalance is presented in graphical form in the Figure 1. Further details are discussed separately in the subsequent paragraphs.

**Hepatitis** is a dataset with two classes where imbalance ratio is equal to 0.26. The class attribute determines whether patient is dead (32) or alive (123). All other attributes are numerical and represent age, sex and other indicators' values gathered by medical scientists. There are missing values - only one column misses more than 43% of values and others up to 19%.

**Lung cancer** is also a two class problem with imbalance ratio 0.12. It refers to lung cancer diagnosis. Minority class

consists of 10 non-neoplastic (normal) lung samples and majority of 86 primary lung adenocarcinomas (tumor) samples. There are no missing values and each sample is described by 7129 genes (numeric attributes).

**Hypothyroid** is a two class problem with strong imbalance ratio, 0.05. Majority class holds attribute 'negative' while minority is diagnosed as 'hypothyroid'. The dataset has a relatively small number of missing values, but one of the columns with more than 90% of missing values was removed in preliminary data preparation.

**Thyroid** is a dataset with three classes; the most numerous class has over 18 times more samples than the first minority class and over 40 times more than the other minority class. The dataset is relatively big, there are not many attributes and no missing values.

**Lung scc cancer** dataset refers to Lung Squamous Cell Carcinoma cancer type. It contains samples described by numerical and nominal attributes and is characterized by high ratio of missing values. Classification in this sets is done by assigning International Classification of Diseases for Oncology, Third Edition ICO-3 Histology Code. The problem has one majority class (Squamous cell carcinoma) and two minority classes: Basaloid squamous cell carcinoma and Keratinizing squamous cell carcinoma.

Prior to proper data processing several rows from original Lung scc cancer dataset were removed due to their belonging to extremely rare class which will not be considered. Also, attributes that missed over 70% of values, carried identifiers, non-relevant information or the same value for all samples were filtered out (more than 20 columns in total). The process of excluding less relevant attributes in terms of further classification called a feature selection is gaining on popularity and was discussed in [35].

## V. RESULTS AND DISCUSSION

The purpose of experiments was to find how the pre-processing compensation methods improve classification of imbalanced medical datasets. The experiments were conducted according to the methodology introduced in Section III on public datasets described in Section IV.

The experiments were performed with use of The Konstanz Information Miner environment (KNIME), Version 3 [18], [19].

### A. Experimental Results for Hepatitis Dataset

Sensitivity mean values for hepatitis dataset are presented in the Table II. The best score was obtained for Naïve Bayes classifier with a hybrid approach: random undersampling and SMOTE and kNN with 5 neighbors combined with random undersampling. Support Vector Machine and Naïve Bayes showed also a high performance when trained on datasets with reduced, equal number of samples for each of the classes. Decision tree algorithm was the worst in this classification no matter which preprocessing method was applied. It can be pointed out that substitution of missing values improved

its performance when random undersampling and hybrid sampling were applied on the dataset.

The accuracy scores (Table III) reach highest values for 3NN (with missing values substitution), 5NN and SVM - no resampling for all of them. Naïve Bayes' best accuracy is worse than for mentioned classifiers but significantly better than for weakly performing decision tree.

In the Figure 2, the highest accuracy scores obtained in the experiment are compared with accuracy scores in cases where sensitivity for given classifier was highest. Only Naïve Bayes with hybrid approach reaches highest sensitivity with highest accuracy.

### B. Experimental Results for Lung Cancer Dataset

For lung cancer dataset sensitivity scores (Table IV) differed a lot across classifiers. The best result was achieved for kNN method. With 3 neighbors and no data preprocessing 9 out of 10 runs gave correct classification for whole minority class. Similar results were attained for 5NN classifier and they were only slightly worse than decision tree and hybrid over- and undersampling. SVM performed poorly but one better score was obtained when dataset was reduced. Naïve Bayes and support vector machine with other types of resampling were not capable to build any model correctly predicting the minority class labels.

This set has all records complete so no tests were made for classification with missing values substitution.

The accuracy scores in Table V were not correlated with sensitivity measure. In general, best values were obtained for classification in not preprocessed datasets with small exceptions for decision tree and SVM.

The comparison of the highest accuracies and the accuracies where the sensitivity was the highest is shown in the Figure 3. Almost all classifiers, except for 5NN, resulted in a high sensitivity and accuracy at the same time - a decision tree and 3NN with no preprocessing, SVM with random undersampling.

### C. Experimental Results for Hypothyroid Disease Dataset

The results for hypothyroid dataset (Table VI) are similar for all classifiers but SVM. A decision tree performed well even if no preprocessing was applied. Other techniques attained the best results when data was either undersampled or also beforehand oversampled. SMOTE also improved classification correctness significantly when comparing to no preprocessing at all. It may be observed that substitution of missing values slightly improved the sensitivity for kNN and SVM.

For all the classifiers without exceptions the accuracy was the best in case of an original dataset and when missing values

Fig. 3: Highest accuracy score vs. accuracy correlated with highest sensitivity score for hepatitis dataset

NOP_SUB	<b>0.9427</b>	0.8346	0.9017	0.8886	0.6206
RU_SUB	0.9152	0.8448	<b>0.9490</b>	<b>0.9495</b>	<b>0.8998</b>
SM_SUB	0.9129	0.8468	0.9426	0.9437	0.5000
SM_RU_SUB	0.9164	0.8427	<b>0.9523</b>	<b>0.9513</b>	0.5000

NOP - no preprocessing, RU - random undersampling, SM - SMOTE, SM\_RU - SMOTE and random undersampling, SUB - substitution of missing values

were substituted by mean values (Table VII).

The comparison of the highest accuracies and the accuracies where sensitivity was the highest presented in the Figure 4 proves that decision tree without preprocessing is the most sensitive to the minority class and gives the most accurate predictions for both classes. For other classifiers where re-sampling was applied on a training dataset, the accuracy scores are slightly worse than the highest scores obtained.

#### D. Experimental Results for Thyroid Disease Dataset

The results for multi-class Thyroid disease data classification showed in the Table VIII vary across the methods applied. The best sensitivity scores were observed for a decision tree with random undersampling alone and when combined with

SMOTE. Next score was obtained by Naïve Bayes and RU, then 3NN, 5NN with the hybrid approach and finally again poorly performing SVM with random undersampling.

All the best accuracy values (table IX) were observed for all classifiers when applied on the original datasets.

The decision tree without preprocessing offers a perfect trade-off between maximum sensitivity and accuracy. In case of other classifiers improvement in sensitivity score causes a decrease of the accuracy (figure 5).

#### E. Experimental Results for Lung Squamous Cell Carcinoma Dataset

The Lung scc cancer is an experimental dataset with two minority classes. Only a decision tree reached outstanding sensitivity score when applied on an undersampled dataset (Table X). Naïve Bayes performed best combined with hybrid resampling approach, but the accuracy was still very low.

NOP - no preprocessing, RU - random undersampling, SM - SMOTE, SM\_RU - SMOTE and random undersampling, SUB - substitution of missing values

For dataset with missing values it was not possible to find a hyperplane for the Support Vector Machine in a finite time, thus no sensitivity scores are presented in this section.

The accuracy for this dataset (table XI) are again mainly the best for no preprocessing.

For the lung scc cancer dataset the differences in the maximum accuracy and the accuracy when the sensitivity was the highest are presented in figure 6. Only a decision tree and Naïve Bayes were shown since other classifiers did not provide satisfactory sensitivity outcomes. Especially in the case of a decision tree the improvement in a sensitivity score cost a double drop in the accuracy score.

#### F. Discussion

In the conducted experiments five datasets were examined. The goal was to find out which preprocessing method and a

NOP - no preprocessing, RU - random undersampling, SM - SMOTE, SM\_RU - SMOTE and random undersampling, SUB - substitution of missing values

classification technique performs best under given conditions. All datasets represented class imbalance problem with different level of class labels distribution. There were binary and multiclass problems, with few or many samples and narrow or vast feature space. The aim was also to demonstrate how different characteristics influence performance of various data treatment methods - resampling and missing values imputation - and certain classification techniques.

Mean sensitivity and accuracy scores were given for each test on the combination of a resampling method and a learning algorithm. As already mentioned, accuracy may be not truly informative when assessing classifier's ability to identify minority samples. The correctly predicted labels mostly belong to majority class while minority class cases are frequently misclassified. Therefore a sensitivity score is more relevant as it indicates how good the predictions were within each class label. The classifiers with a high sensitivity, yet not the highest accuracy, are better in the identification of minority class samples. Consequently, the results of the experimental studies will be ranked by the sensitivity scores and accuracy will be considered as less significant.

For imbalanced two class Hepatitis dataset the best performing classification technique in terms of general accuracy and sensitivity to minority class samples was k-nearest neighbors. The best sensitivity scores were reached when combined with random undersampling. Naïve Bayes with hybrid preprocessing - random undersampling and SMOTE gave similar results to kNN. Most of other classifiers performed well when combined with random undersampling. Additionally, less efficient SVM and decision tree were more sensitive when missing values were substituted by mean values. As more than 5% of values were missing, mean value imputation usually improved the performance of classifiers. All kinds of classifiers trained on resampled datasets were more sensitive than without data preprocessing. The sensitivity and accuracy rates at the level of 70-85% suggest that learning algorithms cannot be considered as a truly reliable solution for the problem of classifying new instances.

The lung cancer dataset was also a two class problem. The characteristics of dataset revealed no missing values, high imbalance ratio and small sample size. Each instance was char-

TABLE XII: Compilation of correctly predicted labels for minority class (True Positives) and majority class (True Negatives)

	Actual number of samples	Predicted with NB NOP	Predicted with NB RU	Change
True Positive	151	117	142	16.56%
True Negative	3012	2977	2869	-3.59%

acterized by 7129 attributes. High dimensionality appeared to be a problem for Naïve Bayes and Support Vector Machine that were not able to create a proper probability model or decision surface with so many parameters in a reasonable classification time. Feature selection would probably help to decrease the dimensionality and improve their performance. kNN with  $k=3$  performed the best taking into account both accuracy and sensitivity when data was not processed. It means that data is well structured and unlabeled samples are most often close to other samples of their actual class. For other classifiers different preprocessing methods significantly improved their ability to recognize minority samples without a rapid decrease of the accuracy.

Hypothyroid is the last of examined binary class problems. The sensitivity scores for all classifiers excluding the Support Vector Machine were similar and no best performing combination can be indicated. The highest sensitivity score was attributed to kNN with 3 and 5 neighbors and hybrid resampling. The number of rows affected by missing values is lower than in case of the hepatitis dataset so a value imputation did not improve the sensitivity significantly. For all classifiers resampling improved sensitivity but accuracy scores remained at the highest level even when no preprocessing was applied. In order to better predict the samples from the minority class, a trade-off between improving the sensitivity and at the same time worsening the overall performance should be accepted. As an example, differences in correct labels predictions for last fold in final iteration of Naïve Bayes trained on a dataset with random undersampling (NB RU) versus trained on original dataset (NB NOP) were compiled in Table XII. It may be observed that after training on the dataset balanced with random undersampling, the classifier identified 1/6 more of minority samples and misclassified less than 4% of actual majority class instances.

Thyroid disease is a three-class problem. The best results were attained for a decision tree algorithm, no matter which preprocessing method was applied. It was due to the precisely defined split conditions and well separated minority class from majority one. Random undersampling with or without SMOTE improved the sensitivity scores for all classifiers tested, while accuracy remained best for datasets without preprocessing. Taking both metrics into account, decision tree with SMOTE reached best results for the problem.

The Lung scc cancer dataset has two minority classes and the third class significantly larger than two others. It could be observed that scores for any classification technique and

preprocessing method performed worse in that case than in the previous scenarios. On average, a half of instances were classified correctly by a decision tree algorithm combined with random undersampling, which is even worse by two times when compared with algorithm applied on not balanced, original dataset. This is an extremely difficult classification problem since the dataset is highly imbalanced - each of positive class instances constitute less than 3% of number of negative instances, there are three class labels and a ratio of missing values is relatively high. No combination of preprocessing method and classification technique can be considered reliable while classifying a new instance. It could be stated the balancing did not succeed in terms of highly uneven distribution of instances between separate classes.

## VI. CONCLUSIONS

Real-life medical datasets are often imbalanced, sparse and high-dimensional. Class imbalance is one of the key problems and it imposes additional difficulties on learning from data.

The point at issue is to what degree should one balance the original dataset or what kind of assumptions will make learning algorithms perform better than when considering the original distribution. The answer is open since this field still lacks a uniform benchmark platform and standardized performance assessments. Although there are many publicly available datasets, a very limited number concerns imbalanced class problems. Data sharing is not common and research groups are required to collect and prepare their own datasets [7]. There is still not much of theoretical understanding on the principles of this problem. Many algorithms that were proposed over years are able to improve classification accuracy over certain benchmarks but will fail over the others.

In the paper several classification techniques and data preprocessing methods were investigated. They were applied on datasets with various characteristics to distinguish factors and conditions that make a learning algorithm perform better. The application of resampling methods for imbalanced datasets enabled attaining higher results in terms of accuracy and sensitivity. The hybrid approach built by the combination of random removal of majority class samples and Synthetic Minority Oversampling Technique overcome single preprocessing techniques.

The paper considered simple, comprehensible algorithms that can be well understood by medical staff. However, in recent days an evolution from traditional learning algorithms towards neural networks and artificial intelligence solutions is observed [33]. Such methods may appear efficient but inability to identify the rules that determine category attribution may constitute a problem with comprehension for medical staff. Nonetheless, other classification techniques - including neural networks - and preprocessing approaches should be investigated in depth.

Another aspect is a computing cost when handling large volume of data with multivariate features which brings the necessity of good feature selection or principal component analysis [34]–[36]. Also, multi-class imbalanced problems

with at least two minority classes where the experts do not agree to aggregate them together require more advanced approaches for example with unequal costs of misclassification between classes [37].

**Abstract**—Neuro-endoscopy is a challenging minimally invasive neurosurgery that requires surgical skills to be acquired using training methods different from the existing apprenticeship model. There are various training systems developed for imparting fundamental technical skills in laparoscopy where as limited systems for neuro-endoscopy. Neuro-Endo-Trainer was a box-trainer developed for endo-nasal transsphenoidal surgical skills training with video based offline evaluation system. The objective of the current study was to develop a modified version (Neuro-Endo-Trainer-Online Assessment System (NET-OAS)) by providing a stand-alone system with online evaluation and real-time feedback. The validation study on a group of 15 novice participants shows the improvement in the technical skills for handling the neuro-endoscope and the tool while performing pick and place activity.

**Index Terms**—Neuro-endoscopy; Vision based surgical skills assessment; surgical skills training; Neuro endo trainer; online evaluation

## I. INTRODUCTION

MINIMALLY invasive neurosurgical procedures have gained the popularity in recent years due to the reduction in postoperative recovery time, morbidity, hospitalization time and cost of patient care [1]. It provides the neurosurgeon with a better visualization method of the complex surgical site with reduced damage to the intricate anatomy of the brain. Neuro-endoscopy is a minimally invasive neurosurgical procedure that uses an endoscope image projected on the 2-dimensional display to access the interior deep structures. The margin of error is minimal and the existing apprenticeship based method of training is not suitable. It requires training for eye-hand coordination, depth perception, and bimanual dexterity. The simulation-based training outside the operating room is getting wide acceptance due to the provision of repeated practice, objective evaluation, real-time feedback and staged development of skills without the supervision of an expert surgeon [2].

Simulation-based training in neuro-endoscopy varies from low-fidelity natural simulations, box trainers, part-task trainers, to intermediate-fidelity synthetic simulators, virtual reality simulators and high-fidelity cadavers and animal models. The box-trainers or part-task trainers are designed to impart training for fundamental technical skills of instrument handling and

eye-hand coordination. The synthetic simulators and virtual reality trainers provide training for anatomy and procedures but give limited haptic feedback. The high-fidelity simulations on cadavers and animals provide training for anatomy and procedures along with haptic feedback and realism [3]–[7].

The evaluation of the surgical activity on the various simulation systems is platform-specific. The assessment methods can be based on direct observation, error metric of the task, sensor-based evaluation of the motion and video-based evaluation of the activity or combination of these. The validation studies on Neurosurgery Education and Training School-Skills Assessment Scale (NETS-SAS) identifies the independent parameters of neurosurgery skills as hand-eye coordination, instrument-tissue manipulation, dexterity, flow of procedure and effectualness [8]. These parameters can be analyzed by the video-based evaluation systems that monitor the activity and movement of the surgeon's hands or tools. The video recording of the activity also provides an opportunity to validate the evaluation using subjective methods.

The video based automatic assessment system can be of two types; offline evaluation and online evaluation. Offline evaluation systems acquire the activity video at reasonable rate and stores the video stream for further analysis. The online evaluation system uses the frame-by-frame analysis, that simultaneously evaluate the activity and also stores it for future reference.

Neuro-Endo-Trainer was a box trainer developed for providing skills training for endo-nasal transsphenoidal surgery (ENTS). It was a pick-and-place task trainer that provides the training for basic fundamental skills using standard variable angled neuro-endoscopes [8]. The evaluation method includes video-based offline evaluation using an auxiliary camera mounted at the top of the box [9]. The existing method of training on Neuro-Endo-Trainer involves the pick and place of one of the six rings in a predefined pattern under the assistance of technical personnel. The activity performed is sub-divided into sub-activity based on the state of the tool and the rings. The sub-activity can be “stationary”, “picking” or “moving”. The state machine is determined using video processing that includes the tooltip tracking, background segmentation, and ring segmentation. The definition of state machine with

the heuristics determined from the video, causes uncertainty and requires a robust task definition system. Therefore, the hardware of the Neuro-Endo-Trainer was augmented with automatic LED-based task definition to determine the state machine. We have developed a stand-alone training system with Neuro-Endo-Trainer to provide online assessment and real-time feedback and defined it as Neuro-Endo-Trainer-Online Assessment System (NET-OAS). Our online automatic assessment system analyzes the activity frame-by-frame and categorizes it as a sub-activity. The relevant parameters of skills training are identified by statistical analysis of the sub-activity. It provides a warning to the trainee neurosurgeon when they make mistakes and provide a detailed synopsis at the end of the activity. The aim of the current study is to validate the developed NET-OAS to establish the level of skills acquisition after staged practice.

## II. BACKGROUND

The low fidelity box-trainers are widely available for laparoscopic skills training [10], [11] whereas they are limited for neuro-endoscopy. The evaluation system for these trainers can be based on subjective or objective measures. The objective evaluation includes Likert-scale based direct observation, sensor-based evaluation and computerized video analysis. The webcam based endoscopic endonasal trainer developed by Hirayama et al. studied the effectualness of the training by evaluating the performance on LapSim simulator before and after the training [3]. Neuro-Endo-Trainer SkullBase-Task-GraspPickPlace developed by Raman et.al was validated using subjective evaluation on different target groups [8].

The video-based evaluation of the surgical activity includes the tracking of the tooltip or tracking the surgeon's hands. There are evaluation systems that use statistical color based image segmentation and tool tracking to identify the tool position and orientation [12], [13]. The automated skills evaluation method in minimally invasive laparoscopic surgeries were done by segmenting the task into sub-tasks (Therbligs) and their kinematic analysis [14]. The feature based tool tracking combined with region-based level set segmentation was used to obtain 3D pose estimation of the instruments and to evaluate the psychomotor skills [15]. There are methods that capture the activity of the subject and track the hand movements using multiple camera feeds [16]. Neuro-Endo-Activity-Tracker provided a video-based automatic evaluation using Gaussian Mixture based background subtraction and tracking of the tooltip using Tracking-Learning-Detection algorithm [9].

## III. METHODOLOGY

NET-OAS consists of low-cost endoscopic system of USB based endoscopic camera that captures the video at 25 fps, variable-angled scopes ( $0^\circ$ ,  $30^\circ$ ,  $45^\circ$ ), LED-based light source, Neuro-Endo-Trainer SkullBase-Task-GraspPickPlace box-trainer mounted with GigE based auxiliary camera, and online evaluation software.

Fig. 1. A. Neuro-Endo-Trainer SkullBase-Task-GraspPickPlace box-trainer mounted with GigE based auxiliary camera, B. Transparent front-part of the peg plate, C. USB camera with endoscope coupler, D. Peg plate with LED

### A. NET-OAS hardware design

The online evaluation system consists of a LED-based task indication method which helps the user to place the ring on the illuminated peg without the assistance of any technician. The peg was illuminated to provide the indication for placement of the ring. The peg plate was printed in two parts: front part of the peg was printed using transparent material by Stereolithography (SLA) technique and back part of the plate was printed using fused deposition modeling (FDM) technique and then both parts were joined using a strong adhesive. The LED array was connected to control circuit using a multiplexer (CD74HC4067). The control circuit consists of ATMEGA328 8 bit micro-controller for the processing, MCP23017 I/O port expander for I/O expansion, 16x2 LCD for display, keypad to provide input, servo motor to control the peg plate and FT232RL serial communication chip to communicate with the PC using serial communication protocol. There are two cameras in the setup; Low-cost USB based endoscopic camera for the visualization of the site that captures feed at 25fps and GigE based auxiliary camera (Basler ACE) capturing at 50 fps for the online evaluation and real-time feedback. The hardware components of NET-OAS is shown in Fig. 1.

### B. NET-OAS software design

The software system of NET-OAS uses a multi-threaded program that processes the two camera streams independently, which maintains the real-time requirement of the system. The complete flow diagram of the NET-OAS is shown in Fig.2 and its user interface is shown in Fig.3. It shows endoscopic and auxiliary streams, options to add the user to the database, configure serial port parameters, select the level of training and option to perform calibration if required. When the user hit the Run button, a new window opens the endoscopic stream with screen display of real-time feedback. After the completion of the activity, the results are shown to the user.

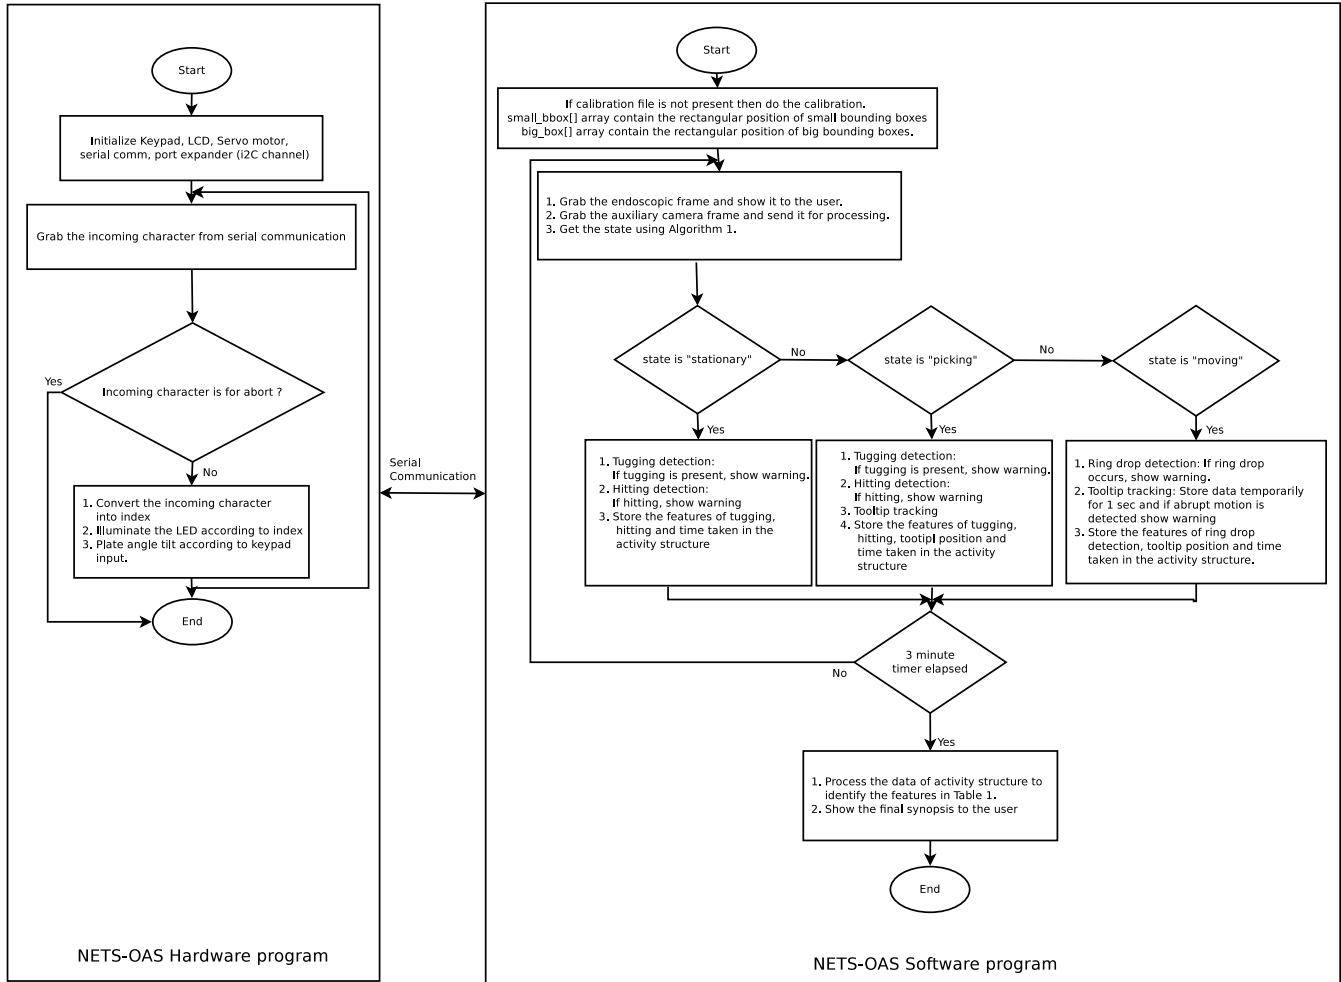

Fig. 2. Flow Diagram of NET-OAS

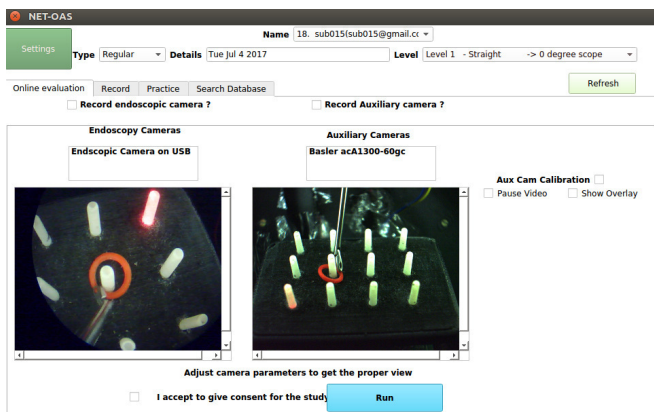

Fig. 3. User interface of NET-OAS

Fig. 4. Bounding box of peps

The main components of the software system are as follows:

1) *Calibration setup*: One-time calibration involves peg-segmentation, ring segmentation, and tooltip bounding box

selection and storing the parameters in the calibration file. The `small_bbox[]` contains the rectangular location of small bounding boxes, `big_bbox[]` contains the location of big bounding boxes as shown in Fig.4. These arrays are used to determine the state machine explained in Algorithm 1. When the software starts, it loads the parameters from the calibration file otherwise prompt the user to perform the calibration.

2) *State machine estimation*: The activity on the NET-OAS in a particular frame can be any of the following

**Algorithm 1** Determine the state machine

---

```

Read the calibration file; Initialize small_bbox[], big_bbox[],
thresh_stationary, thresh_picking, thresh_moving
old_id  $\leftarrow$  -1; current_id  $\leftarrow$  -1;
index_set  $\leftarrow$  true; status  $\leftarrow$  "stationary";
function GET-STATE(image)
  if index_set then
    index_set  $\leftarrow$  false
    for k = 0; k < 12; k++ do
      seg_image  $\leftarrow$  ringSegmentation(image);
      sum_pixels  $\leftarrow$  seg_image[small_bbox[k]];
      if sum_pixels  $\leq$  thresh_picking then
        old_index  $\leftarrow$  k + 1;
        break;
      end if
    end for
    end if
    current_index  $\leftarrow$  random(1 – 12);
    litLED(current_index)
    seg_image  $\leftarrow$  ringSegmentation(image);
    s_old_small  $\leftarrow$  seg_image[small_bbox[old_id]];
    s_old_big  $\leftarrow$  seg_image[small_bbox[old_id]];
    s_current_small  $\leftarrow$  seg_image[small_bbox[current_id]];
    if status == "stationary" then
      if s_old_small  $\geq$  thresh_stationary then
        status  $\leftarrow$  "stationary";
      else
        status  $\leftarrow$  "picking";
      end if
    else if status == "picking" then
      if s_old_big  $\geq$  thresh_picking then
        status  $\leftarrow$  "picking";
      else
        status  $\leftarrow$  "moving";
      end if
    else if status == "moving" then
      if s_current_small  $\geq$  thresh_moving then
        status  $\leftarrow$  "stationary";
        old_id  $\leftarrow$  current_id;
        current_id  $\leftarrow$  random(1 – 12);
        litLED(current_id)
      else
        status  $\leftarrow$  "moving";
      end if
    end if
  end if
  return status
end function

```

---

Fig. 5. State-machine

sub-activity: "stationary", "picking" or "moving". The state machine is initialized with the "stationary" state and the states are updated according to the movement of the ring. The "stationary" state is defined when the ring is stationary and the tool is present/absent. The "picking" state is defined when the tool is near the peg trying to grab the ring till the ring moves out of the peg. The "moving" state is defined when the ring has moved out of the peg until it is placed on the illuminated destination peg. Once the ring has been placed on the peg, the ring segmentation output in the bounding box changes and another peg is illuminated randomly. The state machine is unidirectional and cyclic as shown in Fig.5. The algorithm for state machine estimation is explained in Algorithm 1. Function *ringSegmentation(image)* perform the ring segmentation on the input frame and *litLED(int number)* function illuminate the corresponding peg given in its argument.

3) *Tracking Algorithm*: Tracking-Learning-Detection (TLD) algorithm is used to track the tooltip. TLD initializes from the bounding box and tracking model, retrieved from the calibration file. It is a robust tracking algorithm which tracks the tooltip under blurred conditions and various transformations. The tracking is based on median flow tracker which track the tooltip frame-to-frame and measure the tracking error using efficiency of backtracking. The detection thread is a 3-stage sliding window cascaded classifier, which consists of variance filter, random forest, and nearest neighbor classifier. At the end of the 3rd stage, it provides a set of windows that localizes the appearance of the tool tip. It predicts the next location of the tool tip having the minimum error in tracking or detection stage. The remaining set of appearances is fed to the negative class for better generalization of the tool tip model. Tracking of the tool using TLD algorithm is shown in Fig.6 A. [17].

4) *Ring Drop Detection*: The dropping of the ring is determined in the "moving" state if distance between the tool tip bounding box (determined by TLD) and the *ringSegmentation(image)* is more than a predefined threshold. Fig.6 B shows the image of the ring drop condition.

Fig. 6. Auxiliary camera frame analysis showing: A. Tracking of the tool using TLD algorithm, B. Ring drop determined by the distance between tool-tip and ring segmentation, C. No Hitting D. Hitting determined by counting the subwindows having significant number of contours, E. No- Tugging F. Tugging determined by eccentricity analysis of the ring contour

5) *Hitting Detection*: The hitting of the peg board happens due to poor depth perception of the user. The hitting is detected using image analysis of the successive frames. The difference image is divided into 10x10 grids and hitting is recorded by identifying the number of grids that shows significant movement. The hitting threshold is set experimentally and the Fig.6 C shows the case of no hitting and Fig.6 D shows a hitting instance output.

6) *Tugging detection*: The tugging is detected by analyzing the deformation of the ring in the “stationary” and “picking” state. The ring is segmented based on the hue value obtained from the calibration file. Due to the overlapping of the tool or peg,  $ringSegmentation(image)$  results in two or more contours. The contour with maximum size and the nearest contours are determined and combined. The

$$eccentricity = \frac{\mu_{2,0} + \mu_{0,2} + \sqrt{(\mu_{2,0} - \mu_{0,2})^2 + 4(\mu_{1,1})^2}}{\mu_{2,0} + \mu_{0,2} - \sqrt{(\mu_{2,0} - \mu_{0,2})^2 + 4(\mu_{1,1})^2}}$$

value of the combined contour is sufficient to determine the deformation of the ring in case of tugging. The eccentricity threshold corresponding to tugging is set experimentally.

7) *Tracking data analysis*: Tracking data analysis is done to identify motion smoothness and sudden jerk of the tool tip motion in the “moving” state. Smoothness of the path is measured by taking the standard deviation of the first

TABLE I  
SELECTED FEATURES FOR NET-OAS

Measure from NETS-SAS	Selected objective measure for NET-OAS
<i>Grasping</i>	Average time taken to grasp
	Number of tugging events
<i>Eye-hand coordination</i>	Number of hitting events
	Intensity with which hitting happened
<i>Dexterity</i>	Time taken for moving ring from one peg to another
	Average number of moves
	Smoothness of the path
	Arc length of the path
<i>Instrument tissue manipulation</i>	Number of times curvature value exceeded threshold
<i>Effectualness</i>	Number of times ring dropped

derivative of the tracking data, Arc length of the path is measured by counting number of pixels of the tracking data in the “moving” state. Curvature at each point of tracking data is computed using

$$\kappa = \frac{|\left(\frac{\partial x}{\partial t} * \frac{\partial^2 y}{\partial t^2}\right) - \left(\frac{\partial y}{\partial t} * \frac{\partial^2 x}{\partial t^2}\right)|}{\left(\frac{\partial x}{\partial t}^2 + \frac{\partial y}{\partial t}^2\right)^{\frac{3}{2}}}$$

8) *Real time feedback*: At each frame, the algorithm identifies the current state and provide real time feedback for hitting, tugging and ring drop. Motion smoothness feedback is provided after processing frames of last 1 second. The output is displayed on the endoscopic screen to warn the user. This helps the user to learn and correct the mistakes accordingly.

9) *Feature Extraction and final synopsis*: The activity data structure stores the current sub-activity (“stationary”, “picking” or “moving”) and its related parameters as shown in Table 1. At the end of the activity, the data is processed to give the final synopsis to the user.

#### IV. EXPERIMENTATION AND RESULTS

A group of 15 novices participated in the study of validation of NET-OAS, who were students from a technical university without any medical training. The demo video demonstrating the good and bad endoscopy practice on Neuro-Endo-Trainer was shown before the practice session. There was a pre-test followed by two sessions and a post-test. The pre-test and post-test included the most difficult task level of 45° scope with right tilt plate. Each activity was programmed to be of 3 minutes duration. The first session consisted of practice using 0° and 30° scopes and with straight, left and right tilts of the plate. The second session was conducted three days later and consisted of practice using 30° and 45° scopes and with straight, left and right tilts of the plate. Fig. 7 shows the graph of objective measure for NET-OAS w.r.t training session. The noticeable changes were the increased

Fig. 7. Validation study results: Horizontal axes is the training session, blue marker shows the data point and red line shows the trend-line: A. Average time of grasping the ring, B. Average number of hitting, C. Average hitting intensity D. Average time to move a ring, E. Total number of rings placed F. Average smoothness of the tool tip in “moving” state, G. Average Arc length of the tool tip in “moving” state, H. Number of times curvature exceeded the threshold value or sudden jerk.

average number of moves and average smoothness of the path. There were decreased number and hitting instances, grasping time, average arc length and sudden jerk motion. The self-assessment feedback obtained from the user also shows that the training session on the NET-OAS made them acquainted with the system.

1) *Machine learning for validation study:* For the validation study, activity data obtained from 15 novices (pre-test, post-test, 1st trial of session 1 and last trial of session 2) was considered. Pre-test data was considered as ‘class novice’ and post-test data was considered as ‘class-improved’. The SVM classifier was trained with 11-dimensional feature vector of these classes. For testing, 1st trial of session 1 was considered as ‘class novice’ and the last trial of session 2 was considered as ‘class improved’. The SVM classifier on the testing data classifies feature set of the 1st trial as ‘class novice’ and the last trial of session 2 as ‘class improved’ with the accuracy of 88%.

The practice session example on the NET-OAS and the real-

time feedback provided to the trainee while performing the activity is as shown in Fig. 8 and Fig. 9 respectively.

## V. DISCUSSION

The improvements of NET-OAS as compared to the earlier version include: a complete standalone system, automatic task definition using LED array and serial communication with the hardware, tugging detection algorithm, and ring drop detection. The study used the auxiliary camera for the evaluation of the activity and has not used the endoscopic feed for evaluation.

The main objective of the study was to validate the NET-OAS on completely novice participants to identify whether there is any improvement in skills acquisition. The results show that after stipulated training on the NET-OAS, the participant improved his/her skills on manipulating the endoscope and tool irrespective of their background. The study can be extended to the intermediate trainee neurosurgeons and experts.

## ACKNOWLEDGMENT

We would like to thank all the participants, research scholars of Indian Institute of Technology Delhi who took part

in the study, and the team of Neurosurgery Education and Training School for their support. This work is supported by Department of Health Research, Ministry of Health and Family Welfare, Govt. of India Project Code No: GIA/3/2014-DHR, Department of Science and Technology (DST), Ministry of Science and Technology, Govt. of India Project Code No: SR/FST/LSII-029/2012.

# 2<sup>nd</sup> International Workshop on AI aspects of Reasoning, Information, and Memory

**T**HERE is general realization that computational models of human reasoning can be improved by integration of heterogeneous resources of information, e.g., multidimensional diagrams, images, language, syntax, semantics, memory. While the event targets promotion of integrated computational approaches, we invite contributions from any individual areas related to information, language, memory, reasoning.

## TOPICS

We welcome submissions of papers on the following topics, without limiting to them, across approaches, methods, theories, and applications:

- Reasoning systems — theories and applications
- Proof systems and model checkers
- Theories of computation and information
- Interactive computation and reasoning
- Computation and reasoning with heterogeneous information
- Space and time in information, language, memory, and reasoning
- Partiality, underspecification, vagueness, and possibilities
- Detection of and reasoning with inconsistency
- Logic and language — approaches, theories, methods
- Computational morphology, syntax, semantics, and interfaces between these
- Constraint-based and type-theoretic approaches and grammars
- Logical approaches to multilingual processing
- Logical and computational foundations in machine learning and information retrieval
- Mathematics for linguistics and cognitive science

- Reasoning, information, and memory in computational neuroscience and life sciences
- Interdisciplinary approaches to information, language, memory, and reasoning

**Abstract**—We present a case study on a formalization of a textbook theorem that is listed as #39 at Freek Wiedijk's list of "Top 100 mathematical theorems". We focus on the formalization of the theorem that Pell's equation  $x^2 - Dy^2 = 1$  has infinitely many solutions in positive integers for a given non square natural number  $D$ . We present also a formalization of the theorem that based on the least fundamental solution of the equation we can simply calculate algebraically each remaining solution.

## I. INTRODUCTION

THE work under the rigorous control of proof-assistants on a high formal level of trust eliminates all gaps which sometimes occur in informal proofs, especially in large ones. Any attempt to analyze the details of such formal certification is difficult in principle, however there are some exceptions. There are proof scripts whose authors put an extra effort to improve their readability [1], [2].

### A. Paper Content and Contributions

We present our experience with the formalization of theorems related to the solvability of Pell's equation in the Mizar system [3], where we tried to obtain readable formalization. We focus on the approach represented in the textbook [4]. We show that the effort associated with this formalization is non-trivial, since we have to add to informal proofs all technical details that have been originally omitted.

Note that each fragment of the Mizar proof scripts contained in this paper comes from [5] available in the Mizar distribution.

## II. PELL'S EQUATION

Pell's equation (called alternatively the Fermat equation) is a special case of the quadratic Diophantine equation having the form  $x^2 - Dy^2 = 1$ , with  $D$  be a nonzero integer number. Generally, it is assumed that  $D$  is not a square since otherwise the equation can be solved using the difference of squares  $x^2 - Dy^2 = (x + dy)(x - dy) = 1$ . However in the context of Pell's equation, only non zero pairs of integers are being considered as solutions, excluding the trivial cases  $x = 1$ ,  $y = 0$  and  $x = -1$ ,  $y = 0$ .

The solution of Pell's equation has been applied in many branches of mathematics. As the most basic we indicate here

Supported by Polish National Science Center grant decision n°DEC-2015/19/D/ST6/01473.

that based on solutions for a given non square natural  $D$ , we obtain a rational approximation for  $\sqrt{D}$ . There is also a correspondence between the solvability of Pell's equation and a special case of Dirichlet's unit theorem. It is also important to note that the Stormer's theorem applies Pell's equation to find pairs of consecutive smooth numbers.

From our point of view, the most significant application of Pell's equation was done by Yuri Matiyasevich to prove the undecidability of Hilbert's 10th problem. He analyzes a particular case  $x^2 - (a^2 - 1)y^2 = 1$ , where  $a$  is a natural number. He showed that solutions of such equation may grow exponentially and it suffices to show that every computably enumerable set is diophantine. The solvability of this case and only such a case of Pell's equation has been already formalized in HOL Light [6] and Metamath [7]. However, in the case we can skip a complicated construction of a non trivial solution that is used for the general case, since pair  $\langle a, 1 \rangle$  is a solution.

### A. Formalization in the Mizar System

In our formalization, we show that there exists a solution of Pell's equation for the general case, based on the approach used in the textbook [4] that is very detailed. Nevertheless, fitting this approach to the limitations of a proof-checker system forced us to rebuild significantly the informal reasoning. In several situations we have to use an equivalent approach, to allow the use of already formalized facts in the Mizar Mathematical Library. Finally, we have to extract fragments of proofs as lemmas to highlight the main ideas of main theorems.

## III. FORMALIZATION DETAILS

In this section, we show the details of our formalization. We focus on two main theorems that determine the cardinality of the set that contains each solution of Pell's equation and dependencies between individual solutions. We show also the details of an important lemma that is used in the proof of the first theorem.

### A. Basic lemma

The informal approach that is considered in the textbook [4] and is used to provide existence of at least one solution of Pell's equation is based on the following lemma:

**Lemma 3.1:** If a natural number  $D$  is not the square of a natural number, then there exist infinitely many different pairs of integers  $x, y$  satisfying the inequalities  $y \neq 0$  and  $|x^2 - Dy^2| < 2\sqrt{D} + 1$ .

which we formalized as follows:

```
theorem Th9:
  D is non square implies {[x,y] where x,y is Integer:
    y<>0 & |.x^2-D*y^2|. < 2*sqrt D +1 &
    0<x-y*sqrt D} is infinite
```

It is important to note that in our reformulation we proved a slightly stronger theorem, where the pairs in the considered set satisfy an additional condition  $0 < x - y\sqrt{D}$ . The condition can easily be deduced from the information collected in original informal proof of Lemma 3.1 and significantly facilitates application of the lemma in the main theorem. We distinguished three main stages in the proof of Lemma 3.1.

The first stage can be described as a remark that for each natural number  $n$  greater than 1 there exists a pair of integers  $x, y$  such that  $0 < x - y\sqrt{D} < \frac{1}{n}$  with  $0 < |y| \leq n$ . We extract this stage as a theorem:

```
theorem Th6:
  D is non square & n > 1 implies ex x,y be Integer st
    y<>0 & |.y|. <= n & 0<x-y*sqrt D<1/n
```

where the main idea of the proof can be described in the following way.

Let us consider a finite sequence  $F : \{1, 2, \dots, n+1\} \mapsto \mathbb{R}$  associate to any natural number  $1 \leq i \leq n+1$  the floor  $[(i-1)\sqrt{D} + 1]$ . We have  $0 < F(i) - (i-1)\sqrt{D} \leq 1$  for every  $1 \leq i \leq n+1$ . Moreover,  $\sqrt{D}$  is an irrational number, hence  $F(i) - (i-1)\sqrt{D} \neq F(j) - (j-1)\sqrt{D}$  for every  $1 \leq i < j \leq n+1$ . Then applying the pigeonhole principle (commonly called *Dirichlet's box principle*) it can be seen that there exist natural numbers  $i, j$  such that  $i \neq j$  and  $|(F(i) - (i-1)\sqrt{D}) - (F(j) - (j-1)\sqrt{D})| < \frac{1}{n}$ , where as items we take the numbers  $F(i) - (i-1)\sqrt{D}$  and as containers we take intervals:  $]0, \frac{1}{n}]$ ,  $[\frac{1}{n}, \frac{2}{n}]$ ,  $\dots$ ,  $[\frac{n-1}{n}, 1]$ . Now the proof of Th6 is straightforward if we take  $x := j - i$ ,  $y := F(j) - F(i)$  or  $x := i - j$ ,  $y := F(i) - F(j)$ .

To improve the main idea of Th6 we formulate two theorems: the existence of such finite sequence  $F$  and a dedicated case of the pigeonhole principle:

```
theorem Th4:
  ex F be FinSequence of NAT st len F=n+1 &
    (for k st k in dom F holds F.k=[\ (k-1)*sqrt D/]+1) &
    (D is non square implies F is one-to-one)
```

```
theorem Th5:
  for a,b be Real, F be FinSequence of REAL st
    n>1 & len F=n+1 & (for k st k in dom F holds a<F.k<=b)
  holds
    ex i,j be Nat st i in dom F & j in dom F & i<>j &
      F.i<=F.j & F.j-F.i<(b-a)/n
```

Note that we present theorems as well as the majority of theorems in the paper without proofs which can be found in the proof script `PELLS_EQ.miz`.

The second stage can be formulated as an observation that there exists a pair of integers that fulfills property formulated

in Lemma 3.1. However, the justification of its existence is “informally” repeated in the last stage as the sentence *In virtue of what we have proved before there exists at least one pair of integers  $x, y$  satisfying [ ... ].* Therefore, to avoid repetition, we formulate a theorem that based on the assumption as well as the properties of the pair  $x, y$  formulated in Th6 we can prove an additional property:

```
theorem Th7:
  D is non square & n<>0 & |.y|. <= n & 0<x-y*sqrt D <1/n
  implies |.x^2-D*y^2|. <= 2*sqrt D+1/(n^2)
```

Then justification of this stage is a simple consequence of theorems labeled by Th6, Th7.

The justification of the third stage can be considered as a *complete* proof of Lemma 3.1 that refers to the earlier stages. Note that the justification has the form of an indirect proof, where the whole thesis of Lemma 3.1 is taken as an indirect assumption. A formal justification of the stage can be described as follows.

Let us define a set  $S$  of pairs considered in the Lemma 3.1 and suppose contrary to our claim that  $S$  is finite. Let us consider a function  $f : S \mapsto \mathbb{R}$  that assigns  $x - y\sqrt{D}$  for each pair  $\langle x, y \rangle \in S$ . We have that the range of  $f$ , denoted by  $R$  is finite since  $S$  is finite by the assumption and nonempty by Th8. Consequently, the *infimum* of  $R$  is a member of  $R$  and is positive as each element of  $R$ . Further, there exists a natural number  $n$  such that  $\frac{1}{n}$  is less than the *infimum* of  $R$ . Then from Th6 and Th7 there exists a pair of integers  $x, y$  such that  $y \neq 0$ ,  $|x^2 - Dy^2| < 2\sqrt{D} + 1$ , and  $0 < x - y\sqrt{D} < \frac{1}{n}$ . But the number  $x - y\sqrt{D}$  is a member of  $R$  and is less than the *infimum*, which is impossible.

This finishes the justification of the third stage and consequently, the justification of Lemma 3.1.

## B. Solvability of Pell's equation

The first main theorem that we take into consideration in our formalization is originally formulated as follows:

**Theorem 3.1:** If a natural number  $D$  is not the square of a natural number, then the equation  $x^2 - Dy^2 = 1$  has infinitely many solutions in natural numbers  $x, y$ .

Since the theorem is one of the main results in our formalization, we have put an additional effort to obtain a readable formulation

```
theorem Th14:
  for D be non square Nat holds
    the set of all ab where ab is positive Pell's_solution of D
    is infinite
```

The informal justification can naturally be divided into two main stages. The first one states that Pell's equation has a solution in positive natural numbers and the second one that based on a given solution  $x, y$  we can construct another solution  $x', y'$  where  $x' > x$ ,  $y' > y$ .

The first part of the first stage can be described as a theorem:

theorem Th10:

```
D is non square implies ex k,a,b,c,d be Integer st 0 <> k &
a^2-D*b^2 = k = c^2-D*d^2 &
a,c are_congruent_mod k & b,d are_congruent_mod k &
(|.a.|<>|.c.| or |.b.|<>|.d.|)
```

The proof of the theorem follows the idea of the textbook and includes constructions of successive infinite subsets of the set that is indicated in Lemma 3.1. Denote by  $S$  indicated there set. Note that for each pair  $x, y$  that belongs to  $S$  the expression  $|x^2 - Dy^2|$  can have a finite number of nonzero natural values bounded by  $2\sqrt{D}+1$ . Consequently, there exists an infinite subset  $Z$  of  $S$  for which  $x^2 - Dy^2$  is equal to a fixed number  $k$ . Further, for each pair of  $Z$  we can assign a pair of remainders obtained by dividing by  $k$ . Note that there exist at most  $k^2$  possible pairs of remainders. Therefore, there exists an infinite subset  $R$  of  $Z$  for which the pair of remainders is equal to a fixed one. Moreover we can choose two pairs  $a, b$  and  $c, d$  that belong to  $R$  that fulfil  $|a| \neq |c|$  or  $|b| \neq |d|$ , since both equations can only occur in 4 cases.

To imitate the selection processes of an infinite subset, we use theorem from Mizar Mathematical Library labeled by CARD\_2:101 in the Mizar article [8].

theorem :: CARD\_2:101

```
for F be Function st dom F is infinite & rng F is finite
ex x st x in rng F & F"{x} is infinite;
```

It is important to note that we have to construct all necessary functions and justify their basic properties to use this theorem. In consequence, our formal justification of Th10 has almost 100 steps and is 5.19 times longer than the corresponding part of the informal one, if we compare the number of characters. Note that the proportion, called *de Bruijn factor*, calculated for whole our formalization is 3.62. However, the proportion is not so weak for each fragment of our formalization.

Let us focus on the reasoning contained in the remaining part of the first stage that can be summarized as

theorem Th11:

```
D is non square implies ex x,y be Nat st x^2-D*y^2=1 & y<>0
```

The formal proof of this fact is comparable with the informal one. Therefore we will not focus on its details. However, in this case, we obtain de Bruijn factor equals 0.97.

As in the case of theorem Th9, a fragment of the original proof of Theorem 3.1 that corresponds to the second stage is used directly as the proof of Th14. However, to be able to formulate Th14, we have to introduce two necessary definitions in our formalization.

First we define a solution of a given Pell's equation as each pair of integers

definition

```
let D be Nat;
mode Pell's_solution of D -> Element of [:INT,INT:];
means (it'1)^2 - D * (it'2)^2 = 1
```

where  $it'1$  denotes the first coordinate of it and  $it'2$  denotes the second ones.

Next, we define the concept of positive solutions of Pell's equation. A pair of real numbers is *positive* if both

coordinates are positive and we formalize the adjective as follows:

definition

```
let D1,D2 be real-membered non empty set;
let p be Element of [:D1,D2:];
attr p is positive means :Def2:
p'1 is positive & p'2 is positive;
end;
```

Furthermore, to use the type *positive Pell's\_solution* of  $D$  in the formulation of Th14, it is necessary to show non-emptiness for this type that is that exists at least one object of a given type. Obviously, we can justify this condition based on Th11 if  $D$  is a positive integer that is not a perfect square. We express this observation in the Mizar system as follows:

registration

```
let D be non square Nat;
cluster positive for Pell's_solution of D;
```

Based on this approach, we can start to prove Th14 based on the reasoning in the second stage. The main idea of the reasoning is expressed by the sentence:

*If the equality  $x^2 - Dy^2 = 1$  holds for natural numbers  $x, y$  then, clearly,  $(2x^2 - 1)^2 - D(2xy)^2 = 1$  with  $2xy > y$ .*

Obviously, it shows in a simple way that we can increase any number of times the second coordinate of a solution, generating in consequence infinitely many pairwise different solutions in natural numbers. Such kind of demonstration that a given set has infinite cardinality is typical in informal practice. However, a formalization could not strictly reflect it and we reflect the idea as follows:

Let  $P$  denotes the set of all pairs that correspond to positive solutions of  $x^2 - Dy^2 = 1$ . Suppose, contrary to our claim, that  $P$  is finite. By Th11 the set  $P$  is also non empty. Consequently, the set of the second coordinates of each pair that belongs to  $P$ , denoted by  $P_2$  is also non empty and finite. Further, the *supremum* of  $P_2$  is a member of  $P_2$ . Then there exists a positive pair of integers  $x, y$  such that  $x^2 - Dy^2 = 1$  and  $y$  is the *supremum* of  $P_2$ . It is clear that  $\langle 2x^2 - 1, 2xy \rangle$  is a member of  $P$  since  $(2x^2 - 1)^2 - D(2xy)^2 = 1$ . But then  $2xy$  is a member of  $P_2$  that is greater than the *supremum* of  $P_2$ , which is impossible.

### C. The shape of all solutions of Pell's equation

The second main theorem that we take into consideration in our formalization is originally formulated as follows:

*Theorem 3.2: If  $t_0, u_0$  is the least solution of the equation  $x^2 - Dy^2 = 1$  in natural numbers, then in order that a pair of natural numbers  $t, u$  be a solution of this equation it is necessary and sufficient for the equality  $t + u\sqrt{D} = (t_0 + u_0\sqrt{D})^n$  to hold for a natural number  $n$ .*

It is worth pointing out that the sentence *the least solution* in the context of a pair is quite confusing and requires an explanation. Note that in this context a pair of natural numbers  $x_0, y_0$  is the least solution that satisfies  $x^2 - Dy^2 = 1$  if and only if for each pair of natural numbers  $x_1, y_1$  that also

satisfies the equation holds  $x_0 \leq x_1$  and  $y_0 \leq y_1$ . Obviously, the order that is used here is partial and the least element does not have to exist. However, it has been shown that the order is total on the set of solutions in natural numbers for a given Pell's equation. Therefore, imitating the original approach we prove the following two theorems:

```
theorem Th18:
  D is non square implies
    (p is positive iff p^1+p^2*sqrt D>1)

theorem Th19:
  1<p1^1+p1^2*sqrt D<p2^1+p2^2*sqrt D
  & D is non square
  implies p1^1<p2^1& p1^2<p2^2
```

where variables  $p_1, p_2$  are Pell's solution of  $D$ . Additionally, we define a function that associates the least positive solution of the equation  $x^2 - Dy^2 = 1$  with non square natural number  $D$  as:

```
definition
  let D be non square Nat;
  func min_Pell's_solution_of D ->
    positive Pell's_solution of D means :Def3:
  for p be positive Pell's_solution of D holds
    it^1 <= p^1 & it^2 <= p^2;
```

where based on the registration that there exists a positive Pell's solution of  $D$  as well as theorems Th18, Th19 we prove that such solution exists and is unique.

Using the introduced functor, we can formulate Theorem 3.2 as follows:

```
theorem Th21:
  for D be non square Nat
  for p be Element of [:INT,INT:] holds
    p is positive Pell's_solution of D
  iff ex n be Nat st p^1 + p^2 * sqrt D =
    ((min_Pell's_solution_of D)^1 +
    (min_Pell's_solution_of D)^2*sqrt D)|^n
```

The formulation of Th21 naturally suggests the division of its proof into two parts that justify the necessary and sufficient conditions, respectively. Moreover, the least solution of Pell's equation that is used in the sufficient condition can be simply replaced by any other solution, keeping the correctness of the justification. Therefore, we extract the condition as a theorem:

```
theorem Th20:
  for D be non square Nat, a,b be Integer, n be Nat
  p be positive Pell's_solution of D
  n>0 & a+b*sqrt D=(p^1+ p^2*sqrt D)|^n
  holds [a,b] is positive Pell's_solution of D
```

Note that the proof is immediate if we observe that based on the equality  $a + b\sqrt{D} = (c + d\sqrt{D})^n$  we can provide that  $a - b\sqrt{D} = (c - d\sqrt{D})^n$  and consequently  $a^2 - Db^2 = (c^2 - Dd^2)^n$  under the condition that  $a, b, c, d$  are integer numbers and  $D$  is non square natural number (for more detail see the justification of theorem Th17 in our formalization).

Next, let us focus on the necessary condition, where the originally formulated justification is indirect. A formal justification of the condition is available in our formalization and can be described as follows.

Denote by  $\langle x, y \rangle$  the least positive solution of a given Pell's equation, and suppose that  $\langle t, u \rangle$  is a positive solution of the equation where  $t + u\sqrt{D} \neq (x + y\sqrt{D})^n$  for each natural number  $n$ . Then there exists  $n$  (e.g.  $\left\lceil \frac{\log_{10}(x+y\sqrt{D})}{\log_{10}(t+u\sqrt{D})} \right\rceil$ ) such that

$$(t + u\sqrt{D})^n < x + y\sqrt{D} < (t + u\sqrt{D})^{n+1}. \quad (1)$$

Obviously, there exists a pair of natural numbers  $t_n, u_n$  such that  $t_n + u_n\sqrt{D} = (t + u\sqrt{D})^n$ . By Th17 we have that  $\langle t_n, u_n \rangle$  is a positive solution. Combining this with inequalities (1) multiplied by  $t_n + u_n\sqrt{D}$  we obtain that

$$1 < (x + y\sqrt{D}) \cdot (t_n - u_n\sqrt{D}) = (xt_n - Dy_n) + \sqrt{D}(yt_n - xu_n) < t + u\sqrt{D}. \quad (2)$$

Moreover, it is easy to check that  $xt_n - Dy_n, yt_n - xu_n > 0$  and  $(xt_n - Dy_n)^2 - D(yt_n - xu_n)^2 = 1$ , hence  $\langle xt_n - Dy_n, yt_n - xu_n \rangle$  is a positive solution of considered equation. Then, combining Th19 with (2) we obtain that  $xt_n - Dy_n < x$  and  $yt_n - xu_n < y$ , which contradicts that  $\langle x, y \rangle$  is the least.

This contradiction finally ends a formal justification of Theorem Th21.

#### IV. CONCLUSIONS

Our formalization has so far focused on Pell's equation, their solvability as well as the cardinality and shape of all possible solutions. Now we are working on the first stage of Matiyasevich's theorem.

We show that we can express Pell's equation and prove their properties in the Mizar environment obtaining a human readable formalization. Our effort allowed us to formulate great majority of theorems that precisely describe selected stages of informal deductions. Moreover, our work has provided many additional pieces of information that have been used implicitly in the textbook. Finally, the formalization can also be used as a basic course of formalization for inexperienced Mizar users.

**Abstract**—The Mizar Mathematical Library is one of the largest collections of machine understandable formal proofs encompassing many areas of today mathematics including results from algebra, analysis, topology, and lattice theory. The Mizar system has so far been the only tool able to completely process, certify, and make use of these developments. In this paper, we present the progress in the development of an independent certification mechanism of Mizar proofs based on the Isabelle logical framework. The approach allows rechecking the Mizar formal proofs based on a more succinct and more precisely specified formal infrastructure. Additionally, it necessitates a full formal specification of the mechanisms that ensure the correctness of the defined objects, in particular, the proofs that such mechanisms are correct. The development already covers an important part of the Mizar library foundations. We improve the mechanism for defining Mizar structures and show that it permits simpler validation of proof developments involving such objects. To demonstrate this, we perform a complete translation of the Mizar net of basic algebraic structures including their attributes and certify all the corresponding proofs in Isabelle.

## I. INTRODUCTION

COMPUTER certified formal proofs are today one of the most important techniques used in formal methods. They are used to guarantee the correctness of compilers [1], operating systems [2], hardware [3], as well as to certify mathematical results that involve computation [4]. The Mizar system [5] is one of the oldest computer systems used to certify proofs. Its library, the Mizar Mathematical Library [6] (MML) contains today more than 1200 articles and 60000 proved theorems mainly about mathematics. The Mizar system has so far been the only tool able to process, fully certify, and make use of these formal proof developments.

Algebraic structures are one of the basic building blocks of formal proofs. They are crucial both for the foundations of mathematics and of computer science. This can be witnessed by the formal proof libraries of various interactive proof systems. Indeed, the standard library of Isabelle/HOL [7] defines more than three hundred type classes used in most of its Archive of Formal Proofs [8]. Coq uses its records which include properties in its algebraic foundations, both in the standard library [9], its constructive repository [10], and in the small scale reflection libraries [11] used as a foundation for the Four-Color theorem and the Odd-Order

theorem proofs. Finally, the MML [6] includes more than a hundred structures which together with different attributes correspond to thousands of different algebraic structures. 74% of the Mizar articles depend directly or indirectly on algebraic structures, including the most important domains of mathematics developed in MML, such as topological spaces, vector spaces, lattices, and fuzzy sets [12].

In this paper, we discuss the progress in our project attempting to certify the MML independently. We make use of the Isabelle logical framework [13] to specify the foundations of Mizar [14]. We further define a number of mechanisms that help to translate the Mizar definitions and proofs [15]. We investigate the set theoretic representation of algebraic structures and certify them in the Isabelle logical framework object logic corresponding to the Mizar foundations as well as translate a significant part of the Mizar algebraic structure foundations. After shortly introducing logical frameworks and Isabelle (Section II), as well as Mizar and the corresponding object logic (Section III), the particular contributions of this paper are:

- We provide an infrastructure for more elegant proofs of Mizar structure correctness conditions including structures with multiple fields (Section IV);
- We formalize all basic algebraic Mizar structures in Isabelle/Mizar together with their defining properties including structures that include other structures as components, such as a structure over a field and show that the defined Mizar structures are correctly handled in the presence of attributes and in particular that proofs about such defined algebraic structures can be concise and elegant (Section V).

## II. LOGICAL FRAMEWORKS AND ISABELLE

Nearly all interactive proof assistants today rely on one fixed logic. This allows optimizing a system for that foundations. However, a number of systems focused on modeling actual logical systems. These are referred to as *logical frameworks*, and later a number of such systems became useful not only for modeling the logic but also to work in the specified logic, referred to as *object logic*. The three major logical frameworks are Isabelle [7], Twelf [16], and MMT [17].

Isabelle is today one of the proof systems with the largest libraries of formally proved theorems. It is based on a simple

Supported by Polish National Science Center grant decision n°DEC-2015/19/D/ST6/01473.

type theory with a shallow polymorphism that is implemented in a manually checked kernel. The meta logic provides the user with a set of primitives that makes it convenient to define object logics. The most developed object logics are higher-order logic, untyped set theory, and Lamport's temporal logic of actions.

An Isabelle formalization consists of one or more **theory** files. A theory is a collection of definitions, proved theorems, and notations that allow nicer presentation of terms. An Isabelle **definition** introduces a new identifier that is equal or equivalent (equal as a boolean predicate) to a definition body. A **theorem** or **lemma** consists of the statement and the proof. For most of the proved theorems presented in the rest of the paper, we will omit the proofs, they are fully included in the development. Each **abbreviation** allows for convenient input or output syntax for more complicated terms, without introducing new definitions. These are useful if such a definition would always need to be unfolded and is nicer presented as folded to the user. Most Isabelle proofs are today written in the declarative Isar style [18]. There, intermediate statements are introduced using the **have** keyword and justified using proof methods. For the rest of the paper, the methods and tactics used for the justifications are not essential, it is important to note their correspondence to proof steps that are considered obvious for humans. Finally the **assume** keyword introduces assumptions in proof blocks and **show** is used to denote the goal that is local to the proof block that is to be checked by Isabelle.

### III. MIZAR AND CORRESPONDING OBJECT LOGIC

Mizar is one of the pioneering systems for mathematics formalization that is widely-used and still under active development. The Mizar project from its beginning aimed to make a system for human readable formalization of mathematics, where:

- the proof style was designed to imitate style occurring in the informal mathematical practice,
- the type system tries to express how mathematicians use mathematical objects and how they categorize them.

Therefore, Mizar uses a rich type system and proof style, which makes formalization of mathematics more intuitive and human-readable than in other systems [19], where the main idea of proofs is easy to observe [20]. Such situation occurs especially if the author of a formal proof puts additional effort to manually improve readability or uses dedicated tools [21] that optimize the NP-complete problems of improving legibility [22]. Therefore, it is not surprising that the solutions used in Mizar have been an inspiration to implement the analogical solutions in other systems.

One of these pioneering works in this field was made by J. Harrison [23] who explored the Mizar language. The result of this work was the environment Mizar Mode for HOL enabling writing proofs in a Mizar declarative way [24]. The similar solutions were implemented in other procedural proof assistants, e.g., *Declare* [25], *Isar language for Isabelle* [18], *Mizar-light for HOL Light* [26], *miz3 for HOL Light* [27],

*MMode for Coq or declarative proof language (DPL) for Coq* [28]. However, the similarity between these environments and Mizar system generally is limited to a few rules that are similar to the rules of the S. Jaśkowski natural deduction style [29], responsible for the universal quantifier introduction, the thesis indication, the implication elimination, the introduction of the reasoning by cases. It is worth emphasizing that the way of justification of the reasoning steps in these environments is based on tactics of the particular system that are very different from Mizar by (its equivalent can be found only in Mizar Mode for HOL [23]).

Another significant advantage of the project Mizar, from the point of view of other formal systems, is the library of mathematical knowledge formalized in the Mizar system, MML. However, the exploration of these data requires the sophisticated language constructions and types of Mizar that do not have close equivalents in other systems.

The largest translation of Mizar has been done by Urban [30] to the TPTP first-order language. Although this translation has covered the important part of the MML, it does not constitute the accurate representation of the Fraenkel operator and scheme [29]. Additional work on this solution has enabled the creation of the extensive theorems database of Mizar Problems for Theorem Proving (MPTP) that is used in the process of comparing the performance of leading systems of automatic theorem proving, as well as during the machine learning of the MizAR proof advice system [31].

Kunčar [32] has attempted to recover the Mizar system in the type system of HOL Light. This approach has enabled the translation of the first few simpler theories as transparent higher-order logic theories, however it is not applicable to the whole MML where the more advanced features of the Mizar system type are used. Difficult to reconstruct, are Mizar type mechanisms that check whether some type is a subtype of another type, generate the type of term base on types of subterm, which eliminate inconsistent instantiations and in consequence speed up the verification process. Additionally, two equal terms in Mizar can possess two incompatible types (e.g., see reconsider [33]).

The statements of the theorems in the whole MML have been exported to the MMT logical framework [34]. This allows the use of various MMT services for MML, such as searching the library or providing proof advice, however does not include an independent verification of the proofs or proof automation.

Isabelle already has an object logic Isabelle/ZF [35] based on set theory. Already the foundational axioms of ZF differ from those of Tarski-Grothendieck, and the type system introduced by Mizar is very different from any of the existing object logics in Isabelle. Furthermore, the library of Isabelle/ZF and the automation provided is quite different from that of the proposed research.

We defined an object logic that provides Mizar-like foundations in [14]. Here, we briefly remind its construction. As the foundations of Mizar are based on Jaśkowski first-order natural deduction, we start with the Isabelle/FOL object logic. We introduce one meta-level type for Mizar sets and one for

Mizar types. We introduce the constants that correspond to sets being of particular types and to combine types (the Mizar soft type system allows intersection types [36]), the indefinite description operator, as well as the axioms that specify these constants. With the Isabelle syntax mechanisms, we allow defining Mizar like syntax for statements and definitions, which can later be used to specify the Tarski-Grothendieck foundations of set theory and translate the first few articles of the MML.

#### IV. STRUCTURE REQUIREMENTS

Formalizations of computer systems often need to refer to mathematical structures. In informal computer science practice, such proofs typically use ordered tuples for such structures. For example  $\langle G, +, 0 \rangle$  could be an additive group and  $\langle G, \cdot, 1 \rangle$  a multiplicative one. In the informal approach, the expression “the group  $\langle G, +, 0 \rangle$ ” provides two kinds of information simultaneously: a signature and its properties. The signature says that it is a structure containing the set  $G$ , a binary operation  $+$  and a given element of the set  $0$ . The properties are given as three group axioms. A formal approach to reason about such structures taken by the Mizar system attempts to avoid independent definitions of variants of structures (such as semi-group, monoid, or abelian groups) by specifying the signature separately from the adjectives that correspond to the properties of the structure.

##### A. Structure Element Interpretation

Every Mizar structure signature called *structured type* is defined as a set of assignments. Each assignment is of the form  $sel \rightarrow spec$ , where  $sel$  is a unique structure element label (called selector in the Mizar language) and  $spec$  is the specification of the type of the respective element of the structure. The signature of a group is the `addLoopStr` structure. It is specified in MML as follows:

```
struct (ZeroStr, addMagma) addLoopStr (#
  carrier -> set,
  addF -> BinOp of the carrier,
  ZeroF -> Element of the carrier #);
```

where for example `addF -> BinOp of the carrier` denotes that  $+$  is a binary operation on the field `carrier`. The list of structures given in parentheses immediately after the `struct` keyword, namely `ZeroStr`, `addMagma` are the names of previously defined structures which contain the element `0` (`ZeroStr`) and a set with the binary operator (`addMagma`) respectively.

An Isabelle formalization of a structure type gives rise to a structure prototype. Each instance of the prototype will be a partial function, with the value corresponding to the selector having the respective type specified in the structure prototype. Definitions of this kind, even if common in informal practice, contain a recursive call. The specification can refer to other parts of the structure (in the above example `addF` in `addLoopStr` is a binary operation of the `carrier`). To specify this in Isabelle we further need a meta-level function

which for a given object of structured type and a selector as arguments returns the term present in the object:

**definition** TheSelectorOf (the \_ of \_ 190) **where**  
 func the sel of Term  $\rightarrow$  object means  $\lambda it.$   
 for T be object st [sel, T] in Term holds it = T

In order to use such functions in the context of structures, the actual specifications cannot be simply types, but rather functions that for a given object of a structured type as an argument returns the type. In particular, the `addF` element specification needs to be defined as  $\lambda S. \text{BinOp-of } S$ . To achieve a more Mizar like formulation `addF -> BinOp-of' the' carrier` we further introduce abbreviations for the types with arguments:

**abbreviation** TheS (the'' \_ ) **where**  
 TheS  $\equiv \lambda selector \text{ Term. the selector of Term}$   
**abbreviation** BinOp-of (BinOp-of'' \_ ) **where**  
 BinOp-of' X  $\equiv \lambda it. \text{BinOp-of } X(it)$

This allows representing all assignments of the form  $selector \rightarrow specification$  as a unary predicate (corresponding to the Isabelle definitions of attributes) which describes all partial functions that are the instances of the structure prototype. To allow the computation of the selector of it we add the condition that the selector is in its domain.

**definition** field ( \_  $\rightarrow$  \_ 91) **where**  
 $sel \rightarrow spec \equiv \text{define\_attr } (\lambda it.$   
 the sel of it be spec(it) & sel in dom it)

We can finally define actual structure prototypes. A new structure prototype in Isabelle corresponds to a Mizar mode (non-empty type) which is a partial function that satisfies all the constraints specified in the fields:

**abbreviation**(input) struct (struct \_ - [10,10] 10)  
**where** struct Name Fields  $\equiv$   
 (Name  $\equiv \text{define\_mode}(\lambda it.$   
 it be Function & it is Fields))

The original `addLoopStr` can now be fully formally specified, using a syntax that is very similar to the Mizar original, while at the same time allowing a complete certification:

**definition** struct addLoopStr  
 (# carrier  $\rightarrow$  set';  
 addF  $\rightarrow$  BinOp-of' the' carrier;  
 ZeroF  $\rightarrow$  Element-of' the' carrier #)

##### B. Non-emptiness of Structure Types

A definition of a structure prototype in Mizar provides not only the information about the types of the elements described by the signature but also ensures that there is at least one element of the structure type. For this, the Mizar checker verifies that all the defined structure specifications are non-empty. In Isabelle, we need to actually give a formal proof that the structure exists. We can achieve this by using the Hilbert choice operator  $\epsilon$ , providing for each assignment of the form  $selector \rightarrow specification$  the pair  $\langle selector, \epsilon(specification) \rangle$ . In case of the considered `addLoopStr` structure prototype, we can use:

**term** {[carrier, the set]} $\cup$   
 {[addF, the BinOp-of the set]} $\cup$   
 {[ZeroF, the Element-of the set]}

Proofs of non-emptiness require a lot of effort especially with structures with more elements (some structures have as much as 12 elements). Such proofs ignore the non-emptiness proofs from the structure ancestors. We will, therefore, propose in the next Subsection IV-C a mechanism able to extend an object by the missing elements possibly changing their order. This is desired because a structure definition also implicitly defines:

- the attribute *strict* which means that the domain of the object contains precisely the selectors indicated in the definition and no other selectors;
- the restriction operation which restricts an object to its strict domain.

Therefore, we provide a scheme for defining the correctness of structures. We present this lemma as well as the majority of lemmas in the paper without proofs which can be found in the development.

**lemma** *struct\_scheme*:

**assumes** *df*:

$S \equiv \text{define\_mode}(\lambda \text{it. it be Function \& it is Fields})$

**and** *ex*:

$\text{ex } X \text{ be Function st } X \text{ is Fields \& dom } X = D$

**and** *monotone*: for  $X1 \text{ be Function st } X1 \text{ is Fields}$   
 holds  $D \subseteq \text{dom } X1$

**and** *restriction*: for  $X1 \text{ be Function st } X1 \text{ is Fields}$   
 holds  $X1|D \text{ is Fields}$

**shows**  $(x \text{ be } S \text{ iff } (x \text{ be Function \& } x \text{ is Fields})) \&$   
 $\text{Ex } (\lambda x. x \text{ be } S) \& \text{domain\_of } S = D \&$   
 $(\text{for } X \text{ be } S \text{ holds}$

$\text{the\_restriction\_of } X \text{ to } S \text{ be } (\text{strict } S) \parallel S)$

which given the subproofs for the existence condition *ex* and monotonicity *monotone* allows showing the correctness of the *domain\_of* definition (i.e. existence and uniqueness) for the defined structure *S*, additionally deriving the equality *domain\_of* *S* = *D*, where

**definition** *domain\_of* (*domain'\_of* *\_* 200) **where**

*func* *domain\_of* *M*  $\rightarrow$  *set* *means*

$(\lambda \text{it. } (\text{ex } X \text{ be } M \text{ st it} = \text{dom } X) \&$   
 $(\text{for } X \text{ be } M \text{ holds it} \subseteq \text{dom } X))$

Furthermore, by proving the restriction definition to the equality, we get the information that  $X \mid \text{domain\_of } S$  is of the structured type of *S* which has the attribute *strict*, if *X* is of the structured type of *S*, which completes the definition

**definition** *restriction* (*the'\_restriction'\_of* *\_* to *\_* 190)

**where**

*func* *the\_restriction\_of* *X* to *Struct*  $\rightarrow$

*strict* *Struct*  $\parallel$  *Struct* *equals*

*X*  $\mid$  *domain\_of* *Struct*

where the definition of *strict* is as follows

**definition** *strict* :: *Mode*  $\Rightarrow$  *Attr* (*strict* *\_* 200) **where**

*attr* *strict* *M* *means*

$(\lambda X. X \text{ be } M \& \text{dom } X = \text{domain\_of } M)$

### C. Recursive Structure Correctness Conditions

As discussed in the previous section, the *struct\_scheme* lemma assumptions can be used to show the non-emptiness of a defined structure type *S*. However, the assumptions about each ancestor *A* of the structure are insufficient to be usable as part of the proof for *S*. In particular, there is no condition that would correspond to *restriction*, which could give the information which extensions of *A* (the extensions of the function that describe the object instance) satisfy all the assignments of *A*. For this reason, we propose a version of the assumption in *struct\_scheme* with the additional fourth correctness condition

**definition** *struct\_well\_defined* :: *Attr*  $\Rightarrow$  *Set*  $\Rightarrow$  *o*  
 $(\_ \text{ well defined on } \_ [10,10] 200)$

**where**

*Fields* *well defined on* *D*  $\equiv$

$(\text{ex } X \text{ be Function st } X \text{ is Fields \& dom } X = D)$

$\& (\text{for } X1 \text{ be Fields} \parallel \text{Function holds } D \subseteq \text{dom } X1)$

$\& (\text{for } X1 \text{ be Fields} \parallel \text{Function holds } X1|D \text{ is Fields})$

$\& (\text{for } X1 \text{ be Fields} \parallel \text{Function, } X2 \text{ be Function st}$   
 $D \subseteq \text{dom } X1 \& X1 \subseteq X2 \text{ holds } X2 \text{ is Fields})$

This allows a weaker defining lemma assumption

**lemma** *struct\_well\_defined*:

**assumes** *df*:

$S \equiv \text{define\_mode}(\lambda \text{it. it be Function \& it is Fields})$

**and** *well*: *Fields* *well defined on* *D*

**shows**  $(x \text{ be } S \text{ iff } (x \text{ be Function \& } x \text{ is Fields})) \&$

$\text{Ex } (\lambda x. x \text{ be } S) \& \text{domain\_of } S = D \&$

$(\text{for } X \text{ be } S \text{ holds}$

$(\text{the\_restriction\_of } X \text{ to } S) \text{ be } (\text{strict } S) \parallel S)$

With these modifications, we can show that an existing list of assignments specified for the domain *D* can be modified by adding a new *selector*  $\rightarrow$  *specification* pair assuming that the *selector* is not present in *D* so far, and the *specification* uses the selectors of *D*. An example lemma that allows extending a structure is:

**theorem** *Fields.add\_argM1*:

**assumes** *Fields* *well defined on* *D*

**and** *selector.1* in *D*

**and** not (*selector* in *D*)

**and** for  $X1 \text{ be Fields} \parallel \text{Function holds}$

$\text{ex } S \text{ be } M1 \text{ (the selector.1 of } X1) \text{ st True}$

**shows**

*Fields*  $\mid$  (*selector*  $\rightarrow$   $\lambda S. M1 \text{ (the selector.1 of } S)$ )

*well defined on*  $D \cup \{\text{selector}\}$

This can now be practically used to simplify the non-emptiness proof of *addLoopStr* using the previous proof of the well-definedness of *addMagma* over the set  $\{\text{carrier}\} \cup \{\text{addF}\}$  as follows:

**lemma** *addLoopStr\_well*:

$(\# \text{ carrier} \rightarrow \text{set}')$

$\text{addF} \rightarrow \text{BinOp-of' the' carrier};$

$\text{ZeroF} \rightarrow \text{Element-of' the' carrier } \#)$

*well defined on*  $\{\text{carrier}\} \cup \{\text{addF}\} \cup \{\text{ZeroF}\}$

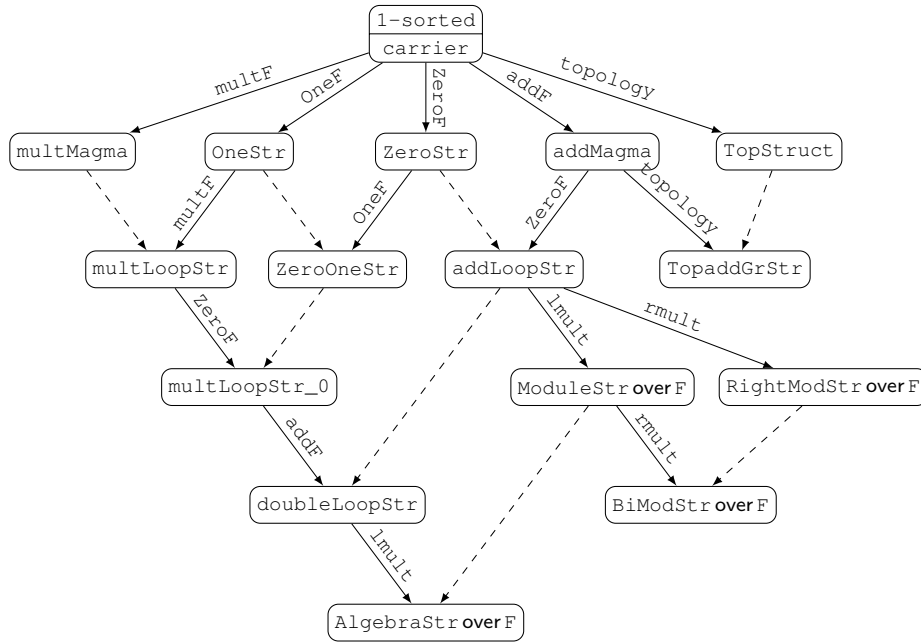

Figure 1. Net of the basic algebraic structures in the Mizar Mathematical Library following [37]. The presented ones have already been covered in our formalization. The arrow captions indicate the added selectors. Solid lines indicate the use of the ancestor structure in the well-definedness proofs, and dashed lines indicate that the ancestor structure is omitted in the proofs.

```

proof (rule Fields_add_argM1[OF addMagma_well])
  show carrier in {carrier} ∪ {addF}

qed
qed

```

where the proof only needs to use the non-emptiness of the type `Element of set`. Furthermore, the fact that the `carrier` is a member of  $\{\text{carrier}\} \cup \{\text{addF}\}$ , as well as the fact that `ZeroF` is not a member of  $\{\text{carrier}\} \cup \{\text{addF}\}$  can both be handled completely automatically by the simplifier in all such proofs.

The well-definedness of `addLoopStr` does not need to rely on that of the `addMagma` ancestor. One could instead extend the list of assignments of `ZeroStr` by `addF → BinOp-of' the' carrier` and change the order. For this purpose we provide the lemma:

```

theorem well_defined_order:
  assumes  $\bigwedge X$ . X is Fields1 iff X is Fields2
    and Fields1 well defined on D1
  shows Fields2 well defined on D1

```

The components described above are sufficient to define all the MML structures (the basic ones are presented in Fig. 1). The construction follows the recursive element addition approach.

Even if the `addLoopStr` proof refers to its ancestors, the inheritance information is not provided again by `structSchemeWell`. The Mizar system allows indicating this information directly in the structure definition by giving a list of all ancestors. In our approach, it is possible to prove a structure inheritance. Such proofs can be always automatically performed by the simplifier.

**theorem** `addLoopStr_inheritance`:

```

assumes X be addLoopStr
shows X be addMagma & X be ZeroStr
using addLoopStr addMagma ZeroStr assms
by simp

```

## V. NET OF BASIC ALGEBRAIC STRUCTURES

Mizar structures together with the inheritance mechanisms significantly facilitate the formalization of computer systems and various domains of mathematics, as well as combining them. For this reason, structures are a challenge for our project, especially the `struct_0` article which defines the elementary structures and their operations.

MML contains today 168 structure signatures. Structure signatures form a net because of multiple inheritances. Nevertheless, 135 of the signatures inherit from `1-sorted`, namely the signature of structures that contain a `carrier` which includes some examples in most developed domains of mathematics in the MML, such as algebra, topology, and the theory of lattices.

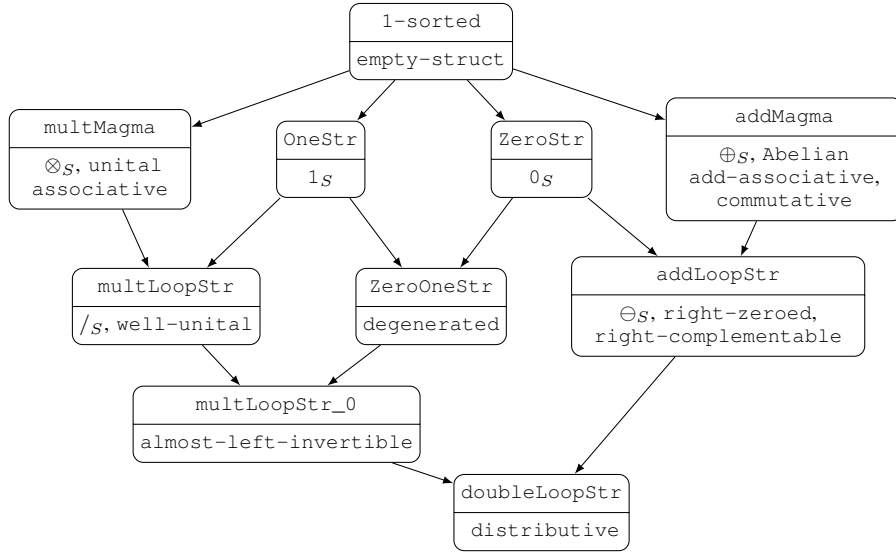

Figure 2. The net of doubleLoopStr structure signature ancestors in the MML. For each node, the adjectives required to define a field as well as the unary and binary operations performed on the elements, are listed below.

The basic structures are depicted in Fig. 1. These 15 signatures are the direct ancestors of 57 other structure signatures in the MML. Furthermore, these 15 are directly used to define 293 Mizar types (this includes non-expandable types [36]), 291 attributes, 962 functors, and 91 predicates.

As structure signatures are mostly used with adjectives, we reformalize the chosen structures along with their attributes to demonstrate that they can be used efficiently in subsequent proofs. In the paper we focus on doubleLoopStr, defined in the MML article ALGSTR\_0:

```

struct (addLoopStr, multLoopStr_0)
  doubleLoopStr (#
    carrier -> set,
    addF -> BinOp of the carrier,
    ZeroF -> Element of the carrier,
    multF -> BinOp of the carrier,
    OneF -> Element of the carrier #)

```

that inherits from both addLoopStr and multLoopStr\_0, i.e., the signatures of additive and multiplicative groups, respectively. The doubleLoopStr structure is also the direct ancestor of the signature or ModuleStr over F used in vector space domains, where  $F$  represents the set of scalar values. A correct definition of ModuleStr over F permits us to verify our model and our approach for structures parametrized by other structures.

#### A. Field Formalization

For our formalization of the signature and basic properties of fields, it was necessary to adapt 20 MML articles. Our reformalization focused on the articles STRUCT\_0, GROUP\_1, RLVECT\_1, ALGSTR\_0, VECTSP\_1, which define all the ancestors of a field (doubleLoopStr), and the main adjectives used in the field definitions, as well as the basic

binary and unary operations. In particular we completely cover ALGSTR\_0 in Isabelle/Mizar, which includes 43 functor and predicate definitions (including 13 correctness condition proofs), 72 registrations: non-emptiness of types and relations between groups of adjectives defined on structures, and 6 signatures including

#### definition

```

struct doubleLoopStr (#
  carrier -> set;
  addF -> BinOp-of' the' carrier;
  multF -> BinOp-of' the' carrier;
  OneF -> Element-of' the' carrier;
  ZeroF -> Element-of' the' carrier #)

```

The signature can be used for more complex algebraic structures by extending it by appropriate adjectives. In particular we exactly imitate the MML definitions:

#### abbreviation

```

Ring ≡ Abelian | add-associative | right-zeroed |
  right-complementable | associative |
  well-unital | distributive |
  non empty-struct || doubleLoopStr

```

#### abbreviation

```

SkewField ≡ non degenerated |
  almost-left-invertible || Ring

```

#### abbreviation

```

Field ≡ commutative || SkewField

```

The adjectives used in the above definitions have been specified for the various ancestors of doubleLoopStr (see Fig. 2). Such definitions have been moved to earliest possible structures as part of the MML refactoring. This allows easy import of developed theories, which we want to now evaluate in Isabelle/Mizar. Consider the theory of additive groups. It is

<pre> definition   let S be ZeroStr;   func 0.S -&gt; Element of S equals     the ZeroF of S; end;  definition   let S be OneStr;   func 1.S -&gt; Element of S equals     the OneF of S; end;  definition   let M be addMagma;   let x,y be Element of M;   func x + y -&gt; Element of M equals     (the addF of M).(x,y); end;  definition   let M be multMagma;   let x,y be Element of M;   func x * y -&gt; Element of M equals     (the multF of M).(x,y); end; </pre>	<pre> <b>definition</b> struct_0.def_6.prefix ( 0_ [1000] 99) <b>where</b>   func 0<sub>S</sub> → Element-of-struct S equals     the ZeroF of S <b>schematic.goal</b> struct_0.def_6:   <b>assumes</b> S be ZeroStr <b>shows</b> ?X  <b>definition</b> struct_0.def_7.prefix (1_ [1000] 99) <b>where</b>   func 1<sub>S</sub> → Element-of-struct S equals     the OneF of S <b>schematic.goal</b> struct_0.def_7:   <b>assumes</b> S be OneStr <b>shows</b> ?X  <b>definition</b> algstr_0.def_1 ( _ ⊕_ _ [66,1000,67] 66) <b>where</b>   func x ⊕<sub>M</sub> y → Element-of-struct M equals     (the addF of M) . ---	--

Figure 3. Selected definitions of highlighted elements and binary operations in `doubleLoopStr` originally formulated in the MML and their Isabelle/Mizar reformulations.

<pre> definition   let M be addLoopStr, x be Element of M;   assume A1: x is left_complementable     right_add-cancelable;   func -x -&gt; Element of M means     it + x = 0.M; end;  definition   let M be multLoopStr, x be Element of M;   assume A1: x is left_invertible     right_mult-cancelable;   func /x -&gt; Element of M means     it * x = 1.M; end; </pre>	<pre> <b>definition</b> algstr_0.def_13 (⊖_ _ [1000, 86] 87) <b>where</b>   assume x is left-complementable<sub>M</sub>   right-add-cancelable<sub>M</sub>   func ⊖<sub>M</sub> x → Element-of-struct M means     (λit. it ⊕<sub>M</sub> x = 0<sub>M</sub>) <b>schematic.goal</b> algstr_0.def_13:   <b>assumes</b> M be addLoopStr     x be Element-of-struct M <b>shows</b> ?X  <b>definition</b> algstr_0.def_30 (/_ _ [1000, 99] 98) <b>where</b>   assume x is left-invertible<sub>M</sub>   right-mult-cancelable<sub>M</sub>   func /<sub>M</sub> x → Element-of-struct M means     (λit. it ⊗<sub>M</sub> x = 1<sub>M</sub>) <b>schematic.goal</b> algstr_0.def_30[rule_format]:   <b>assumes</b> M be multLoopStr     x be Element-of-struct M <b>shows</b> ?X </pre>
---	--

Figure 4. Selected conditional definitions of unary operations from `ALGSTR_0` originally formulated in the MML and their Isabelle/Mizar reformulation.

mostly defined over the structure `addLoopStr` with the adjectives `add-associative`, `right_zeroed` `right_complementable`. As `addLoopStr` is an ancestor of the `doubleLoopStr` signature, this set of adjectives is a subset of that used for example for rings, therefore, properties of additive group can be used in the context of rings in the MML.

Moreover, Mizar allows the use of functors defined on ancestors with arguments of further types. We show the definitions of the selected elements and operations of `doubleLoopStr`, namely `0`, `1`, `+`, and `*` are defined in Fig. 3. In Mizar, the patterns of the symbols are given in previously specified dictionaries, while in Isabelle these need to be given in the definition block. Furthermore, the definition is split into two parts: the pattern without the argument types and the definition theorems. This allows reducing the number

of visible arguments corresponding to hidden arguments in Mizar, as well as allows interpreting conditional definitions (see Fig. 4). The conditions need to appear in the pattern in the Isabelle/Mizar approach. More details are given in the `Mizar_defs` theory file.

As case studies, we show that the proposed way to model structures and their inheritance is sufficient not only to define attributes and functors but also is adequate for imitating Mizar-style formalization. For this purpose, we reformalize (so far manually) selected theorems that concern, e.g. the additive and multiplicative groups, and use them in the context of `doubleLoopStr`. Here we show a single selected proof of the statement that the product of two elements is zero if and only if at least one of them is zero (see Fig. 5). Note that the justification of steps refer to theories developed

```

theorem Th12:

Figure 5. A property of fields originally formulated in the VECTSP\_1 article and its Isabelle/Mizar reformulation.

for multLoopStr\_0, multLoopStr, ZeroStr structures (see steps that use label A in justifications). Additionally, each such justification uses some of the attributes indicated in the step labeled by T.

We make use of Isabelle features to model the proofs in such a way that the Isabelle/Mizar language can be as close as possible to the Mizar one. This simplifies the comparison of both proofs. The proofs in our certification contain more steps than the Mizar ones. This is mainly due to the lack of the Mizar automation in our system, e.g., type inference, equational calculus [38], definitional expansions [39]. Additionally, we still have to directly indicate the background information, such as registrations, that are processed automatically by Mizar. We are currently working on mechanisms that would reduce the numbers of additional steps required.

## VI. CONCLUSION

We have presented the progress in our project aiming to independently certify Mizar proofs in the Isabelle logical framework. The proposed recursive approach to structures allows more readable proofs of well-definedness, as well as a more concise way to specify structure inheritance. We verified the provided mechanisms by reformalizing the complete Mizar

article defining basic algebraic structures ALGSTR\_0, as well as parts of several articles that define and prove properties of structures contain other structures as fields. The experiments confirm that the proposed approach is convenient for proving structure properties.

The Isabelle/Mizar formalization currently includes 31 theorems, 97 registrations including 6 reductions, 86 definitions where 37 of them required Mizar-style justifications and 4 redefinitions concerning MML structures. The total size of the development is 416 kB and 9742 lines of code. It is available at:

<http://cl-informatik.uibk.ac.at/cek/fedcsis2017/>

### A. Future Work

Our certification work has so far focused on the foundations, definitions, and registrations available in the Mizar language. A natural next step would be to allow an implicit use of the background knowledge. Without it, redundant steps in reasoning to represent information computed the Mizar type-inference mechanisms have been necessary so far. Furthermore, we plan to translate the whole MML into the Isabelle/Mizar environment in an automated way and with the help of automatically finding related concepts between

logics [40], as well as by improving the currently available Isabelle automation for Mizar [41] we hope to cross-verify large parts of the translated MML in Isabelle which is also one of the important steps in the creation of a combined formal library spanning multiple foundations and systems [42].

**Abstract**—In the paper we describe a formalization of the notion of a nominative data with simple names and complex values in the Mizar proof assistant. Such data can be considered as a partial variable assignment which allows arbitrarily deep nesting and can be useful for formalizing semantics of programs that operate in real time environment and/or process complex data structures and for reasoning about the behavior of such programs.

## I. INTRODUCTION

THE importance of the problem of elaborating the theory of programming and connecting it with software development practice was recognized by many researchers. In particular, it was mentioned as one of the grand challenges in computing by T. Hoare in his influential talk “The Verifying Compiler: a Grand Challenge for computing research of the 21st century” [1] with the implication that an important step towards solution of this challenge is development of a verifying compiler that should have a high impact on software quality and reliability. More generally, one may argue that development of practical tools and methods of automatic static analysis of a program (e.g. model checking, verification against a formal specification using logical methods and theorem provers, etc.) that can make sure that it has the desired runtime properties before the program is run is an important research topic.

However, nowadays software is used in many application domains and the traditional idea of proving properties of the input-output relation associated with a program is not always sufficient.

For example, practically relevant safety properties of software in a real-time embedded system [2], [3] (that is a part of a larger hardware-software system which interacts with the physical environment using sensors and actuators) or a cyber-physical system [2], [3], [4] (e.g. that consist of networks of computing devices that interact with physical environment) normally can be expressed not in the form of a property of a program or its input-output relation itself, but in terms of admissible behaviors of a larger software-hardware system and an environment to which it belongs.

The way of proving such properties depends on the chosen mathematical model of the hardware and the environment and it is important to note that such a proof is practically relevant only under the assumption that the model relative to which

safety is proven adequately represents the behavior of the real system and its environment, and the environment usually includes unknown and/or random elements, and the scope of the model usually is limited.

As a toy example, suppose that a program  $P$  can control the behavior of a physical system  $S$  by assigning and modifying the value of a certain parameter  $p$ . The behavior of  $S$  is described by a differential equation  $\frac{d}{dt}x(t) = f(p, t, x(t))$ , where  $f$  is some fixed real-valued function. Assume that:

- $p$  is updated by  $P$  at discrete time moments  $t = t_1, t_2, \dots$  determined by  $P$ , between which  $p$  remains constant (so on each bounded closed time interval  $p$  can be considered a piecewise constant function);
- $P$  controls  $S$  in the open-loop fashion, i.e.  $P$  has no or does not use feedback from  $S$ .

Then one may formalize the above mentioned equation as a switched system [5] where  $p$  is a switching signal (if  $P$  uses some feedback from  $S$  it may be considered as a kind of a hybrid dynamical system [6]) and assume that its solutions  $t \mapsto x(t)$  defined on intervals of the form  $[0, T)$ ,  $T \in (0, +\infty) \cup \{+\infty\}$  describe all possible evolutions of the state of the system in continuous time which start at the initial time moment  $t = 0$ .

Suppose that we want to check that the composite (“cyber-physical”) system consisting of  $S$  together with the program  $P$  and a computing device which executes it, which we will denote as “ $S + P$ ”, has the following property which we will call “*NONNEG*”: if  $x(0) \geq 0$ , then  $x(t) \geq 0$  for all real  $t \geq 0$  for any solution  $x$  which is defined at  $t = 0$  and cannot be continuously extended forward in time (i.e. the value  $x$  that describes some characteristic of the system  $S$  does not fall below 0, if it starts at or above 0).

In order to check, if it holds for a particular  $f$  and  $P$ , it is necessary to formulate precisely the semantics of  $P$ .

For example, suppose that  $f$  has a simple polynomial form  $f(u, v, w) = uw^2$ , so that the equation has the form  $\frac{d}{dt}x(t) = p(t)x^2(t)$ , and the program  $P$  is given in the source code form in some imperative programming language with C-like syntax as in Algorithm I (where  $L1$ – $L6$  are labels).

A common way of giving an operational semantics [7] to programs in languages of this type is to define the notion of a program state that includes the information about its current point of execution and the current content of its variables, and

**Algorithm 1** Example

---

```

L1: i = 0;
L2: for (; i < 10; i++) { // i = 0, 1, ..., 9
L3:   p = i; // assign p the value of i
L4:   sleep(1); // wait for 1 second
L5: }
L6:

```

---

define a state transition system that describes the possible paths of evolution (“runs”) of the program state during execution. Then reasoning about the relation between the program states at different program execution points can be done using e.g. the Floyd-Hoare logic [8], [9], [10].

The content of variables in a program state is usually formalized as a function mapping names of program variables to their values (*variable assignment*). The commonly used notation for such an assignment has the form  $[var_1 \mapsto value_1, var_2 \mapsto value_2, \dots]$ , where  $var_i$  are variables and  $value_i$  are the values that the variables have. In  $P$  we can consider  $i$  a normal read/write variable the value of which is stored in the memory or a CPU register. The variable  $p$  and the assignment to it can have different interpretations (e.g. normal memory location, a write-only register/hardware port, etc.).

Using the labels  $L1$ – $L6$  to identify program execution points, and variable assignments to represent the content of variables, a program state can be formalized as a pair “(*label*, *variable assignment*)”, and a possible run of  $P$  can have the form of a sequence such as:

$(L1, [i \mapsto 0, p \mapsto 0]), (L2, [i \mapsto 0, p \mapsto 0]),$   
 $(L3, [i \mapsto 0, p \mapsto 0]), (L4, [i \mapsto 0, p \mapsto 0]),$   
 $(L5, [i \mapsto 0, p \mapsto 0]), (L2, [i \mapsto 0, p \mapsto 0]),$   
 $(L3, [i \mapsto 1, p \mapsto 0]), (L4, [i \mapsto 1, p \mapsto 1]), \dots$

Obviously, in our case *NONNEG* cannot be checked by looking at such runs of  $P$  alone, instead the behavior of  $S$  and the timing of interaction between  $P$  and  $S$  should be taken into account. In particular, runs of  $P$  should be augmented with timing information to obtain a switching signal  $p$  that determines the behavior of  $S$  and ultimately allows one to check if *NONNEG* holds for  $S + P$ .

A convenient way to add timing information and the behavior of  $S$  to runs of  $P$  is to extend the program state, or, more specifically, extend the variable assignment with variables that represent time ( $t$ ) and the state of  $S$  ( $x$ ), although, of course, they differ in nature from  $i$  and  $p$ . Ignoring the execution time of instructions other than “sleep(1)”, this extended idealized run of  $S + P$  can have the form:

$(L1, [i \mapsto 0, p \mapsto 0, t \mapsto 0, x \mapsto x_0]),$   
 $(L2, [i \mapsto 0, p \mapsto 0, t \mapsto 0, x \mapsto x_0]),$   
 $(L3, [i \mapsto 0, p \mapsto 0, t \mapsto 0, x \mapsto x_0]),$   
 $(L4, [i \mapsto 0, p \mapsto 0, t \mapsto 0, x \mapsto x_0]),$   
 $(L5, [i \mapsto 0, p \mapsto 0, t \mapsto 1, x \mapsto x_1]),$   
 $(L2, [i \mapsto 0, p \mapsto 0, t \mapsto 1, x \mapsto x_1]),$   
 $(L3, [i \mapsto 1, p \mapsto 0, t \mapsto 1, x \mapsto x_1]),$   
 $(L4, [i \mapsto 1, p \mapsto 1, t \mapsto 1, x \mapsto x_1]), \dots$

where  $x_i = x(i)$  for a solution  $x$  of the switched system  $\frac{d}{dt}x(t) = p(t)x^2(t)$ ,  $x(0) = x_0$ , where

$$p(t) = \begin{cases} i, & t \in [i, i+1), i \in \{0, 1, \dots, 9\}, \\ 9, & t \geq 10. \end{cases}$$

Note that if  $x_0 \neq 0$ , this solution  $x$  dominates the solution  $y$  of the initial value problem  $\frac{d}{dt}y(t) = y^2(t)$ ,  $y(1) = x_0$  for  $t \geq 1$ , which is  $y(t) = 1/(1 + x_0^{-1} - t)$  and which has a finite time blow-up at  $t = 1 + x_0^{-1}$  (i.e.  $\lim_{t \rightarrow 1+x_0^{-1}-} x(t) = \infty$ ), so  $x$  is undefined (and cannot be continuously extended) past the time  $1 + x_0^{-1}$ . The physical meaning of this situation is model- and application-specific, e.g. it may represent a physical event after which the current model cannot represent adequately  $S$ , or may be a modeling artifact. Some results and discussion of the physical meaning of finite time blow-up situations can be found e.g. in [11], [12], [13], [14].

In any case, such situations cannot be ignored during model analysis and property checking and has to be represented in a run of  $S + P$ . E.g., although if  $x_0 \geq 0$ , then  $x(t) \geq 0$  on the maximal interval of its existence, which is bounded from above, *NONNEG* does not hold since it requires  $x(t) \geq 0$  to hold for all real  $t \geq 0$  for such an  $x$ .

Although the model of  $S$  may lose its meaning after  $t = 1 + x_0^{-1}$ , depending on the model and application, the run of a program  $P$  may still have sense past this time moment (e.g. if  $S$  represents a physical system remotely controlled by a computer running  $P$ , a finite time blow-up indicates a critical failure in  $S$ , then  $P$  may continue running after this event).

Naturally, the situation can be represented by *partial variable assignments* in the extended run of  $S + P$ , e.g.:

$(L1, [i \mapsto 0, p \mapsto 1, t \mapsto 2]),$

means that  $x$  is genuinely undefined, but other variables are defined, meaningful and have assigned values at time  $t = 2$ .

Basically, a partial variable assignment  $d$  is a set of pairs of *names* and *values*, where names are chosen from some fixed set  $V$ , but not all elements of  $V$  may appear in  $d$  as names (e.g.  $V = \{i, p, t, x\}$ ,  $d = [i \mapsto 0, p \mapsto 1, t \mapsto 2]$ ). Such assignments are also called *nominative sets* [15].

In contrast, a variable assignment can be called *total*, if all elements of  $V$  appear in it as names (e.g.  $V = \{i, p, t, x\}$ ,  $d = [i \mapsto 0, p \mapsto 1, t \mapsto 2, x \mapsto 3]$ ).

Obviously, total variable assignments can be formalized mathematically as total functions on  $V$  and partial assignments (nominative sets) can be formalized as partial functions on  $V$ .

Reasoning about total variable assignments is well supported in tools that aid formal specification and verification of software, e.g. proof assistants [16] such as Isabelle, Coq, PVS, etc. In particular, Isabelle/HOL “record” data types are convenient for introducing total assignments with a predefined set of names. Otherwise, they may be formalized as functions on a type of names.

On the other hand, partial variable assignments are usually implemented manually on top of total assignments using option types (data types that add a special “none”/undefined value to an existing type), and a built-in library of basic

operations on them that reflect program operations is generally not available. Another issue is that built-in or library data types that represent partial variable assignments with (arbitrarily deep) nesting such as

```
[ local_vars ↦ [i ↦ 1, j ↦ 0],
  IO_interface ↦ [p ↦ 1],
  global_time ↦ 1,
  system_S_state ↦ [x ↦ 1],
  anotherSystemState ↦ [
    subsystem1 ↦ [y ↦ 1, z ↦ 1],
    subsystem2 ↦ [y ↦ 1, z ↦ 1]] ]
```

are also not available (i.e. partial variable assignments where the values of some variables themselves can be partial variable assignments). However, such assignments can be very useful to reflect the typical way in which data is grouped in programs and formalize programs that operate on complex data structures, e.g. such partial assignments naturally formalize data encoded in the popular JSON (JavaScript Object Notation) data format widely used in web applications.

In this paper we propose a library (written in the Mizar proof assistant [17], [18]) that provides a formalization of nominative sets and operations on them. The Mizar system has its own proof verifier<sup>1</sup> used to verify the logical correctness of proofs written in the Mizar language<sup>2</sup>. The system contains a very rich library (based on an axiomatic set theory [29]) of formalized mathematical theories called Mizar Mathematical Library (MML).<sup>3,4</sup> It has also a library support for the notion of a partial function without using option types. It is then well-suited for formalizing the mentioned partial variable assignments with nesting, and, more generally, has a potential for developing formalizations of models of real-time and cyber-physical systems and logics for reasoning about them.

We hope that it will be useful for formalizing models of hardware-software systems and applying logical methods to verification such systems. In this direction we developed an extension of the Floyd-Hoare logic [10] that takes advantage of partial variable assignments and also supports partially defined pre- and post-condition predicates. More information about it can be found in [10].

In our library we use the theory of *nominative data* [15], [37], [38] from the *composition-nominative approach* [37] to program semantics: partial variable assignments are formalized

as so-called nominative data with simple (unstructured) names and complex (structured) values. They are also called *Type SC* (simple names, complex values) nominative data, or nominative data of the type  $TND_{SC}$  [15]. They have hierarchical structure and can be considered as labeled oriented trees with arcs labeled with names.

The set of nominative data over a given set of (simple/basic) names  $V$  and set of atomic (basic) values  $A$  is denoted as  $ND(V, A)$  and is defined as follows [15]:

$$ND(V, A) = \bigcup_{k \geq 0} ND_k(V, A),$$

where

$$ND_0(V, A) = A \cup \{\emptyset\},$$

$$ND_{k+1}(V, A) = A \cup \left( V \xrightarrow{n} ND_k(V, A) \right), \quad k \geq 0.$$

where for any set  $X$ ,  $V \xrightarrow{n} X$  denotes the set of all partial functions from  $V$  to  $X$ , the domain of which is a finite set, and  $\emptyset$  is the empty set which is considered to be the empty nominative data and alternatively denoted as  $[]$ . The elements of  $V \xrightarrow{n} X$  are also called nominative data with simple names and simple values, or *Type SS* nominative data over a set of names  $V$  and a set of values  $X$ .

If  $v_1, v_2, \dots, v_n \in V$  are pairwise different (simple) names, and  $a_1, a_2, \dots, a_n$  are elements of  $ND(V, A)$ , then  $[v_1 \mapsto d_1, v_2 \mapsto d_2, \dots, v_n \mapsto d_n]$  denotes the unique nominative data  $d \in ND(V, A)$  such that the domain of  $d$  (the set on which  $d$ , as a function, is defined) is  $\{v_1, v_2, \dots, v_n\}$  and  $d(v_i) = a_i$  for  $i = 1, 2, \dots, n$ .

For example, if  $a, b, c$  are distinct names (arbitrary objects), then  $[a \mapsto [a \mapsto 1, b \mapsto []], c \mapsto 2] \in ND(\{a, b, c\}, \{1, 2\})$ .

The elements of  $A$  are called *atomic nominative data*, while the elements of  $ND(V, A) \setminus A$  are called *non-atomic nominative data*.

The basic operations on Type SC nominative data are:

- *Naming* – creating a nominative data of the form  $[v \mapsto d]$  from a given nominative data  $d$  and a name  $v$  (this is denoted as  $\Rightarrow v(d)$ ), or a nominative data of the form  $[v_1 \mapsto [v_1 \mapsto [v_2 \mapsto \dots [v_n \mapsto d] \dots]]$  from a given nominative data  $d$  and a finite sequence of names  $v_1, v_2, \dots, v_n$  (this is denoted as  $\Rightarrow v_1 v_2 \dots v_n(d)$ ). For example, if  $v_3, v_4$  are different names, then  $\Rightarrow v_1 v_2 ([v_3 \mapsto 1, v_4 \mapsto 2]) = [v_1 \mapsto [v_2 \mapsto [v_3 \mapsto 1, v_4 \mapsto 2]]]$ .
- *Denaming* – obtaining the value corresponding to a given name  $v$  or a sequence of names  $v_1, v_2, \dots, v_n$  in a given non-atomic nominative data  $d$  (i.e.  $d \notin A$ ; if  $d \in A$ , denaming is undefined on  $d$ ). I.e., if  $d = [u_1 \mapsto a_1, u_2 \mapsto a_2, \dots, u_m \mapsto a_m]$  and  $v = u_i$  for some  $i$ , then  $a_i$  is the result of denaming the name  $v$  in  $d$  (it is denoted as  $v \Rightarrow (d)$ , so  $u_i \Rightarrow (d) = a_i$ ; it is assumed that  $v \Rightarrow (d)$  is undefined, if  $v$  is not among  $u_1, \dots, u_m$ ). For a sequence of names  $v_1, \dots, v_n$ , denaming of a nominative data  $d$  is denoted as  $v_1 v_2 \dots v_n \Rightarrow_a (d)$  and has the following

<sup>1</sup>Research on using specialized external systems to increase computational power of the Mizar system is also conducted [19], [20], [21].

<sup>2</sup>The Mizar language is a declarative language designed to write mathematical documents. It contains rules for writing traditional mathematical items (e.g. definitions, theorems, proof steps, etc.). It also provides syntactic constructions to launch specialized algorithms (e.g. term identifications, term reductions [22], flexary connectives [23], definitional expansions [24]) which increase the computational power of the verifier (e.g. equational calculus [25], [26], properties of functors and predicates [27], [28]).

<sup>3</sup>MML contains developments on various domains of mathematics, including set theory, calculus, topology, lattice theory [30], group theory, category theory, algebra [31], rough sets [32], and others.

<sup>4</sup>Because of the size, the MML is also a subject of research on optimization of its structure, including the improvement of legibility of proofs [33], [34], [35] and removing duplications of theorems and definitions [36].

meaning:  $v_1 v_2 \dots v_n \Rightarrow_a (d) = v_n \Rightarrow (\dots (v_2 \Rightarrow (v_1 \Rightarrow (d)) \dots))$ , (it is assumed that  $v_1 v_2 \dots v_n \Rightarrow_a (d)$  is undefined, if  $v_k \Rightarrow (\dots (v_2 \Rightarrow (v_1 \Rightarrow (d)) \dots)$  is undefined for some  $k \leq n$ ). For example, if  $u, w$  are different names, then

$v \Rightarrow ([v \mapsto [w \mapsto 1], w \mapsto 2]) = [w \mapsto 1]$ ,

$vw \Rightarrow_a ([v \mapsto [w \mapsto 1], w \mapsto 2]) = 1$ ,

$u \Rightarrow ([w \mapsto 1])$  is undefined.

- *(Global) overlapping* is an operation with two arguments – non-atomic nominative data  $d_1, d_2$  which means joining  $d_1$  and  $d_2$  and resolving name conflicts in the favor of the second argument  $d_2$ . It is denoted as  $d_1 \nabla d_2$  or as  $d_1 \nabla_a d_2$ . So, if  $d_1 = [u_1 \mapsto a_1, \dots, u_n \mapsto a_n]$  and  $d_2 = [v_1 \mapsto b_1, \dots, v_m \mapsto b_m]$  and  $u_{j_1}, u_{j_2}, \dots, u_{j_k}$  is the list of all elements of the set  $\{u_1, \dots, u_n\} \setminus \{v_1, \dots, v_m\}$ , then  $d_1 \nabla d_2 = [u_{j_1} \mapsto a_{j_1}, \dots, u_{j_k} \mapsto a_{j_k}, v_1 \mapsto b_1, \dots, v_m \mapsto b_m]$ . For example, if  $v_1, v_2, v_3, v_4$  are pairwise different names, then  $[v_1 \mapsto 1, v_2 \mapsto 2] \nabla [v_2 \mapsto 3, v_4 \mapsto 4] = [v_1 \mapsto 1, v_2 \mapsto 3, v_4 \mapsto 4]$ ,
- *Local overlapping* is an operation with two arguments – nominative data  $d_1, d_2$  and a name parameter  $u$ , which means the global overlapping of  $d_1$  and  $\Rightarrow u(d_2)$ . It is denoted as  $d_1 \nabla_a^u d_2$ , so  $d_1 \nabla_a^u d_2 = d_1 \nabla [u \mapsto d_2]$ . For example, if  $v_1, v_2, v_3, v_4$  are names and  $v_1, v_2$  are different, then  $[v_1 \mapsto 1] \nabla_a^{v_2 v_3} [v_4 \mapsto 2] = [v_1 \mapsto 1, v_2 \mapsto [v_3 \mapsto [v_4 \mapsto 2]]]$ .

The set  $ND(V, A)$  together with the operations of naming, denaming, and local overlapping is called the algebra of nominative data of the type  $TND_{SC}$  [15, Definition 5].

## II. DEFINITION OF NOMINATIVE DATA IN MIZAR

We implemented our library in the form of a Mizar paper entitled `NOMIN_1.MIZ` [39], in which we formalized the carrier set and the operations of the algebra of nominative data of the type  $TND_{SC}$ .

Below we describe the main definitions and results available in this Mizar paper. Because of space limitations we omit the text of full formal proofs of the theorems and correctness conditions of definitions stated below and certain technical lemmas that are used only in these proofs, but note that these formal proofs were checked for correctness with the help of the Mizar system.<sup>5</sup>

We formally defined a nominative set (*NominativeSet*) over an arbitrary set of names  $V$  and an arbitrary set of atomic values  $A$  as a partial function (`PartFunc` [41]) from  $V$  to  $A$  as follows:

```
definition
  let V,A be set;
  mode NominativeSet of V,A is PartFunc of V,A;
end;
```

<sup>5</sup>The details on syntax and semantics of the Mizar language can be found in [40].

We defined the notion of a Type SS nominative data (*TypeSSNominativeData*) as a nominative set with the finite graph:

```
registration
  let V,A be set;
  cluster finite for NominativeSet of V,A;
end;

definition
  let V,A be set;
  mode TypeSSNominativeData of V,A
    is finite NominativeSet of V,A;
end;
```

We defined the set  $NDSS(V, A)$  of all Type SS nominative data as follows:

```
definition
  let V,A be set;
  func NDSS(V,A) -> set equals
    the set of all D
      where D is TypeSSNominativeData of V,A;
end;
```

and proved that it is nonempty for all sets  $V$  and  $A$ :

```
registration
  let V,A be set;
  cluster NDSS(V,A) -> non empty;
end;
```

The following definitions introduce the notion of a type SC nominative (*TypeSCNominativeData*), including nonatomic nominative data (*NonatomicND*).

```
definition
  let V,A be set;
  let S be FinSequence;
  pred S IsNDRankSeq V,A means
    S.1 = NDSS(V,A) &
    for n being Nat st n in dom S & n+1 in dom S
      holds S.(n+1) = NDSS(V,A \ / S.n);
end;

definition
  let V,A be set;
  mode NonatomicND of V,A -> Function means
    ex S being FinSequence st S IsNDRankSeq V,A &
    it in Union S;
end;

definition
  let V,A be set;
  mode TypeSCNominativeData of V,A -> set means
    it in A or it is NonatomicND of V,A;
end;

definition
  let V,A be set;
  let D be TypeSCNominativeData of V,A;
  attr D is atomicND means
    D in A;
  attr D is non-atomicND means
    D is NonatomicND of V,A;
end;

registration
  let V be set; let A be non empty set;
  cluster atomicND
```

```

    for TypeSCNominativeData of V,A;
end;

```

```

registration
  let V,A be set;
  cluster non-atomicND
  for TypeSCNominativeData of V,A;
end;

```

where *FinSequence* denotes a finite sequence [42], *.* (dot) denotes a function application [43], *dom* is the domain of the function [44], and *Union* denotes the union of the codomain of the function [45].

Then, we proved several theorems suitable for defining new *IsNDRankSeq* sequences:

```

theorem
  for S being FinSequence st S IsNDRankSeq V,A
  for n being Nat st n in dom S holds
    S|n IsNDRankSeq V,A;

theorem
  for S being FinSequence st S IsNDRankSeq V,A
  holds
    S ^ <*NDSS(V,A \ / S.len S)*> IsNDRankSeq V,A;

theorem
  for F being FinSequence st F IsNDRankSeq V,A
  ex S being FinSequence st len S = 1 + len F
  & S IsNDRankSeq V,A &
  for n being Nat st n in dom S holds
    S.n = NDSS(V,A \ / (<*A*>^F).n);

```

and two simple examples of such sequences:

```

theorem
  <*NDSS(V,A)*> IsNDRankSeq V,A;

theorem
  <*NDSS(V,A),NDSS(V,A \ / NDSS(V,A))*>
  IsNDRankSeq V,A;

```

where *len* is the length of the finite sequence [42], *<\* \*>* constructs finite sequences [42], *^* denotes the concatenation of two finite sequences [42], and *|* is the restriction of a function to a set [44].

Below we state several examples of the sets and types of nominative data introduced above:

```

theorem
  v in V & a in A implies v.-->a in NDSS(V,A);

theorem
  v in V & a in A implies
  v.-->a is NonatomicND of V,A;

theorem
  v in V & v1 in V & a1 in A implies
  v.-->(v1.-->a1) in NDSS(V,A \ / NDSS(V,A));

theorem
  v in V & v1 in V & a1 in A implies
  v.-->(v1.-->a1) is NonatomicND of V,A;

theorem
  v in V & v1 in V & a in A & a1 in A implies
  (v,v1)-->(a,a1) in NDSS(V,A);

theorem
  v in V & v1 in V & a in A & a1 in A implies

```

```

  (v,v1)-->(a,a1) is NonatomicND of V,A;

```

where *v*, *v1*, *a*, *a1* are arbitrary objects, *v.-->a* is a one element function  $\{[v,a]\}$  [46], and  $(u,v) \rightarrow (a,b)$  is a two element function  $\{[u,a],[v,b]\}$  [47].

### III. OPERATIONS ON NOMINATIVE DATA

We defined the denaming operation on nonatomic nominative data of Type SC for a single name ( $v \Rightarrow (d)$ ) as follows:

```

definition
  let V,A be set;
  let v be object;
  let D be NonatomicND of V,A
  such that v in dom D;
  func denaming(v,D) ->
    TypeSCNominativeData of V,A equals
    D.v;
end;

```

We defined the naming operation on nonatomic nominative data of Type SC for a single name ( $\Rightarrow v(d)$ ) as follows:

```

definition
  let V,A be set;
  let v,D be object;
  assume D is TypeSCNominativeData of V,A;
  assume v in V;
  func naming(V,A,v,D) -> NonatomicND of V,A
  equals
  v .--> D;
end;

```

We defined the naming operation on nonatomic nominative data of Type SC for a sequence of names ( $\Rightarrow v_1 v_2 \dots v_n(d)$ ) as follows:

```

definition
  let V,A be set;
  let a be object;
  let f be V-valued FinSequence;
  assume len f > 0;
  func namingSeq(V,A,f,a) -> FinSequence means
  len it = len f &
  t.1 = naming(V,A,f.len f,a) &
  for n being Nat st 1 <= n < len it holds
    it.(n+1) = naming(V,A,f.(len f-n),it.n);
end;

```

```

definition
  let V,A be set;
  let f be V-valued FinSequence;
  let a be object;
  func naming(V,A,f,a) -> set equals
  namingSeq(V,A,f,a).len(namingSeq(V,A,f,a));
end;

```

where *V*-valued states that the range of a relation is included in *V* [44].

Below we state several basic properties of the introduced operations:

```

theorem
  for f being V-valued FinSequence holds
  1 <= n <= len f implies
  namingSeq(V,A,f,a).n is NonatomicND of V,A;

theorem

```

```

for f being V-valued FinSequence st len f > 0
holds naming(V,A,f,a) is NonatomicND of V,A;

```

```

theorem
for V being non empty set
for v being Element of V holds
naming(V,A,<*v*>,a) = naming(V,A,v,a);

```

```

theorem
for V being non empty set
for v1,v2 being Element of V st
for D being TypeSCNominativeData of V,A
holds
naming(V,A,<*v1,v2*>,D) = v1.-->(v2.-->D);

```

The following theorem shows that denaming applied to the result of naming applied to a data  $d$  results in  $d$ , if denaming and naming concern the same name  $v$ :

```

theorem
for D being TypeSCNominativeData of V,A holds
v in V implies
denaming(v,naming(V,A,v,D)) = D;

```

The following theorem states an identity for naming applied to the result of denaming:

```

theorem
v in dom D implies
naming(V,A,v,denaming(v,D)) = v.-->D.v;

```

We defined the global overlapping on nominative data of Type SC as follows:

```

definition
let V,A be set;
let d1,d2 be object such that
d1 is TypeSCNominativeData of V,A and
d2 is TypeSCNominativeData of V,A;
func global_overlapping(V,A,d1,d2)
-> TypeSCNominativeData of V,A means
ex f1,f2 being Function st f1 = d1 & f2 = d2
& it = f2 \ / (f1 | (dom(f1) \ dom(f2)))
if not d1 in A & not d2 in A
otherwise
it = the TypeSCNominativeData of V,A;
end;

```

We defined the local overlapping with single name parameter  $v$  on nominative data of Type SC as follows:

```

definition
let V,A be set;
let d1,d2,v be object;
func local_overlapping(V,A,d1,d2,v)
-> TypeSCNominativeData of V,A equals
global_overlapping(V,A,d1,naming(V,A,v,d2));
end;

```

Below we state several basic properties of the global overlapping:

```

theorem
for d1,d2 being NonatomicND of V,A
st not d1 in A & not d2 in A holds
global_overlapping(V,A,d1,d2)
= d2 \ / (d1 | (dom(d1) \ dom(d2)));

```

```

theorem
for d1,d2 being NonatomicND of V,A

```

```

st not d1 in A & not d2 in A
& dom d1 c= dom d2
holds global_overlapping(V,A,d1,d2) = d2;

```

```

theorem
v in V &
not v.-->a1 in A & not v.-->a2 in A &
a1 is TypeSCNominativeData of V,A &
a2 is TypeSCNominativeData of V,A
implies
global_overlapping(V,A,v.-->a1,v.-->a2)
= v.-->a2;

```

Below we introduce the set  $ND(V,A)$  of all nominative data of Type SC over a set of names  $V$  and a set of values  $A$ . This is the carrier of the algebra of nominative data.

```

definition
let V,A be set;
func ND(V,A) -> set equals
the set of all D
where D is TypeSCNominativeData of V,A;
end;

```

```

registration
let V,A be set;
cluster ND(V,A) -> non empty;
end;

```

$ND(V,A)$  can be also expressed as the union of the range of the function  $FNDSC(V,A)$  defined as:

```

definition
let V,A be set;
func FNDSC(V,A) -> Function means
dom it = NAT & it.0 = A &
for n being Nat holds
it.(n+1) = NDSS(V,A \ / it.n);
end;

```

Finally, we defined the operations of the algebra of nominative data as functions on  $ND(V,A)$  as follows:

```

definition
let V,A be set;
let v be object;
func denaming(V,A,v)
-> PartFunc of ND(V,A),ND(V,A) means
dom it = ND(V,A) \ A &
for D being NonatomicND of V,A st not D in A
holds it.D = denaming(v,D);
end;

```

```

definition
let V,A be set;
let v be object;
func naming(V,A,v)
-> Function of ND(V,A),ND(V,A) means
for D being TypeSCNominativeData of V,A holds
it.D = naming(V,A,v,D);
end;

```

```

definition
let V,A be set;
let v be object;
func local_overlapping(V,A,v)
-> PartFunc of [:ND(V,A),ND(V,A):],ND(V,A)
means
dom it = [: ND(V,A) \ A , ND(V,A) \ A :] &

```

```

for d1,d2 being NonatomicND of V,A
  st not d1 in A & not d2 in A holds
  it. [d1,d2] = local_overlapping(V,A,d1,d2,v);
end;

```

where  $[ : A, B : ]$  is the Cartesian product of sets  $A$  and  $B$  [48].

#### IV. CONCLUSION

We have proposed a library of Mizar definitions of the carrier set and the operations of the algebra of nominative data of the type  $TND_{SC}$  (nominative data with simple names and complex values) which are essentially partial variable assignments that allow arbitrarily deep nesting. We have also formalized theorems that describe basic properties of nominative data and operations on them in Mizar. The obtained results can be useful for formalizing semantics of programs that operate in real time environment and/or process complex data structures and for reasoning about the behavior of such programs. We plan to formalize an extension of the Floyd-Hoare logic [10] in Mizar that allows reasoning about programs by taking advantage of the formalized notion of a nominative data in further papers. We plan to continue the work described in this paper as follows: 1) To introduce notions of predicates and functions on nominative data in Mizar – predicates on nominative data will be used to represent the semantics of pre- and postconditions and functions on nominative data can serve as semantic models of programs. 2) To define operations on partial functions and predicates on nominative data which represent semantics of common programming language constructs such as sequential execution, branching, cycle, etc. Sets of predicates and functions on nominative data together with such operations form a program algebra. 3) To define a special Floyd-Hoare composition using the introduced notions of predicates and functions (programs) on nominative data. 4) To formulate inference rules for the Floyd-Hoare logic for programs on nominative data with partial pre- and postconditions and prove soundness of this inference system in Mizar.

Email: {adamn, arturk}@math.uwb.edu.pl

**Abstract**—In this paper we present the methodology of implementing a new enhancement of the Mizar proof checker based on enabling special processing of Euclidean predicates, i.e. binary predicates which fulfill a specific variant of transitivity postulated by Euclid. Typically, every proof step in formal mathematical reasoning is associated with a formula to be proved and a list of references used to justify the formula. With the proposed enhancement, the Euclidean property of given relations can be registered during their definition, and so the verification of some proof steps related to these relations can be automated to avoid explicit referencing.

## I. INTRODUCTION

THE Mizar system [1], [2], [3] is a computer proof-assistant system used for encoding formal mathematical data (definitions and theorems) and verifying mathematical proofs. The system comprises a dedicated formal computer language – the Mizar language, a collection of command-line tools including the VERIFIER and a repository of formal texts – Mizar Mathematical Library (MML) that have been written in the Mizar language and machine-verified for their logical correctness by the VERIFIER.

The Mizar language preserves many features of natural language mathematical writing. It is designed to write declarative-style documents both readable for humans and effectively processed by computers.<sup>1</sup> The feature-rich language enables producing rigorous and semantically unambiguous texts. Apart from rules for writing traditional mathematical items (e.g. definitions, lemmas, theorems, proof steps, etc.) it also provides syntactic constructions to launch specialized algorithms for processing particular mechanisms (e.g. term identifications, term reductions [7], flexary connectives [8]) increasing computational power of VERIFIER (e.g. equational calculus [9], [10]). There have also been experiments on using specialized external systems to increase computational power of the Mizar system in selected domains [11], [12], [13].

Mizar allows registering various properties of predicates and functors [14] when defining new notions. Let us briefly recall that the set of currently implemented properties includes involutiveness and projectivity for unary operations, as well as commutativity and idempotence for binary operations. As far as binary predicates are concerned, which is directly related to the topic of this paper, the current version of the Mizar system supports registering reflexivity, irreflexivity, symmetry, asymmetry and connectedness. The transitivity

property has been analyzed and implemented most recently [15].

Table I presents how many registrations of predicate properties are used in the MML. The data has been collected with Mizar Version 8.1.05 working with the MML Version 5.37.1275.<sup>2</sup>

Property	Occurrences	Articles
reflexivity	138	91
irreflexivity	11	10
symmetry	122	82
asymmetry	6	6
connectedness	4	4
total	281	119

Table I

PREDICATE PROPERTIES OCCURRENCES

On the other hand, Table II shows the impact of registering predicate properties for proofs stored in the library as the number of errors occurring after removing registrations of the properties from texts, and the numbers of articles with such errors.

Property	Errors	Affected articles
reflexivity	356	44
irreflexivity	9	2
symmetry	498	47
asymmetry	6	4
connectedness	65	4
total	934	73

Table II

PREDICATE PROPERTIES IMPACT

In this paper we propose strengthening the Mizar system by implementing the representation of two new properties – *rightEuclidean* and *leftEuclidean*.<sup>3</sup> The properties are described in Section II. In Section III we present some examples of Euclidean properties found in the current MML. In Section IV we indicate several directions of further development of processing properties in Mizar.

## II. THE EUCLIDEAN PROPERTY

An example of a property which does not have its corresponding representation in Mizar yet is the Euclidean property.

<sup>2</sup>Computations were carried out at the Computer Center of University of Białystok <http://uco.uwb.edu.pl>

<sup>3</sup>An experimental version of the VERIFIER executable file for the Linux platform implementing the new features as well as other supplementary resources required for it to work with the current MML are available at [http://alioth.uwb.edu.pl/~artur/euclidean/euclidean\\_ver.zip](http://alioth.uwb.edu.pl/~artur/euclidean/euclidean_ver.zip).

<sup>1</sup>The legibility of proofs is a subject of ongoing research [4], [5], [6].

This property appears, most notably, in the set of axiomatic statements given at the start of Book I of Euclid's *The Elements* [16] as Common Notion 1, which states that: *Things which are equal to the same thing are also equal to each other.*<sup>4</sup> Formally speaking, a binary relation  $R$  on a set  $X$  is Euclidean (sometimes called right Euclidean) if it satisfies the following condition:  $\forall a, b, c \in X (a R b \wedge a R c \rightarrow b R c)$ .

Dually, a relation  $R$  on  $X$  may be called left Euclidean if  $\forall a, b, c \in X (b R a \wedge c R a \rightarrow b R c)$ .

The property of being Euclidean is a variant of transitivity, but the properties are indeed different. A transitive relation is Euclidean only if it is also symmetric. Only a symmetric Euclidean relation is transitive. A relation which is both Euclidean and reflexive is also symmetric and therefore it is an equivalence relation.

In the sequel we describe an enhancement of the Mizar system supporting automatic processing of Euclidean predicates. The automation involves specific computations performed during the verification process.<sup>5</sup>

To enable such an automation, when a new predicate is being defined, if it is Euclidean, it should be declared as such. The declaration is placed within a definitional block with the following Mizar syntax for right Euclidean:

```

definition
  let  $x_1$  be  $\theta_1$ ,  $x_2$  be  $\theta_2$ , ...,  $x_n$  be  $\theta_n$ ,  $y_1, y_2$  be  $\theta_{n+1}$ ;
  pred  $\pi(y_1, y_2)$  means :ident:
     $\Phi(x_1, x_2, \dots, x_n, y_1, y_2)$ ;
  rightEuclidean
  proof
    thus for  $a, b, c$  being  $\theta_{n+1}$ 
      st  $\Phi(x_1, x_2, \dots, x_n, a, b) \ \& \ \Phi(x_1, x_2, \dots, x_n, a, c)$ 
      holds  $\Phi(x_1, x_2, \dots, x_n, b, c)$ ;
    end;
  end;

```

and left Euclidean, respectively:

```

definition
  let  $x_1$  be  $\theta_1$ ,  $x_2$  be  $\theta_2$ , ...,  $x_n$  be  $\theta_n$ ,  $y_1, y_2$  be  $\theta_{n+1}$ ;
  pred  $\pi(y_1, y_2)$  means :ident:
     $\Phi(x_1, x_2, \dots, x_n, y_1, y_2)$ ;
  leftEuclidean
  proof
    thus for  $a, b, c$  being  $\theta_{n+1}$ 
      st  $\Phi(x_1, x_2, \dots, x_n, b, a) \ \& \ \Phi(x_1, x_2, \dots, x_n, c, a)$ 
      holds  $\Phi(x_1, x_2, \dots, x_n, b, c)$ ;
    end;
  end;

```

The statements of the formulas of correctness proofs shown in both the above definitions must be proved according to a special formula expressing the corresponding property of the defined predicate. For example, having such a definition, whenever VERIFIER meets a conjunction of formulas  $\pi(a, b)$  and  $\pi(a, c)$  within an inference, and the predicate  $\pi$  is known to be right Euclidean, then the set of premises in the inference is enlarged by the automatically generated formula  $\pi(b, c)$ , which may help to justify the proof step.

It should be noted that the form of definitions and a corresponding correctness proof can in general be more complicated when the definition has several cases. Below is a formal representation of the correctness proof structure in the case of a definition with three explicit cases ( $\Gamma_1(x_1, x_2, \dots, x_n, y_1, y_2)$ ,  $\Gamma_2(x_1, x_2, \dots, x_n, y_1, y_2)$  and  $\Gamma_3(x_1, x_2, \dots, x_n, y_1, y_2)$ ) as well as the default case (introduced by **otherwise**):

```

definition
  let  $x_1$  be  $\theta_1$ ,  $x_2$  be  $\theta_2$ , ...,  $x_n$  be  $\theta_n$ ,  $y_1, y_2$  be  $\theta_{n+1}$ ;
  pred  $\pi(y_1, y_2)$  means :ident:
     $\Phi_1(x_1, x_2, \dots, x_n, y_1, y_2)$  if  $\Gamma_1(x_1, x_2, \dots, x_n, y_1, y_2)$ ,
     $\Phi_2(x_1, x_2, \dots, x_n, y_1, y_2)$  if  $\Gamma_2(x_1, x_2, \dots, x_n, y_1, y_2)$ ,
     $\Phi_3(x_1, x_2, \dots, x_n, y_1, y_2)$  if  $\Gamma_3(x_1, x_2, \dots, x_n, y_1, y_2)$ 
    otherwise  $\Phi_n(x_1, x_2, \dots, x_n, y_1, y_2)$ ;
  consistency;
  rightEuclidean
  proof
    thus for  $a, b, c$  being  $\theta_{n+1}$  st
      (
        ( $\Gamma_1(x_1, x_2, \dots, x_n, a, b)$  implies  $\Phi_1(x_1, x_2, \dots, x_n, a, b)$ ) &
        ( $\Gamma_2(x_1, x_2, \dots, x_n, a, b)$  implies  $\Phi_2(x_1, x_2, \dots, x_n, a, b)$ ) &
        ( $\Gamma_3(x_1, x_2, \dots, x_n, a, b)$  implies  $\Phi_3(x_1, x_2, \dots, x_n, a, b)$ ) &
        (not  $\Gamma_1(x_1, x_2, \dots, x_n, a, b)$  &
         not  $\Gamma_2(x_1, x_2, \dots, x_n, a, b)$  &
         not  $\Gamma_3(x_1, x_2, \dots, x_n, a, b)$  implies
           $\Phi_n(x_1, x_2, \dots, x_n, a, b)$ ) &
        ( $\Gamma_1(x_1, x_2, \dots, x_n, a, c)$  implies  $\Phi_1(x_1, x_2, \dots, x_n, a, c)$ ) &
        ( $\Gamma_2(x_1, x_2, \dots, x_n, a, c)$  implies  $\Phi_2(x_1, x_2, \dots, x_n, a, c)$ ) &
        ( $\Gamma_3(x_1, x_2, \dots, x_n, a, c)$  implies  $\Phi_3(x_1, x_2, \dots, x_n, a, c)$ ) &
        (not  $\Gamma_1(x_1, x_2, \dots, x_n, a, c)$  &
         not  $\Gamma_2(x_1, x_2, \dots, x_n, a, c)$  &
         not  $\Gamma_3(x_1, x_2, \dots, x_n, a, c)$  implies
           $\Phi_n(x_1, x_2, \dots, x_n, a, c)$ )
      ) holds
      (
        ( $\Gamma_1(x_1, x_2, \dots, x_n, b, c)$  implies  $\Phi_1(x_1, x_2, \dots, x_n, b, c)$ ) &
        ( $\Gamma_2(x_1, x_2, \dots, x_n, b, c)$  implies  $\Phi_2(x_1, x_2, \dots, x_n, b, c)$ ) &
        ( $\Gamma_3(x_1, x_2, \dots, x_n, b, c)$  implies  $\Phi_3(x_1, x_2, \dots, x_n, b, c)$ ) &
        (not  $\Gamma_1(x_1, x_2, \dots, x_n, b, c)$  &
         not  $\Gamma_2(x_1, x_2, \dots, x_n, b, c)$  &
         not  $\Gamma_3(x_1, x_2, \dots, x_n, b, c)$  implies
           $\Phi_n(x_1, x_2, \dots, x_n, b, c)$ )
      )
    end;
  end;

```

The proof for a left Euclidean predicate with an analogous set of conditions would look like this:

```

definition
  let  $x_1$  be  $\theta_1$ ,  $x_2$  be  $\theta_2$ , ...,  $x_n$  be  $\theta_n$ ,  $y_1, y_2$  be  $\theta_{n+1}$ ;
  pred  $\pi(y_1, y_2)$  means :ident:
     $\Phi_1(x_1, x_2, \dots, x_n, y_1, y_2)$  if  $\Gamma_1(x_1, x_2, \dots, x_n, y_1, y_2)$ ,
     $\Phi_2(x_1, x_2, \dots, x_n, y_1, y_2)$  if  $\Gamma_2(x_1, x_2, \dots, x_n, y_1, y_2)$ ,
     $\Phi_3(x_1, x_2, \dots, x_n, y_1, y_2)$  if  $\Gamma_3(x_1, x_2, \dots, x_n, y_1, y_2)$ 
    otherwise  $\Phi_n(x_1, x_2, \dots, x_n, y_1, y_2)$ ;
  consistency;
  leftEuclidean
  proof
    thus for  $a, b, c$  being  $\theta_{n+1}$  st
      (
        ( $\Gamma_1(x_1, x_2, \dots, x_n, b, a)$  implies  $\Phi_1(x_1, x_2, \dots, x_n, b, a)$ ) &
        ( $\Gamma_2(x_1, x_2, \dots, x_n, b, a)$  implies  $\Phi_2(x_1, x_2, \dots, x_n, b, a)$ ) &
        ( $\Gamma_3(x_1, x_2, \dots, x_n, b, a)$  implies  $\Phi_3(x_1, x_2, \dots, x_n, b, a)$ ) &
        (not  $\Gamma_1(x_1, x_2, \dots, x_n, b, a)$  &
         not  $\Gamma_2(x_1, x_2, \dots, x_n, b, a)$  &
         not  $\Gamma_3(x_1, x_2, \dots, x_n, b, a)$  implies
           $\Phi_n(x_1, x_2, \dots, x_n, b, a)$ ) &
        ( $\Gamma_1(x_1, x_2, \dots, x_n, c, a)$  implies  $\Phi_1(x_1, x_2, \dots, x_n, c, a)$ ) &
        ( $\Gamma_2(x_1, x_2, \dots, x_n, c, a)$  implies  $\Phi_2(x_1, x_2, \dots, x_n, c, a)$ ) &
        ( $\Gamma_3(x_1, x_2, \dots, x_n, c, a)$  implies  $\Phi_3(x_1, x_2, \dots, x_n, c, a)$ ) &
        (not  $\Gamma_1(x_1, x_2, \dots, x_n, c, a)$  &
         not  $\Gamma_2(x_1, x_2, \dots, x_n, c, a)$  &
         not  $\Gamma_3(x_1, x_2, \dots, x_n, c, a)$  implies
           $\Phi_n(x_1, x_2, \dots, x_n, c, a)$ )
      )
    end;
  end;

```

<sup>4</sup>[https://proofwiki.org/wiki/Axiom:Euclid%27s\\_Common\\_Notions](https://proofwiki.org/wiki/Axiom:Euclid%27s_Common_Notions)

<sup>5</sup>Other such automations are, for example, processing of adjectives [17] and definitional expansions [18].

```

(not  $\Gamma_1(x_1, x_2, \dots, x_n, c, a)$  &
 not  $\Gamma_2(x_1, x_2, \dots, x_n, c, a)$  &
 not  $\Gamma_3(x_1, x_2, \dots, x_n, c, a)$  implies
   $\Phi_n(x_1, x_2, \dots, x_n, c, a)$ )
) holds
(
 ( $\Gamma_1(x_1, x_2, \dots, x_n, b, c)$  implies  $\Phi_1(x_1, x_2, \dots, x_n, b, c)$ ) &
 ( $\Gamma_2(x_1, x_2, \dots, x_n, b, c)$  implies  $\Phi_2(x_1, x_2, \dots, x_n, b, c)$ ) &
 ( $\Gamma_3(x_1, x_2, \dots, x_n, b, c)$  implies  $\Phi_3(x_1, x_2, \dots, x_n, b, c)$ ) &
 (not  $\Gamma_1(x_1, x_2, \dots, x_n, b, c)$  &
 not  $\Gamma_2(x_1, x_2, \dots, x_n, b, c)$  &
 not  $\Gamma_3(x_1, x_2, \dots, x_n, b, c)$  implies
   $\Phi_n(x_1, x_2, \dots, x_n, b, c)$ )
);
end;
end;

```

### III. EXAMPLES

To search for examples of predicates that fulfill the Euclidean properties one needs to use a parser capable of processing MML articles. For example, there is a free customizable parser<sup>6</sup> [19] implemented using the popular open-source GNU parser generator suite: `flex` and `bison` that gets in line with the free license on which the Mizar Mathematical Library is distributed [20]. It should be noted that the parser works with the “Weakly Strict Mizar” (WS-Mizar) representation of Mizar texts. With the current Mizar system one can generate a WS-Mizar document from a Mizar article using the `wsm-parser` tool. Customized parsing actions allow filtering out theorems stated as implications resembling the Euclidean conditions, i.e. in which the antecedent contains a conjunction of two instances of predicative formulas and the consequent is also the same predicate (with appropriately instantiated variables). As a result, such theorems could be eliminated from the MML in order to avoid redundancy [21].

Our first example of a definition which naturally possesses the Euclidean property comes from a Mizar article about Tarski’s classes and ranks [22].

```

definition
  let F,G be Relation;
  pred F,G are_fiberwise_equipotent means
    for x being object holds
      card Coim(F,x) = card Coim(G,x);
  reflexivity;
  symmetry;
end;

```

It should be noted that the properties of `reflexivity` and `symmetry` have already been identified and proved for this definition.

The Euclidean property of this definition is expressed as theorem `CLASSES1:76`:

```

theorem
  for F,G,H being Function
  st F,G are_fiberwise_equipotent &
    F,H are_fiberwise_equipotent holds
    G,H are_fiberwise_equipotent

```

<sup>6</sup>It can be downloaded from a dedicated Git repository <https://github.com/MizarProject/wsm-tools>. The distribution includes a simple Makefile for use with GNU make, which contains instructions to generate both the lexer and parser source code and build an executable called `wsm-parser` with customized syntactic actions.

The above theorem is quite popular (in total it is referenced 54 times in 12 various Mizar articles). In order to be possibly as general as in the original definition, i.e. the equipotence should be provable for arbitrary relations. This theorem can obviously be generated without any problems to this form:

```

theorem
  for F,G,H being Relation
  st F,G are_fiberwise_equipotent &
    F,H are_fiberwise_equipotent holds
    G,H are_fiberwise_equipotent

```

Another example of a theorem stating the right Euclidean property for a binary predicate is located in an article about midpoint algebras, in particular its theorem `MIDSP_1:21` [23]:

```

theorem Th21:
  p ## q & p ## r implies q ## r

```

This theorem does not have any references in the library yet.

Another example comes from a Mizar article devoted to parallelity spaces [24].

```

definition
  let PS be non empty ParStr;
  let a,b,c,d be Element of PS;
  pred a,b '||' c,d means
    [[a,b],[c,d]] in the CONGR of PS;
end;

```

Defining a new shortcut type for nonempty parallelity spaces and reserving the type for free variables including `a`, `b`, `c` and `d` to be used in the sequel

```

definition
  mode ParSp is ParSp-like non empty ParStr;
end;

```

```

reserve PS for ParSp,
  a,b,c,d for Element of PS;

```

the article provides the following theorem `PARSP_1:35`:

```

theorem Th35:
  a,b '||' a,c & a,b '||' a,d implies
  a,b '||' c,d

```

This theorem is referenced twice, only in the article introducing the notion. The above example is particularly interesting, because it shows that the Euclidean property can also be interpreted for predicates with more than two parameters. Namely, in this case the `'||'` predicate has four nominal arguments, but if we fix the first pair and consider only the last two, then the theorem clearly states a variant of the right Euclidean property.

### IV. CONCLUSIONS AND FURTHER WORK

This work falls under the continuous development of the Mizar system aimed at a still better representation of mathematical concepts taken for granted by working mathematicians in their writings. Following the addition of some automation for such commonly used relation properties like reflexivity, irreflexivity, symmetry, asymmetry, antisymmetry and most

recently transitivity, we report on the experiment of implementing the left- and right- Euclidean properties. The number of Euclidean predicates detected in the current Mizar library is not big, but enriching the set of properties automatically processed by the VERIFIER is potentially useful for developing further formalizations in a more natural way without explicit references to theorems stating ‘naturally obvious’ properties. The availability of various properties might in future result in devising ways of handling collections of properties which often go together, e.g. the equivalence relation being a conjunction of three properties.

Another direction of future development might be connected with the extension of predicate properties for the ones which are not necessarily binary, but can be treated as such if we fix the values of their arguments. In general, properties known for binary predicates, can be introduced for  $n$ -ary predicates, where  $2 \leq n$ , with  $n - 2$  fixed arguments.

**Abstract**—The height of a rational number  $\frac{p}{q}$  is denoted by  $h(\frac{p}{q})$  and equals  $\max(|p|, |q|)$  provided  $\frac{p}{q}$  is written in lowest terms. The height of a rational tuple  $(x_1, \dots, x_n)$  is denoted by  $h(x_1, \dots, x_n)$  and equals  $\max(h(x_1), \dots, h(x_n))$ . Let  $G_n = \{x_i + 1 = x_k : i, k \in \{1, \dots, n\}\} \cup \{x_i \cdot x_j = x_k : i, j, k \in \{1, \dots, n\}\}$ . Let  $f(1) = 1$ , and let  $f(n+1) = 2^{f(n)}$  for every positive integer  $n$ . We conjecture: (1) if a system  $S \subseteq G_n$  has only finitely many solutions in rationals  $x_1, \dots, x_n$ , then each such solution  $(x_1, \dots, x_n)$  satisfies  $h(x_1, \dots, x_n) \leq \begin{cases} 1 & (\text{if } n = 1) \\ 2^{2^{n-2}} & (\text{if } n \geq 2) \end{cases}$ ; (2) if a system  $S \subseteq G_n$  has only finitely many solutions in non-negative rationals  $x_1, \dots, x_n$ , then each such solution  $(x_1, \dots, x_n)$  satisfies  $h(x_1, \dots, x_n) \leq f(2n)$ . We prove: (1) both conjectures imply that there exists an algorithm which takes as input a Diophantine equation, returns an integer, and this integer is greater than the heights of rational solutions, if the solution set is finite; (2) both conjectures imply that the question whether or not a given Diophantine equation has only finitely many rational solutions is decidable by a single query to an oracle that decides whether or not a given Diophantine equation has a rational solution.

**Index Terms**—Diophantine equation which has only finitely many rational solutions, Hilbert's Tenth Problem for  $\mathbb{Q}$ , relative decidability, upper bound on the heights of rational solutions.

## I. Introduction

THE height of a rational number  $\frac{p}{q}$  is denoted by  $h(\frac{p}{q})$  and equals  $\max(|p|, |q|)$  provided  $\frac{p}{q}$  is written in lowest terms. The height of a rational tuple  $(x_1, \dots, x_n)$  is denoted by  $h(x_1, \dots, x_n)$  and equals  $\max(h(x_1), \dots, h(x_n))$ . We attempt to formulate a conjecture which implies a positive answer to the following open problem:

*Is there an algorithm which takes as input a Diophantine equation, returns an integer, and this integer is greater than the heights of rational solutions, if the solution set is finite?*

## II. Conjecture 1 and its equivalent form

**Observation 1.** Only  $x_1 = 0$  and  $x_1 = 1$  solve the equation  $x_1 \cdot x_1 = x_1$  in integers (rationals, real numbers, complex num-

bers). For each integer  $n \geq 2$ , the following system

$$\begin{cases} x_1 \cdot x_1 = x_1 \\ x_1 + 1 = x_2 \\ x_1 \cdot x_2 = x_2 \\ \forall i \in \{2, \dots, n-1\} \ x_i \cdot x_i = x_{i+1} \text{ (if } n \geq 3) \end{cases}$$

has exactly one integer (rational, real, complex) solution, namely  $(1, 2, 4, 16, 256, \dots, 2^{2^{n-3}}, 2^{2^{n-2}})$ .

Let

$$G_n = \{x_i + 1 = x_k : i, k \in \{1, \dots, n\}\} \cup$$

$$\{x_i \cdot x_j = x_k : i, j, k \in \{1, \dots, n\}\}$$

**Conjecture 1.** If a system  $S \subseteq G_n$  has only finitely many solutions in rationals  $x_1, \dots, x_n$ , then each such solution  $(x_1, \dots, x_n)$  satisfies

$$h(x_1, \dots, x_n) \leq \begin{cases} 1 & (\text{if } n = 1) \\ 2^{2^{n-2}} & (\text{if } n \geq 2) \end{cases}$$

Observation 1 implies that the bound

$$\begin{cases} 1 & (\text{if } n = 1) \\ 2^{2^{n-2}} & (\text{if } n \geq 2) \end{cases}$$

cannot be decreased.

Conjecture 1 is equivalent to the following conjecture on rational arithmetic: if rational numbers  $x_1, \dots, x_n$  satisfy

$$h(x_1, \dots, x_n) > \begin{cases} 1 & (\text{if } n = 1) \\ 2^{2^{n-2}} & (\text{if } n \geq 2) \end{cases}$$

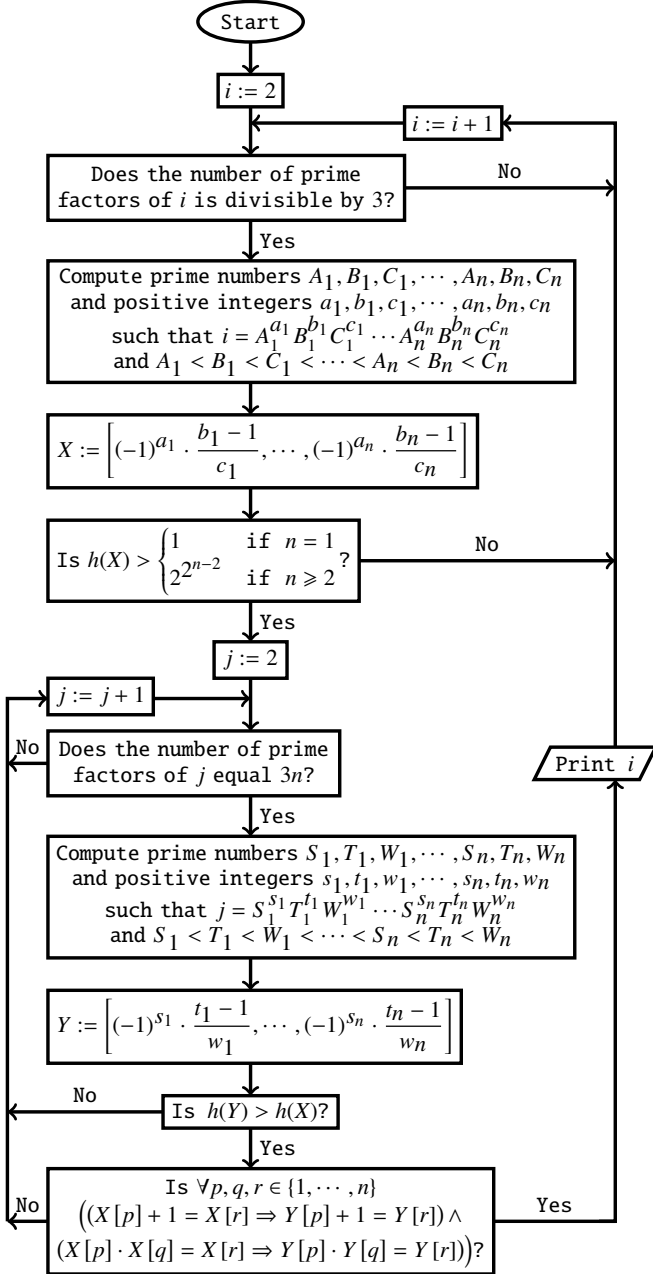

then there exist rational numbers  $y_1, \dots, y_n$  such that

$$h(x_1, \dots, x_n) < h(y_1, \dots, y_n)$$

and for every  $i, j, k \in \{1, \dots, n\}$

$$(x_i + 1 = x_k \implies y_i + 1 = y_k) \wedge (x_i \cdot x_j = x_k \implies y_i \cdot y_j = y_k)$$

**Theorem 1.** Conjecture 1 is true if and only if the execution of Flowchart 1 prints infinitely many numbers.

Flowchart 1: An infinite-time computation which decides whether or not Conjecture 1 is true

*Proof.* Let  $\Gamma_3$  denote the set of all integers  $i \geq 2$  whose number of prime factors is divisible by 3. The claimed equivalence is true because the algorithm from Flowchart 1 applies a surjective function  $\eta: \Gamma_3 \rightarrow \bigcup_{n=1}^{\infty} \mathbb{Q}^n$ .  $\square$

**Corollary 1.** *Conjecture 1 can be written in the form  $\forall x \in \mathbb{N} \exists y \in \mathbb{N} \phi(x, y)$ , where  $\phi(x, y)$  is a computable predicate.*

### III. Algebraic lemmas – part 1

Let  $\mathcal{R}$  denote the class of all rings, and let  $\mathcal{Rng}$  denote the class of all rings  $K$  that extend  $\mathbb{Z}$ . Let

$$E_n = \{1 = x_k : k \in \{1, \dots, n\}\} \cup$$

$$\{x_i + x_j = x_k : i, j, k \in \{1, \dots, n\}\} \cup$$

$$\{x_i \cdot x_j = x_k : i, j, k \in \{1, \dots, n\}\}$$

**Lemma 1.** ([12, p. 720]) *Let  $D(x_1, \dots, x_p) \in \mathbb{Z}[x_1, \dots, x_p]$ . Assume that  $d_i = \deg(D, x_i) \geq 1$  for each  $i \in \{1, \dots, p\}$ . We can compute a positive integer  $n > p$  and a system  $T \subseteq E_n$  which satisfies the following three conditions:*

**Condition 1.** *If  $K \in \mathcal{Rng} \cup \{\mathbb{N}, \mathbb{N} \setminus \{0\}\}$ , then*

$$\forall \tilde{x}_1, \dots, \tilde{x}_p \in K \left( D(\tilde{x}_1, \dots, \tilde{x}_p) = 0 \iff \right.$$

$$\left. \exists \tilde{x}_{p+1}, \dots, \tilde{x}_n \in K \left( \tilde{x}_1, \dots, \tilde{x}_p, \tilde{x}_{p+1}, \dots, \tilde{x}_n \right) \text{ solves } T \right)$$

**Condition 2.** *If  $K \in \mathcal{Rng} \cup \{\mathbb{N}, \mathbb{N} \setminus \{0\}\}$ , then for each  $\tilde{x}_1, \dots, \tilde{x}_p \in K$  with  $D(\tilde{x}_1, \dots, \tilde{x}_p) = 0$ , there exists a unique tuple  $(\tilde{x}_{p+1}, \dots, \tilde{x}_n) \in K^{n-p}$  such that the tuple  $(\tilde{x}_1, \dots, \tilde{x}_p, \tilde{x}_{p+1}, \dots, \tilde{x}_n)$  solves  $T$ .*

**Condition 3.** *If  $M$  denotes the maximum of the absolute values of the coefficients of  $D(x_1, \dots, x_p)$ , then*

$$n = (M + 2)(d_1 + 1) \cdots (d_p + 1) - 1$$

*Conditions 1 and 2 imply that for each  $K \in \mathcal{Rng} \cup \{\mathbb{N}, \mathbb{N} \setminus \{0\}\}$ , the equation  $D(x_1, \dots, x_p) = 0$  and the system  $T$  have the same number of solutions in  $K$ .*

**Lemma 2.** ([8, p. 100]) *If  $L \in \mathcal{R} \cup \{\mathbb{N}, \mathbb{N} \setminus \{0\}\}$  and  $x, y, z \in L$ , then  $z(x + y - z) = 0$  if and only if*

$$(zx + 1)(zy + 1) = z^2(xy + 1) + 1$$

Let  $\alpha, \beta$ , and  $\gamma$  denote variables.

**Lemma 3.** *If  $L \in \mathcal{R} \cup \{\mathbb{N}, \mathbb{N} \setminus \{0\}\}$  and  $x, y, z \in L$ , then  $x + y = z$  if and only if*

$$(zx + 1)(zy + 1) = z^2(xy + 1) + 1 \quad (1)$$

and

$$((z + 1)x + 1)((z + 1)y + 1) = (z + 1)^2(xy + 1) + 1 \quad (2)$$

*We can express equations (1) and (2) as a system  $\mathcal{F}$  such that  $\mathcal{F}$  involves  $x, y, z$  and 20 new variables and  $\mathcal{F}$  consists of equations of the forms  $\alpha + 1 = \gamma$  and  $\alpha \cdot \beta = \gamma$ .*

*Proof.* By Lemma 2, equation (1) is equivalent to

$$z(x + y - z) = 0 \quad (3)$$

and equation (2) is equivalent to

$$(z + 1)(x + (y + 1) - (z + 1)) = 0 \quad (4)$$

The conjunction of equations (3) and (4) is equivalent to  $x + y = z$ . The new 20 variables express the following 20 polynomials:

$$\begin{aligned}
&zx, \quad zx+1, \quad zy, \quad zy+1, \quad z^2, \quad xy, \quad xy+1, \\
&z^2(xy+1), \quad z^2(xy+1)+1, \quad z+1, \quad (z+1)x, \\
&(z+1)x+1, \quad y+1, \quad (z+1)(y+1), \quad (z+1)(y+1)+1, \\
&(z+1)^2, \quad x(y+1), \quad x(y+1)+1, \\
&(z+1)^2(x(y+1)+1), \quad (z+1)^2(x(y+1)+1)+1.
\end{aligned}$$

□

**Lemma 4.** (cf. Observation 4) Let  $D(x_1, \dots, x_p) \in \mathbb{Z}[x_1, \dots, x_p]$ . Assume that  $\deg(D, x_i) \geq 1$  for each  $i \in \{1, \dots, p\}$ . We can compute a positive integer  $n > p$  and a system  $T \subseteq G_n$  which satisfies the following two conditions:

**Condition 4.** If  $K \in \mathcal{Rng} \cup \{\mathbb{N}, \mathbb{N} \setminus \{0\}\}$ , then

$$\forall \tilde{x}_1, \dots, \tilde{x}_p \in K \left( D(\tilde{x}_1, \dots, \tilde{x}_p) = 0 \iff \right.$$

$$\left. \exists \tilde{x}_{p+1}, \dots, \tilde{x}_n \in K \left( D(\tilde{x}_1, \dots, \tilde{x}_p, \tilde{x}_{p+1}, \dots, \tilde{x}_n) \text{ solves } T \right) \right)$$

**Condition 5.** If  $K \in \mathcal{Rng} \cup \{\mathbb{N}, \mathbb{N} \setminus \{0\}\}$ , then for each  $\tilde{x}_1, \dots, \tilde{x}_p \in K$  with  $D(\tilde{x}_1, \dots, \tilde{x}_p) = 0$ , there exists a unique tuple  $(\tilde{x}_{p+1}, \dots, \tilde{x}_n) \in K^{n-p}$  such that the tuple  $(\tilde{x}_1, \dots, \tilde{x}_p, \tilde{x}_{p+1}, \dots, \tilde{x}_n)$  solves  $T$ .

Conditions 4 and 5 imply that for each  $K \in \mathcal{Rng} \cup \{\mathbb{N}, \mathbb{N} \setminus \{0\}\}$ , the equation  $D(x_1, \dots, x_p) = 0$  and the system  $T$  have the same number of solutions in  $K$ .

*Proof.* Let the system  $T \subseteq E_n$  be given by Lemma 1. For every  $L \in \mathcal{R} \cup \{\mathbb{N}, \mathbb{N} \setminus \{0\}\}$ ,

$$\forall x \in L \left( x = 1 \iff (x \cdot x = x \wedge x \cdot (x+1) = x+1) \right)$$

Therefore, if there exists  $m \in \{1, \dots, n\}$  such that the equation  $1 = x_m$  belongs to  $T$ , then we introduce a new variable  $y$  and replace in  $T$  each equation of the form  $1 = x_k$  by the equations  $x_k \cdot x_k = x_k$ ,  $x_k + 1 = y$ ,  $x_k \cdot y = y$ . Next, we apply Lemma 3 to each equation of the form  $x_i + x_j = x_k$  that belongs to  $T$  and replace in  $T$  each such equation by an equivalent system of equations of the forms  $\alpha + 1 = \gamma$  and  $\alpha \cdot \beta = \gamma$ . □

#### IV. The main consequence of Conjecture 1

**Theorem 2.** Conjecture 1 implies that there is an algorithm which takes as input a Diophantine equation, returns an integer, and this integer is greater than the heights of rational solutions, if the solution set is finite.

*Proof.* It follows from Lemma 4 for  $K = \mathbb{Q}$ . The claim of Theorem 2 also follows from Observation 4. □

**Corollary 2.** Conjecture 1 implies that the set of all Diophantine equations which have infinitely many rational solutions is recursively enumerable. Assuming Conjecture 1, a single query to the halting oracle decides whether or not a given Diophantine equation has infinitely many rational solutions. By the Davis-Putnam-Robinson-Matiyasevich theorem, the same is true for an oracle that decides whether or not a given Diophantine equation has an integer solution.

For many Diophantine equations we know that the number of rational solutions is finite by Faltings' theorem. Faltings' theorem tells that certain curves have finitely many rational points, but no known proof gives any bound on the sizes of the numerators and denominators of the coordinates of those points, see [5, p. 722]. In all such cases Conjecture 1 allows us to compute such a bound. If this bound is small enough, that allows us to find all rational solutions by an exhaustive search. For example, the equation  $x_1^5 - x_1 = x_2^2 - x_2$  has only finitely many rational solutions ([7, p. 212]). The known rational solutions are:  $(-1, 0)$ ,  $(-1, 1)$ ,  $(0, 0)$ ,  $(0, 1)$ ,  $(1, 0)$ ,  $(1, 1)$ ,  $(2, -5)$ ,  $(2, 6)$ ,  $(3, -15)$ ,  $(3, 16)$ ,  $(30, -4929)$ ,  $(30, 4930)$ ,  $(\frac{1}{4}, \frac{15}{32})$ ,  $(\frac{1}{4}, \frac{17}{32})$ ,  $(-\frac{15}{16}, -\frac{185}{1024})$ ,  $(-\frac{15}{16}, \frac{1209}{1024})$ , and the existence of other solutions is an open question, see [10, pp. 223–224]. The system

$$\begin{cases}
x_3 + 1 = x_2 \\
x_2 \cdot x_3 = x_4 \\
x_5 + 1 = x_1 \\
x_1 \cdot x_1 = x_6 \\
x_6 \cdot x_6 = x_7 \\
x_7 \cdot x_5 = x_4
\end{cases}$$

is equivalent to  $x_1^5 - x_1 = x_2^2 - x_2$ . By Conjecture 1,  $h(x_1^4) = h(x_7) \leq h(x_1, \dots, x_7) \leq 2^{2^{7-2}} = 2^{32}$ . Therefore,  $h(x_1) \leq (2^{32})^{\frac{1}{4}} = 256$ . Assuming that Conjecture 1 holds, the following MuPAD code finds all rational solutions of the equation  $x_1^5 - x_1 = x_2^2 - x_2$ .

```

solutions:={}:
for i from -256 to 256 do
for j from 1 to 256 do
x:=i/j:
y:=4*x^5-4*x+1:
p:=numer(y):
q:=denom(y):
if numlib::issqr(p) and numlib::issqr(q) then
z1:=sqrt(p/q):
z2:=-sqrt(p/q):
y1:=(z1+1)/2:
y2:=(z2+1)/2:
solutions:=solutions union {[x,y1],[x,y2]}:
end_if:
end_for:
end_for:
print(solutions):

```

The code solves the equivalent equation

$$4x_1^5 - 4x_1 + 1 = (2x_2 - 1)^2$$

and displays the already presented solutions.

MuPAD is a general-purpose computer algebra system. The commercial version of MuPAD is no longer available as a stand-alone product, but only as the Symbolic Math Toolbox of MATLAB. Fortunately, this and the next code can be executed by MuPAD Light, which was offered for free for research and education until autumn 2005.

#### V. Algebraic lemmas – part 2

**Lemma 5.** Lemmas 2 and 3 are not necessary for proving that in the rational domain each Diophantine equation is

equivalent to a system of equations of the forms  $\alpha + 1 = \gamma$  and  $\alpha \cdot \beta = \gamma$ .

*Proof.* By Lemma 1, an arbitrary Diophantine equation is equivalent to a system  $T \subseteq E_n$ , where  $n$  and  $T$  can be computed. If there exists  $m \in \{1, \dots, n\}$  such that the equation  $1 = x_m$  belongs to  $T$ , then we introduce a new variable  $t$  and replace in  $T$  each equation of the form  $1 = x_k$  by the equations  $x_k \cdot x_k = x_k$ ,  $x_k + 1 = t$ , and  $x_k \cdot t = t$ . For each rational number  $y$ , we have  $y^2 + 1 \neq 0$  and  $y(y^2 + 1) + 1 \neq 0$ . Hence, for each rational numbers  $x, y, z$ ,

$$x + y = z \iff x(y^2 + 1) + y(y^2 + 1) = z(y^2 + 1) \iff$$

$$x(y^2 + 1) + y(y^2 + 1) + 1 = z(y^2 + 1) + 1 \iff$$

$$(y(y^2 + 1) + 1) \cdot \left( \frac{x(y^2 + 1)}{y(y^2 + 1) + 1} + 1 \right) = z(y^2 + 1) + 1$$

We transform the last equation into an equivalent system  $W \subseteq G_{12}$  in such a way that the variables  $x_1, \dots, x_{12}$  correspond to the following rational expressions:

$$x, y, z, y^2, y^2 + 1, y(y^2 + 1), y(y^2 + 1) + 1, x(y^2 + 1),$$

$$\frac{x(y^2 + 1)}{y(y^2 + 1) + 1}, \frac{x(y^2 + 1)}{y(y^2 + 1) + 1} + 1, z(y^2 + 1), z(y^2 + 1) + 1.$$

In this way, we replace in  $T$  each equation of the form  $x_i + x_j = x_k$  by an equivalent system of equations of the forms  $\alpha + 1 = \gamma$  and  $\alpha \cdot \beta = \gamma$ .  $\square$

The next lemma enable us to prove Theorem 2 without using Lemma 4.

**Lemma 6.** *For solutions in a field, each system  $S \subseteq E_n$  is equivalent to  $T_1 \vee \dots \vee T_p$ , where each  $T_i$  is a system of equations of the forms  $\alpha + 1 = \gamma$  and  $\alpha \cdot \beta = \gamma$ .*

*Proof.* Acting as in the proof of Lemma 5, we eliminate from  $S$  all equations of the form  $1 = x_k$ . Let  $m$  denote the number of equations of the form  $x_i + x_j = x_k$  that belong to  $S$ . We can assume that  $m > 0$ . Let the variables  $y, z, t, w, s$ , and  $r$  be new. Let

$$S_1 = (S \setminus \{x_i + x_j = x_k\}) \cup$$

$$\{x_i + 1 = y, \quad x_k + 1 = y, \quad x_j + 1 = z, \quad z \cdot x_j = x_j\}$$

and let

$$S_2 = (S \setminus \{x_i + x_j = x_k\}) \cup$$

$$\{t \cdot x_j = x_i, \quad t + 1 = w, \quad w \cdot x_j = x_k, \quad x_j + 1 = s, \quad r \cdot x_j = s\}$$

The system  $S_1$  expresses that  $x_i + x_j = x_k$  and  $x_j = 0$ . The system  $S_2$  expresses that  $x_i + x_j = x_k$  and  $x_j \neq 0$ . Therefore,  $S \iff (S_1 \vee S_2)$ . We have described a procedure which transforms  $S$  into  $S_1$  and  $S_2$ . We iterate this procedure for  $S_1$  and  $S_2$  and finally obtain the systems  $T_1, \dots, T_{2^m}$  without equations of the form  $x_i + x_j = x_k$ . The systems  $T_1, \dots, T_{2^m}$  satisfy  $S \iff (T_1 \vee \dots \vee T_{2^m})$  and they contain only equations of the forms  $\alpha + 1 = \gamma$  and  $\alpha \cdot \beta = \gamma$ .  $\square$

## VI. Systems which have infinitely many rational solutions

**Lemma 7.** ([9, p. 391]) *If 2 has an odd exponent in the prime factorization of a positive integer  $n$ , then  $n$  can be written as the sum of three squares of integers.*

**Lemma 8.** *For each positive rational number  $z$ ,  $z$  or  $2z$  can be written as the sum of three squares of rational numbers.*

*Proof.* We find positive integers  $p$  and  $q$  with  $z = \frac{p}{q}$ . If 2 has an odd exponent in the prime factorization of  $pq$ , then by Lemma 7 there exist integers  $i_1, i_2, i_3$  such that  $pq = i_1^2 + i_2^2 + i_3^2$ . Hence,

$$z = \left(\frac{i_1}{q}\right)^2 + \left(\frac{i_2}{q}\right)^2 + \left(\frac{i_3}{q}\right)^2$$

If 2 has an even exponent in the prime factorization of  $pq$ , then by Lemma 7 there exist integers  $j_1, j_2, j_3$  such that  $2pq = j_1^2 + j_2^2 + j_3^2$ . Hence,

$$2z = \left(\frac{j_1}{q}\right)^2 + \left(\frac{j_2}{q}\right)^2 + \left(\frac{j_3}{q}\right)^2$$

$\square$

**Lemma 9.** *A rational number  $z$  can be written as the sum of three squares of rational numbers if and only if there exist rational numbers  $r, s, t$  such that  $z = r^2(s^2(t^2 + 1) + 1)$ .*

*Proof.* Let  $H(r, s, t) = r^2(s^2(t^2 + 1) + 1)$ . Of course,

$$H(r, s, t) = r^2 + (rs)^2 + (rst)^2$$

We prove that for each rational numbers  $a, b, c$  there exist rational numbers  $r, s, t$  such that  $a^2 + b^2 + c^2 = H(r, s, t)$ . Without loss of generality we can assume that  $|a| \leq |b| \leq |c|$ . If  $b = 0$ , then  $a = 0$  and  $a^2 + b^2 + c^2 = H(c, 0, 0)$ . If  $b \neq 0$ , then  $c \neq 0$  and  $a^2 + b^2 + c^2 = H\left(c, \frac{b}{c}, \frac{a}{b}\right)$ .  $\square$

**Lemma 10.** ([1, p. 125]) *The equation  $x^3 + y^3 = 4981$  has infinitely many solutions in positive rationals and each such solution  $(x, y)$  satisfies  $h(x, y) > 10^{16} \cdot 10^6$ .*

**Theorem 3.** *There exists a system  $\mathcal{T} \subseteq G_{28}$  such that  $\mathcal{T}$  has infinitely many solutions in rationals  $x_1, \dots, x_{28}$  and each such solution  $(x_1, \dots, x_{28})$  has height greater than  $2^{227}$ .*

*Proof.* We define:

$$\Omega = \{\rho \in \mathbb{Q} \cap (0, \infty) : \exists y \in \mathbb{Q} \quad (\rho \cdot y)^3 + y^3 = 4981\}$$

Let  $\Omega_1$  denote the set of all positive rationals  $\rho$  such that the system

$$\begin{cases} (\rho \cdot y)^3 + y^3 &= 4981 \\ \rho^3 &= a^2 + b^2 + c^2 \end{cases}$$

is solvable in rationals. Let  $\Omega_2$  denote the set of all positive rationals  $\rho$  such that the system

$$\begin{cases} (\rho \cdot y)^3 + y^3 &= 4981 \\ 2\rho^3 &= a^2 + b^2 + c^2 \end{cases}$$

is solvable in rationals. Lemma 10 implies that the set  $\Omega$  is infinite. By Lemma 8,  $\Omega = \Omega_1 \cup \Omega_2$ . Therefore,  $\Omega_1$  is infinite (Case 1) or  $\Omega_2$  is infinite (Case 2).

Case 1. In this case the system

$$\begin{cases} x^3 + y^3 = 4981 \\ \frac{x^3}{y^3} = a^2 + b^2 + c^2 \end{cases}$$

has infinitely many rational solutions. By this and Lemma 9, the system

$$\begin{cases} x^3 + y^3 = 4981 \\ \frac{x^3}{y^3} = r^2 (s^2 (t^2 + 1) + 1) \end{cases}$$

has infinitely many rational solutions. We transform the above system into an equivalent system  $\mathcal{T} \subseteq G_{27}$  in such a way that the variables  $x_1, \dots, x_{27}$  correspond to the following rational expressions:

$$x, y, x^2, x^3, y^2, y^3, \frac{x^3}{y^3}, \frac{x^3}{y^3} + 1,$$

$$1, 2, 4, 16, 17, 289, \frac{289}{4}, \frac{289}{4} + 1, 293, 4981,$$

$$t, t^2, t^2 + 1, s, s^2, s^2(t^2 + 1), s^2(t^2 + 1) + 1, r, r^2.$$

The system  $\mathcal{T}$  has infinitely many solutions in rationals  $x_1, \dots, x_{27}$ . Lemma 10 implies that each rational tuple  $(x_1, \dots, x_{27})$  that solves  $\mathcal{T}$  satisfies

$$h(x_1, \dots, x_{27}) \geq h(x_1^3, x_2^3) = (h(x_1, x_2))^3 > 10^{48} \cdot 10^6 > 2^{227}$$

Since  $G_{27} \subseteq G_{28}$ ,  $\mathcal{T} \subseteq G_{28}$  and the proof for Case 1 is complete.

Case 2. In this case the system

$$\begin{cases} x^3 + y^3 = 4981 \\ 2 \cdot \frac{x^3}{y^3} = a^2 + b^2 + c^2 \end{cases}$$

has infinitely many rational solutions. By this and Lemma 9, the system

$$\begin{cases} x^3 + y^3 = 4981 \\ 2 \cdot \frac{x^3}{y^3} = r^2 (s^2 (t^2 + 1) + 1) \end{cases}$$

has infinitely many rational solutions. We transform the above system into an equivalent system  $\mathcal{T} \subseteq G_{28}$  in such a way that the variables  $x_1, \dots, x_{28}$  correspond to the following rational expressions:

$$x, y, x^2, x^3, y^2, y^3, \frac{x^3}{y^3}, 2 \cdot \frac{x^3}{y^3}, \frac{x^3}{y^3} + 1,$$

$$1, 2, 4, 16, 17, 289, \frac{289}{4}, \frac{289}{4} + 1, 293, 4981,$$

$$t, t^2, t^2 + 1, s, s^2, s^2(t^2 + 1), s^2(t^2 + 1) + 1, r, r^2.$$

The system  $\mathcal{T}$  has infinitely many solutions in rationals  $x_1, \dots, x_{28}$ . Lemma 10 implies that each rational tuple  $(x_1, \dots, x_{28})$  that solves  $\mathcal{T}$  satisfies

$$h(x_1, \dots, x_{28}) \geq h(x_1^3, x_2^3) = (h(x_1, x_2))^3 > 10^{48} \cdot 10^6 > 2^{227}$$

□

For a positive integer  $n$ , let  $\mu(n)$  denote the smallest positive integer  $m$  such that each system  $\mathcal{S} \subseteq G_n$  solvable in rationals

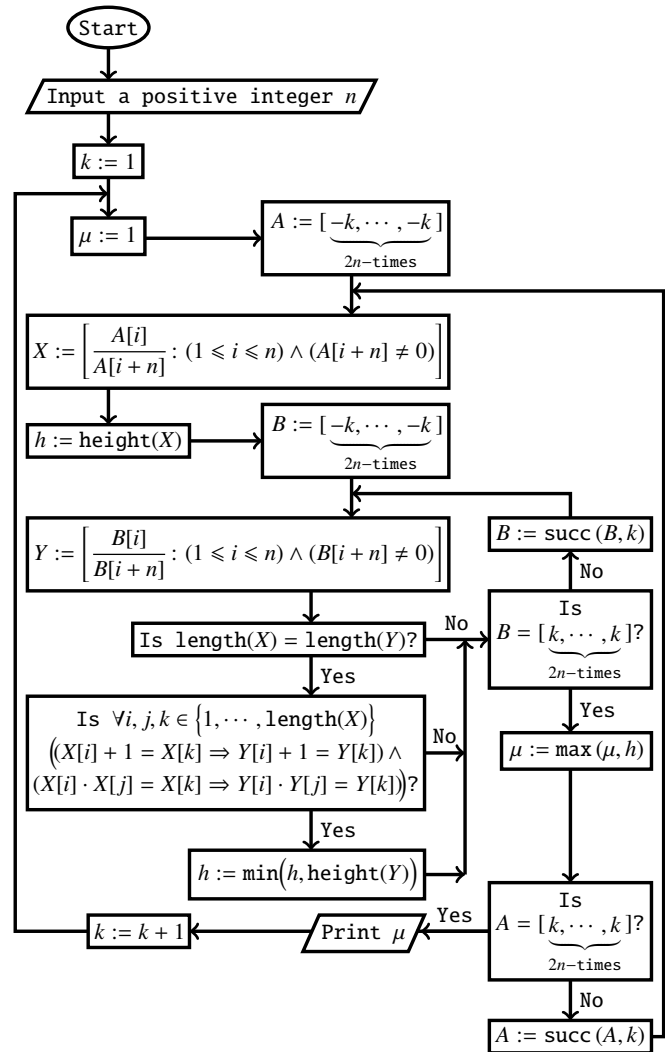

$x_1, \dots, x_n$  has a rational solution  $(x_1, \dots, x_n)$  whose height is not greater than  $m$ . Obviously,  $\mu(1) = 1$ . Observation 1 implies that  $\mu(n) \geq 2^{2^{n-2}}$  for every integer  $n \geq 2$ . Theorem 3 implies that  $\mu(28) > 2^{2^{27}}$ .

**Theorem 4.** The function  $\mu: \mathbb{N} \setminus \{0\} \rightarrow \mathbb{N} \setminus \{0\}$  is computable in the limit.

*Proof.* Let us agree that the empty tuple has height 0. For a positive integer  $w$  and a tuple

$$(x_1, \dots, x_n) \in ([-w, w] \cap \mathbb{Z})^n \setminus \underbrace{\{(w, \dots, w)\}}_{n\text{-times}}$$

let  $\text{succ}((x_1, \dots, x_n), w)$  denote the successor of  $(x_1, \dots, x_n)$  in the co-lexicographic order on  $([-w, w] \cap \mathbb{Z})^n$ . Flowchart 2 illustrates an infinite-time computation of  $\mu(n)$ .

Flowchart 2: An infinite-time computation of  $\mu(n)$

□

The next MuPAD code implements the algorithm from Flowchart 2. In MuPAD,  $\text{nops}(\cdot)$  denotes the length of a list.

The code is useless for practical computations because the algorithm from Flowchart 2 is very time-consuming.

```

succ:=proc(X,w)
local p,i;
begin
p:=1:
while (p<=nops(X) and X[p]=w) do p:=p+1
end_while:
for i from 1 to p-1 do X[i]:=-w end_for:
X[p]:=X[p]+1:
return(X):
end_proc:

```

```

ratios:=proc(X)
local T,u,i;
begin
T:=[]:
u:=nops(X)/2:
for i from 1 to u do
if X[i+u]<>0 then T:=append(T,X[i]/X[i+u])
end_if:
end_for:
return(T):
end_proc:

```

```

fit:=proc(X,Y)
local f,s,i,j,k;
begin
f:=TRUE:
if nops(X)<>nops(Y) then f:=FALSE end_if:
s:=min(nops(X),nops(Y)):
for i from 1 to s do
for j from 1 to s do
for k from 1 to s do
if X[i]+1=X[k] and Y[i]+1<>Y[k] then
f:=FALSE end_if:
if X[i]*X[j]=X[k] and Y[i]*Y[j]<>Y[k] then
f:=FALSE end_if:
end_for:
end_for:
end_for:
return(f):
end_proc:

```

```

height:=proc(X)
local h,i;
begin
h:=0:
for i from 1 to nops(X) do
h:=max(h,abs( numer(X[i]),denom(X[i]))):
end_for:
return(h):
end_proc:

```

```

input("Enter a positive integer:",n):

```

## VII. Conjecture 2 and its equivalent form

Let  $[\cdot]$  denote the integer part function.

**Lemma 11.** *For every non-negative real numbers  $x$  and  $y$ ,  $x + 1 = y$  implies that  $2^{2^{[x]}} \cdot 2^{2^{[y]}} = 2^{2^{[y]}}$ .*

*Proof.* For every non-negative real numbers  $x$  and  $y$ ,  $x + 1 = y$  implies that  $[x] + 1 = [y]$ .  $\square$

Let  $f(1) = 1$ , and let  $f(n + 1) = 2^{2^{f(n)}}$  for every positive integer  $n$ . Let  $g(1) = 0$ , and let  $g(n + 1) = 2^{2^{g(n)}}$  for every positive integer  $n$ .

**Conjecture 2.** *If a system  $S \subseteq G_n$  has only finitely many solutions in non-negative rationals  $x_1, \dots, x_n$ , then each such solution  $(x_1, \dots, x_n)$  satisfies  $h(x_1, \dots, x_n) \leq f(2n)$ .*

Observations 2 and 3 justify Conjecture 2.

**Observation 2.** *For every system  $S \subseteq G_n$  which involves all the variables  $x_1, \dots, x_n$ , the following new system*

$$S \cup \left\{ 2^{2^{[x_k]}} = y_k : k \in \{1, \dots, n\} \right\} \cup \bigcup_{x_i+1=x_k \in S} \{y_i \cdot y_i = y_k\}$$

*is equivalent to  $S$ . If the system  $S$  has only finitely many solutions in non-negative rationals  $x_1, \dots, x_n$ , then the new system has only finitely many solutions in non-negative rationals  $x_1, \dots, x_n, y_1, \dots, y_n$ .*

*Proof.* It follows from Lemma 11.  $\square$

**Observation 3.** *For every positive integer  $n$ , the following system*

$$\begin{cases} x_1 \cdot x_1 = x_1 \\ \forall i \in \{1, \dots, n-1\} \ 2^{2^{[x_i]}} = x_{i+1} \text{ (if } n > 1) \end{cases}$$

*has exactly two solutions in non-negative rationals, namely  $(g(1), \dots, g(n))$  and  $(f(1), \dots, f(n))$ . The second solution has greater height.*

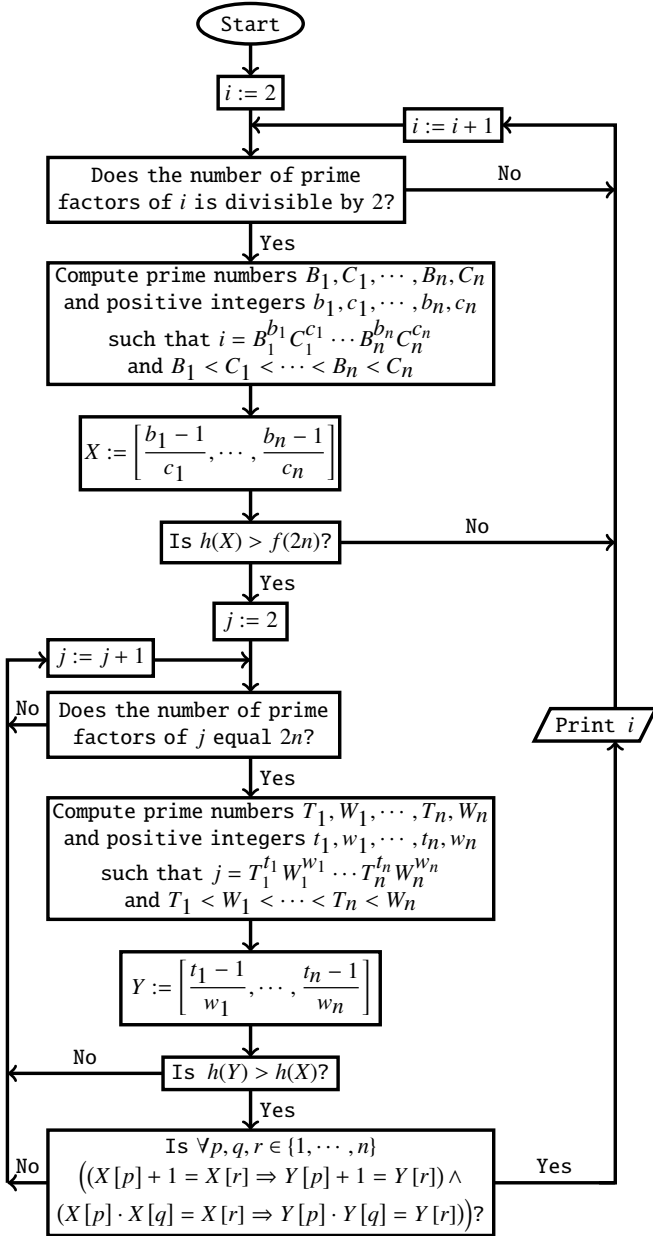

Conjecture 2 is equivalent to the following conjecture on rational arithmetic: if non-negative rational numbers  $x_1, \dots, x_n$  satisfy  $h(x_1, \dots, x_n) > f(2n)$ , then there exist non-negative rational numbers  $y_1, \dots, y_n$  such that

$$h(x_1, \dots, x_n) < h(y_1, \dots, y_n)$$

and for every  $i, j, k \in \{1, \dots, n\}$

$$(x_i + 1 = x_k \implies y_i + 1 = y_k) \wedge (x_i \cdot x_j = x_k \implies y_i \cdot y_j = y_k)$$

**Theorem 5.** *Conjecture 2 is true if and only if the execution of Flowchart 3 prints infinitely many numbers.*

Flowchart 3: An infinite-time computation which decides whether or not Conjecture 2 is true

*Proof.* Let  $\Gamma_2$  denote the set of all integers  $i \geq 2$  whose number of prime factors is divisible by 2. The claimed equivalence is true because the algorithm from Flowchart 3 applies a surjective function from  $\Gamma_2$  to  $\bigcup_{n=1}^{\infty} (\mathbb{Q} \cap [0, \infty))^n$ .  $\square$

**Corollary 3.** Conjecture 2 can be written in the form  $\forall x \in \mathbb{N} \exists y \in \mathbb{N} \psi(x, y)$ , where  $\psi(x, y)$  is a computable predicate.

### VIII. Algebraic lemmas – part 3

**Lemma 12.** (cf. [8, p. 100]) For every non-negative real numbers  $x, y, z$ ,  $x + y = z$  if and only if

$$((z+1)x+1)((z+1)(y+1)+1) = (z+1)^2(x(y+1)+1)+1 \quad (5)$$

*Proof.* The left side of equation (5) minus the right side of equation (5) equals  $(z+1)(x+y-z)$ .  $\square$

**Lemma 13.** In non-negative rationals, the equation  $x + y = z$  is equivalent to a system which consists of equations of the forms  $\alpha + 1 = \gamma$  and  $\alpha \cdot \beta = \gamma$ .

*Proof.* It follows from Lemma 12.  $\square$

**Lemma 14.** Let  $D(x_1, \dots, x_p) \in \mathbb{Z}[x_1, \dots, x_p]$ . Assume that  $\deg(D, x_i) \geq 1$  for each  $i \in \{1, \dots, p\}$ . We can compute a positive integer  $n > p$  and a system  $\mathcal{T} \subseteq G_n$  which satisfies the following two conditions:

**Condition 6.** For every non-negative rationals  $\tilde{x}_1, \dots, \tilde{x}_p$ ,

$$D(\tilde{x}_1, \dots, \tilde{x}_p) = 0 \iff$$

$\exists \tilde{x}_{p+1}, \dots, \tilde{x}_n \in \mathbb{Q} \cap [0, \infty) (\tilde{x}_1, \dots, \tilde{x}_p, \tilde{x}_{p+1}, \dots, \tilde{x}_n) \text{ solves } \mathcal{T}$

**Condition 7.** If non-negative rationals  $\tilde{x}_1, \dots, \tilde{x}_p$  satisfy  $D(\tilde{x}_1, \dots, \tilde{x}_p) = 0$ , then there exists a unique tuple  $(\tilde{x}_{p+1}, \dots, \tilde{x}_n) \in (\mathbb{Q} \cap [0, \infty))^{n-p}$  such that the tuple  $(\tilde{x}_1, \dots, \tilde{x}_p, \tilde{x}_{p+1}, \dots, \tilde{x}_n)$  solves  $\mathcal{T}$ .

Conditions 6 and 7 imply that the equation  $D(x_1, \dots, x_p) = 0$  and the system  $\mathcal{T}$  have the same number of solutions in non-negative rationals.

*Proof.* We write down the polynomial  $D(x_1, \dots, x_p)$  and replace each coefficient by the successor of its absolute value. Let  $\tilde{D}(x_1, \dots, x_p)$  denote the obtained polynomial. The polynomials  $D(x_1, \dots, x_p) + \tilde{D}(x_1, \dots, x_p)$  and  $\tilde{D}(x_1, \dots, x_p)$  have positive integer coefficients. The equation  $D(x_1, \dots, x_p) = 0$  is equivalent to

$$D(x_1, \dots, x_p) + \tilde{D}(x_1, \dots, x_p) + 1 = \tilde{D}(x_1, \dots, x_p) + 1$$

There exist a positive integer  $a$  and a finite non-empty list  $A$  such that

$$D(x_1, \dots, x_p) + \tilde{D}(x_1, \dots, x_p) + 1 = \left( \left( \sum_{(i_1, j_1, \dots, i_k, j_k) \in A} x_{i_1}^{j_1} \dots x_{i_k}^{j_k} + 1 \right) + \dots \right) + 1 \quad (6)$$

$a \text{ units}$

and all the numbers  $k, i_1, j_1, \dots, i_k, j_k$  belong to  $\mathbb{N} \setminus \{0\}$ . There exist a positive integer  $b$  and a finite non-empty list  $B$  such that

$$\tilde{D}(x_1, \dots, x_p) + 1 = \left( \left( \sum_{(i_1, j_1, \dots, i_k, j_k) \in B} x_{i_1}^{j_1} \dots x_{i_k}^{j_k} + 1 \right) + \dots \right) + 1 \quad (7)$$

$b \text{ units}$

and all the numbers  $k, i_1, j_1, \dots, i_k, j_k$  belong to  $\mathbb{N} \setminus \{0\}$ . By Lemma 13, we can equivalently express the equality of the right sides of equations (6) and (7) using only equations of the forms  $\alpha + 1 = \gamma$  and  $\alpha \cdot \beta = \gamma$ . Consequently, we can effectively find the system  $\mathcal{T}$ .  $\square$

**Observation 4.** Combining the above reasoning with Lemma 3 for  $L = \mathbb{Q}$ , we can prove Lemma 4 for  $K = \mathbb{Q}$ .

### IX. Consequences of Conjecture 2

**Theorem 6.** *If we assume Conjecture 2 and a Diophantine equation  $D(x_1, \dots, x_p) = 0$  has only finitely many solutions in non-negative rationals, then an upper bound for their heights can be computed.*

*Proof.* It follows from Lemma 14.  $\square$

**Theorem 7.** *If we assume Conjecture 2 and a Diophantine equation  $D(x_1, \dots, x_p) = 0$  has only finitely many rational solutions, then an upper bound for their heights can be computed by applying Theorem 6 to the equation*

$$\prod_{(i_1, \dots, i_p) \in \{1, 2\}^p} D((-1)^{i_1} \cdot x_1, \dots, (-1)^{i_p} \cdot x_p) = 0$$

**Corollary 4.** *Conjecture 2 implies that the set of all Diophantine equations which have infinitely many rational solutions is recursively enumerable. Assuming Conjecture 2, a single query to the halting oracle decides whether or not a given Diophantine equation has infinitely many rational solutions. By the Davis-Putnam-Robinson-Matiyasevich theorem, the same is true for an oracle that decides whether or not a given Diophantine equation has an integer solution.*

### X. Theorems on relative decidability

**Question ([3]).** *Can the twin prime problem be solved with a single use of a halting oracle?*

Let  $\xi(3) = 4$ , and let  $\xi(n+1) = \xi(n)!$  for every integer  $n \geq 3$ . For an integer  $n \geq 3$ , let  $\Psi_n$  denote the statement: if a system  $S \subseteq \{x_i! = x_{i+1} : 1 \leq i \leq n-1\} \cup \{x_i \cdot x_j = x_{j+1} : 1 \leq i \leq j \leq n-1\}$  has only finitely many solutions in positive integers  $x_1, \dots, x_n$ , then each such solution  $(x_1, \dots, x_n)$  satisfies  $x_1, \dots, x_n \leq \xi(n)$ .

**Theorem 8.** ([13]) *The statement  $\Psi_{16}$  proves the implication: if there exists a twin prime greater than  $\xi(14)$ , then there are infinitely many twin primes.*

**Corollary 5.** *Assuming the statement  $\Psi_{16}$ , a single query to the halting oracle decides the validity of the twin prime conjecture.*

**Conjecture 3.** *Harvey Friedman's conjecture in [4]: the set of all Diophantine equations which have only finitely many rational solutions is not recursively enumerable.*

Conjecture 3 implies Conjecture 4.

**Conjecture 4.** *The set of all Diophantine equations which have only finitely many rational solutions is not computable.*

By Theorem 2, Conjecture 1 implies Conjecture 5. By Theorem 7, Conjecture 2 implies Conjecture 5.

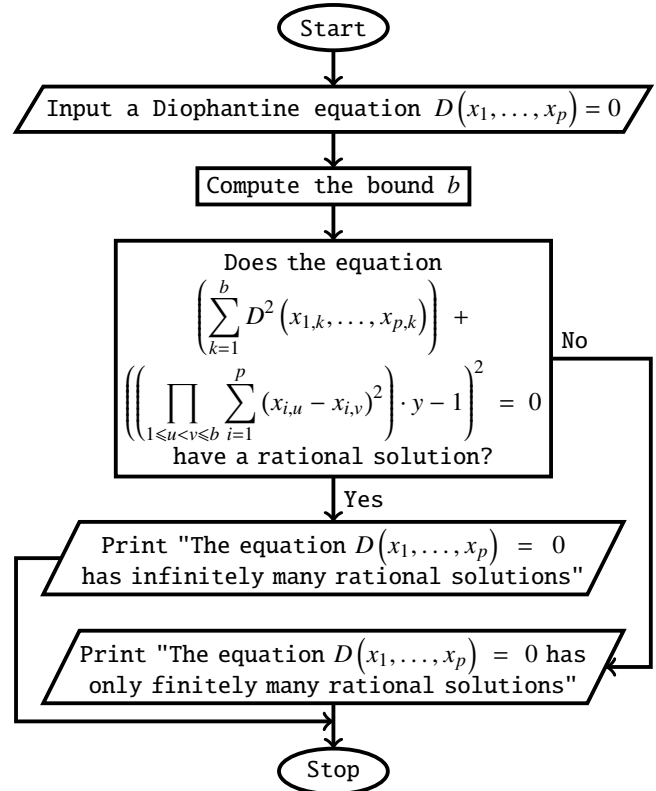

**Conjecture 5.** *There is an algorithm which takes as input a Diophantine equation  $D(x_1, \dots, x_p) = 0$ , returns an integer  $b \geq 2$ , where  $b$  is greater than the number of rational solutions, if the solution set is finite.*

**Guess** ([6, p. 16]). *The question whether or not a given Diophantine equation has only finitely many rational solutions is decidable with an oracle that decides whether or not a given Diophantine equation has a rational solution.*

Originally, Minhyong Kim formulated the Guess as follows: for rational solutions, the finiteness problem is decidable relative to the existence problem. Conjecture 4 and the Guess imply that there is no algorithm which decides whether or not a Diophantine equation has a rational solution. Martin Davis' conjecture in [2, p. 729] implies the same.

**Theorem 9.** *Conjecture 5 implies that the question whether or not a given Diophantine equation has only finitely many rational solutions is decidable by a single query to an oracle that decides whether or not a given Diophantine equation has a rational solution.*

*Proof.* Assuming that Conjecture 5 holds, the execution of Flowchart 4 decides whether or not a Diophantine equation  $D(x_1, \dots, x_p) = 0$  has only finitely many rational solutions.

Flowchart 4: Conjecture 5 implies the Guess

$\square$

**Corollary 6.** *Conjecture 5 implies that the question whether or not a given Diophantine equation has only finitely many rational solutions is decidable by a single query to an oracle that decides whether or not a given Diophantine equation has an integer solution.*

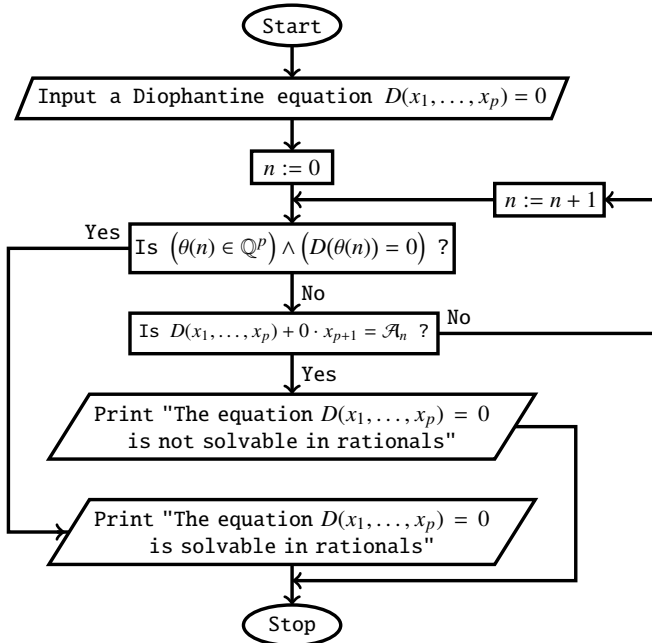

**Lemma 15.** A Diophantine equation  $D(x_1, \dots, x_p) = 0$  has no solutions in rationals (alternatively, non-negative integers)  $x_1, \dots, x_p$  if and only if the equation  $D(x_1, \dots, x_p) + 0 \cdot x_{p+1} = 0$  has only finitely many solutions in rationals (respectively, non-negative integers)  $x_1, \dots, x_{p+1}$ .

**Theorem 10.** If the set of all Diophantine equations which have only finitely many rational solutions is recursively enumerable, then there exists an algorithm which decides whether or not a Diophantine equation has a rational solution.

*Proof.* For a non-negative integer  $n$ , we define

$$\theta(n) = \begin{cases} \eta(n+2) & (\text{if } n+2 \in \Gamma_3) \\ 0 & (\text{if } n+2 \notin \Gamma_3) \end{cases}$$

where  $\eta$  and  $\Gamma_3$  were defined in the proof of Theorem 1. The function  $\theta: \mathbb{N} \rightarrow \bigcup_{n=1}^{\infty} \mathbb{Q}^n$  is computable and surjective. Suppose that  $\{\mathcal{A}_n = 0\}_{n=0}^{\infty}$  is a computable sequence of all Diophantine equations which have only finitely many rational solutions. By Lemma 15, the execution of Flowchart 5 decides whether or not a Diophantine equation  $D(x_1, \dots, x_p) = 0$  has a rational solution.

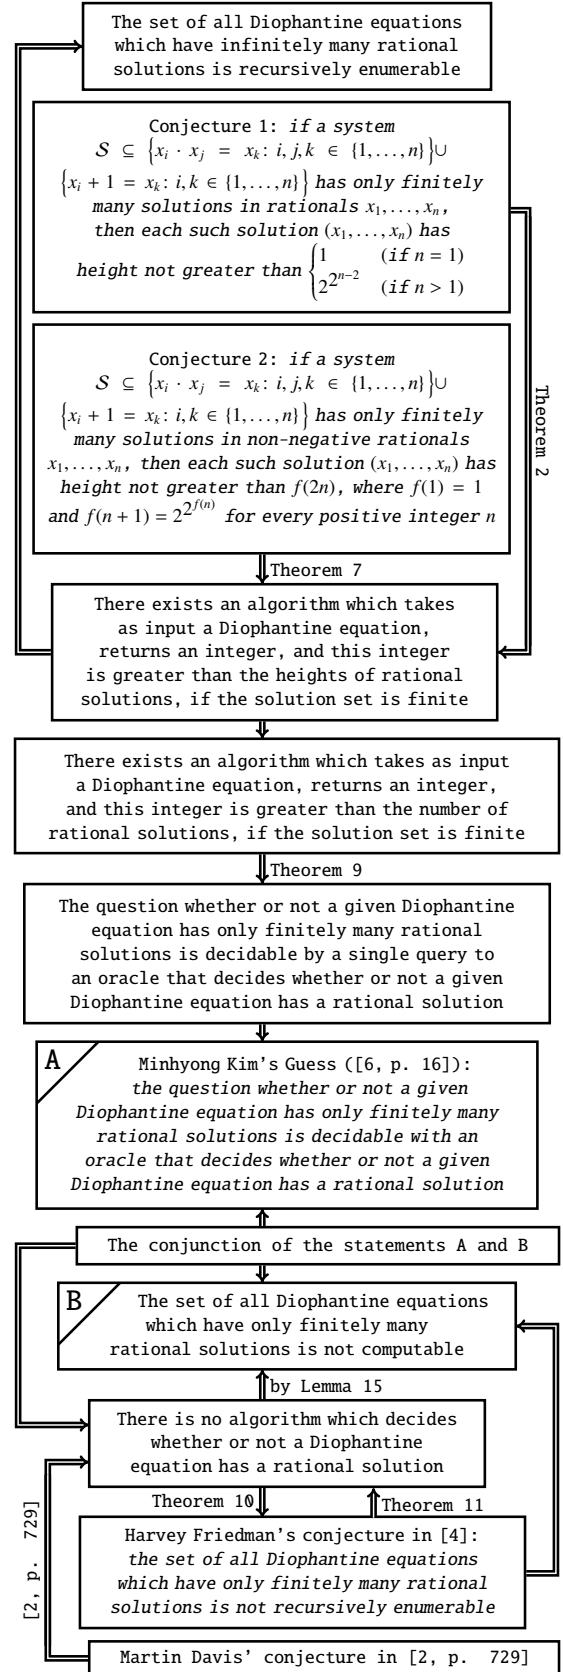

Flowchart 5: An algorithm that decides the solvability of a Diophantine equation  $D(x_1, \dots, x_p) = 0$  in rationals, if the set of all Diophantine equations which have at most finitely many rational solutions is recursively enumerable  $\square$

**Acknowledgement.** Apoloniusz Tyszk a wrote the mathematical part of the article. The other authors prepared computer programs in *MuPAD*.

#### XI. SUMMARY OF THE MAIN THEOREMS AND CONJECTURES

Flowchart 6 provides an overview of the main theorems and conjectures.

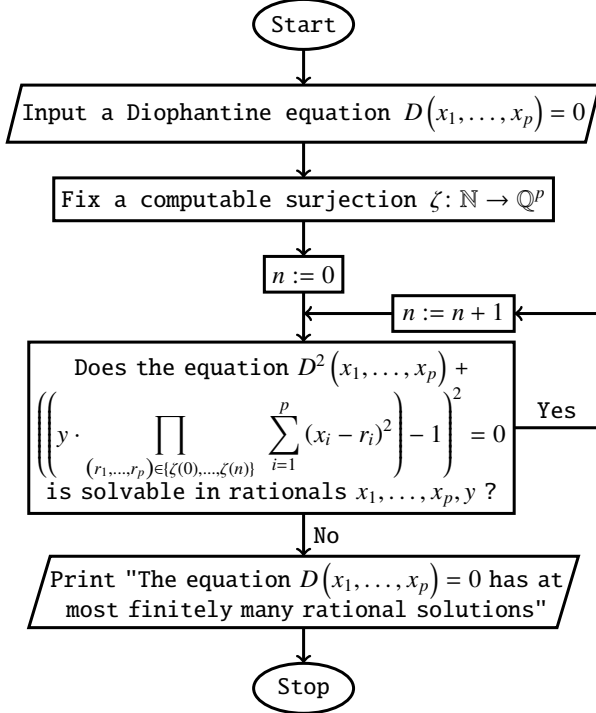

Flowchart 6: Implications between conjectures

## XII. ADDED IN PROOF

**Theorem 11.** *A positive solution to Hilbert's Tenth Problem for  $\mathbb{Q}$  implies that Friedman's conjecture is false.*

*Proof.* Assume a positive solution to Hilbert's Tenth Problem for  $\mathbb{Q}$ . The algorithm presented in Flowchart 7 stops if and only if a Diophantine equation  $D(x_1, \dots, x_p) = 0$  has at most finitely many rational solutions.

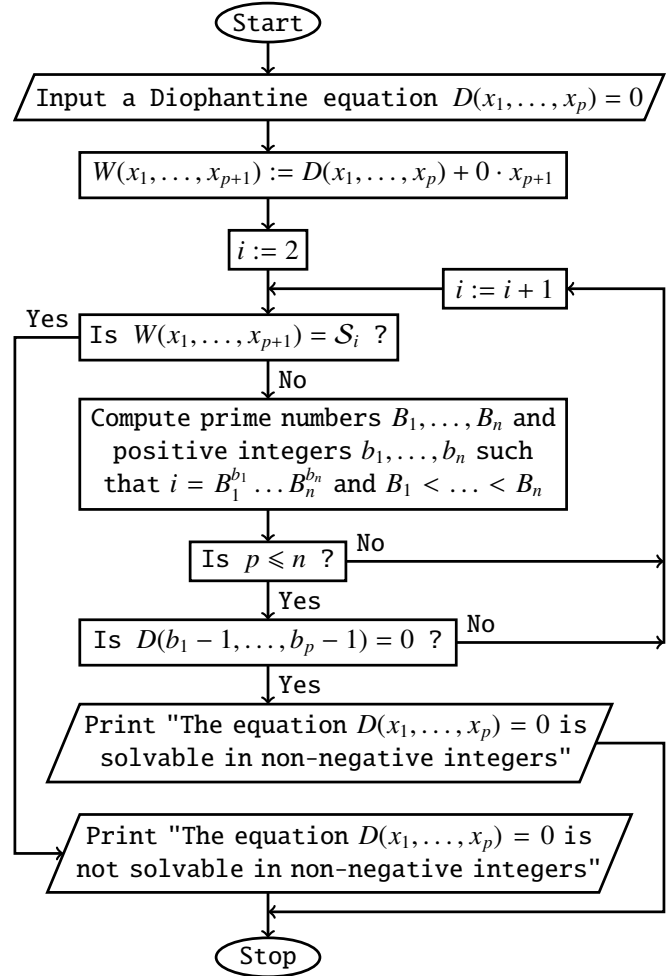

Flowchart 7: A positive solution to Hilbert's Tenth Problem for  $\mathbb{Q}$  implies that Friedman's conjecture is false

□

The set of all Diophantine equations which have at most finitely many solutions in non-negative integers is not recursively enumerable (Smoryński's theorem), see [11, p. 104, Corollary 1].

**Theorem 12.** *If the set of all Diophantine equations which have at most finitely many solutions in non-negative integers is recursively enumerable, then there exists an algorithm which decides whether or not a given Diophantine equation has a solution in non-negative integers. By this and Matiyasevich's theorem, the set of all Diophantine equations which have at most finitely many solutions in non-negative integers is not recursively enumerable.*

*Proof.* Suppose that  $\{S_i = 0\}_{i=2}^\infty$  is a computable sequence of all Diophantine equations which have at most finitely many solutions in non-negative integers. The algorithm presented in Flowchart 8 uses a computable surjection from  $\mathbb{N} \setminus \{0, 1\}$  onto  $\mathbb{N}^p$ . By this and Lemma 15, the execution of Flowchart 8 decides whether or not a Diophantine equation  $D(x_1, \dots, x_p) = 0$  has a solution in non-negative integers.

Flowchart 8: A new proof of Smoryński's theorem

**Abstract**—The issue of decision-making and teleological reasoning of autonomous agents constitutes the current work topic for many researchers. The author of [1] presents a framework allowing for teleological reasoning with the use of values and the possibility of autonomous goal-setting by a device. In this paper we propose to extend this framework by a new manner of representation of the level of value promotion including the required modifications of the reasoning mechanism. The proposed model may become a formal foundation for the realization of the autonomous agent.

## I. INTRODUCTION

A DISTINCTIVE feature of modern technical devices is their increasing self-sufficiency. One may presume that in the future the user will only formulate the most rudimentary rules of how the device works, whereas the everyday aspects of system operation will be regulated completely autonomously. The most advanced types of such devices are e.g. self-driving vehicles, where the user merely sets the journey's destination and the vehicle develops the itinerary on its own and makes hundreds of traffic-related decisions.

In major decision-making models it is usually assumed that the purpose of system operation is to accomplish some state of affairs pre-declared by the user ([2], [3], [4], and many others). Many authors (including [1], [5]) believe, however, that increasingly complex devices must be endowed with the ability to not only find the best possible way to attain the state of affairs set by the user, but also the ability to set their own goals themselves; the model proposed in this paper is based on this assumption.

[1] presents a framework allowing for autonomous (based on values which should be promoted) goal-setting by a device. The model relies on the differentiation between several kinds of goals: abstract (that is, minimal levels to which values should be promoted) and material (that is, particular states of affairs which realize abstract goals).

The objective of this paper consists in proposing for the model from [1] a new method of the representation of the levels to which particular decision options promote various values as well as a modification of the reasoning mechanism

allowing for autonomous setting and realization of goals. The proposed mechanism may serve as a formal foundation for the realization of the autonomous agent. We plan to attain our goal by introducing a numeric representation of the levels of value promotion. Such a method of representation of value levels (for single values as well as for value sets) will facilitate their comparison, leading to easier and quicker (searching orders' sets *O* and *OR* will not be necessary) reasoning. Additionally, for systems in which values are connected with the physical parameters of a device or the environment we propose a basic mechanism for automatic translation of physical units into the levels of promotion of values, allowing the possibility of its development and adjustment to evaluate other values difficult to measure, e.g. the degree of resemblance to the pattern, security level evaluation (such as in [6], [7], [8], [9]), etc. Our model was built on the basis of the framework of teleological reasoning from [1] (further referred to as the GVR model). Due to length limitations, the GVR model will not be presented in the paper. The detailed description and its discussion can be found in [1].

## II. NUMERIC REPRESENTATION OF THE LEVELS OF VALUE PROMOTION BY PARTICULAR SITUATIONS

The underlying objective of this paper is to propose a new semantics for the model described in [1], which would allow for a numeric representation of the levels to which given situations promote various values. This task consists of two main parts: first, a proposal and discussion of the numeric method of representation of the level to which given values are promoted; then the development of the mechanism of determining this level, of determining the cumulative evaluation of value sets, the mechanism of comparing them (equivalents of the *O* and *OR* relations), and discussion of the properties of the proposed semantics.

### A. Numeric representation of levels to which various situations promote particular values

In the model presented in [1] the exemplary level to which a given value (e.g.  $v_i$ ) is promoted by a given situation (e.g.

$x_j$ ) is presented as  $v_i(x_j) \in V(X)$  (without a definition of the kind and range of values which can be taken). The relations between the levels to which a given value ( $v_i$ ) is promoted by situations  $x_1$  and  $x_2$  are regulated by a partial order  $O_i$ . Our model assumes that  $v_i(x_j)$  will be expressed with a number from the range  $\langle 0; 1 \rangle$ , where  $v_i(x_j) = 0$  means that a value  $v_i$  is not promoted by a situation  $x_j$ , a value  $v_i(x_j) = 1$  means that a value  $v_i$  is promoted by  $x_j$  to the maximal possible level, though we assume that the accomplishment of the maximal fulfillment of the value is not possible – the value may be promoted very close to the maximal value, but cannot reach it. Such representation allows us to compare the levels to which the same value is promoted by various situations (order  $O$  will be a total order).

Assuming a numeric representation of the level of promotion of values one cannot miss the fact that not all values are equally important to each user. The simplest solution would be to assign some weight to each value (from the range  $\langle 0; 1 \rangle$ ), though this proposition is a far cry from the way humans reason. In real decision-making, a person does not assign constant weights to various values. In most cases, the weight of a given value depends on the user's preferences, external factors, and the level to which the value is promoted.

*Definition 1 (Function of the weight):* Let  $\Omega_i : v_i(x_j) \rightarrow \langle 0; 1 \rangle$  be a function of the weight referring to a value  $v_i$ . We assume that every function of the weight in the range  $\langle 0; 1 \rangle$  will be a constant and increasing function (this assumption is indispensable for the preservation of the features of the GVR model). For every value  $v_i \in V$  exists maximally one function  $\Omega_i$ . Let  $\Omega$  be a set of weights' functions.

By  $vo_i(x_j) = \Omega_i(v_i(x_j))$  we will denote the level of promotion of a value  $v_i$  by situations  $x_j$  taking into account weight  $\Omega_i$ . A value  $vo_i(x_j)$  will denote the relative level to which a situation  $x_j$  promotes a value  $v_i$ . Let  $VO(x) = \{vo_i(x_j) | vo_i(x_j) = \Omega_i(v_i(x_j)) \wedge v_i(x_j) \in V(X)\}$  be the set of all values  $vo_i$  in all situations.

The most basic kind of function  $\Omega$  is a linear function  $\Omega_i(v_i(x)) = a(v_i(x))$ , where  $a$  is a constant from the range  $\langle 0; 1 \rangle$ ; it is, however, possible to define more complex functions which would better express the relative preferences between values.

### B. Transition from physical values to the evaluation of the promotion level of particular values

The promotion levels of certain values that are considered in the model are measured in various different methods and possess their individual physical representation. This is because, each of them deals with another state of related but diverse events.

*Definition 2 (function  $\Phi$ ):* Let  $\Phi_i : pv_i(x) \rightarrow \langle 0; 1 \rangle$  be a function that normalizes the level of a physical value  $pv_i(x)$  and transforms it into  $v_i(x)$ . Let  $\Phi$  be the set of transformation functions. Our model can make use of several different transformation functions which can be additionally declared, depending on the nature of the values. Whenever we are unsure of how the transformation function should be defined for a

particular case, we can choose the default form which is the following: In order to normalise the physical values we will use the following normalisation function:  $v_i(x) = \Phi_1(pv_i(x)) = (pv_i(x) - \min(pv_i)) / (\max(pv_i) + e_{pv_i} - \min(pv_i))$  where:

- $pv_i$  - is the actual level of the value from the set of physical values  $PV$ .
- $x$  - is the situation that promotes the certain value.
- $\min(pv_i)$  - is the minimal level of the value  $pv_i$ .
- $\max(pv_i)$  - is the maximal level of the value  $pv_i$ .
- $e_{pv_i}$  - is an arbitrarily small positive quantity.

The result of  $\Phi_1(pv_i(x))$  is the level of the corresponding value  $v_i(x)$ . For values where higher levels indicate a worse state we inverse the result of the normalisation function:  $1 - \Phi_1(pv_i(x))$ . The derivative of function  $\Phi_1$  will always produce a positive number.

### C. Cumulative evaluation of the level of promotion of a value set by a given situation

In the model discussed in [1] a given situation may promote various values to various extents. It is represented by set  $V^Z(x_n)$ , where  $V^Z$  is a subset (named  $Z$ ) of value set  $V$ . By  $V^{x_n}$  we denote set of all values promoted by situation  $x_n$ . By  $V^Z(x_n)$  we denote a set of estimations of the levels of promotion of values constituting set  $V^Z$  by a situation  $x_n \in X$ . If  $V^Z = \{v_z, v_t\}$ , then  $V^Z(x_n) = \{v_z(x_n), v_t(x_n)\}$ . The GVR model also introduces the order relation  $OR$  between promotion sets to which various values are promoted by various situations (def. 8 in [1]). Properties of the  $OR$  order are discussed in [1].

Since our model assumes that the grounds for evaluation are relative levels to which particular values are promoted by situations, in our model the correspondent of set  $V(X)$  will be set  $VO(X)$  and its subsets.

For the realization of value-based reasoning to be possible, it is indispensable to define the correspondent of order  $OR$  for the new semantics. Introducing the numeric representation of the level to which a given situation promotes a given value ( $v_i(x_n)$ ) and the weight function  $\Omega$  provides the possibility to develop a mechanism able to determine the cumulative evaluation of the promotion of a value set by a given situation.

Firstly, we assume that the cumulative evaluation of the level to which a given value set will be promoted by a given action will be a number from the range  $\langle 0; 1 \rangle$ , where 0 is interpreted as the minimal level of promotion and 1 is interpreted as the maximal level of promotion (impossible to attain). Such a relation will enable the comparison of various situations, including those which promote different values.

*Definition 3 (function  $\Theta$ ):* Let  $\Theta : VO^Z(x) \rightarrow \langle 0; 1 \rangle$  be a function returning the cumulative evaluation of the level to which a situation  $x$  promotes a value set  $V^Z$ . If:

- $V^Z = \{v_1\}$  then  $\Theta(VO^Z(x)) = vo_1(x)$
- $V^Z = \{v_1, v_2\}$ , then  $\Theta(VO^Z(x)) = vo_1(x) + vo_2(x) - vo_1(x)vo_2(x)$
- $V^Z = \{v_1, v_2, v_3\}$ , then the value returned by function  $\Theta$  is determined in the following manner: first, we

determine  $\Theta(VO^{v_{o1}, v_{o2}}(x))$  for  $V^{v_{o1}, v_{o2}} = \{v_{o1}, v_{o2}\}$ , then we determine  $\Theta(VO^Z(x)) = \Theta(V^{v_{o1}, v_{o2}}(x)) + v_{o3}(x) - \Theta(VO^{v_{o1}, v_{o2}}(x))v_{o3}(x)$

- In case of a higher number of values in set  $V^Z$  the cumulative value  $\Theta(VO^Z(x))$  is determined analogously to the previous case.

Properties of function  $\Theta$ : (1) The value returned by function  $\Theta$  is independent of the order in which particular values from  $V^Z$  are reviewed. (2) Function  $\Theta$  is monotonic (here as monotonic we understand not only its being non-increasing, but also the fact that adding a new value which promotes a given situation increases the cumulative evaluation  $\Theta(VO^Z(x))$ ). As we have already noticed, values must not be treated equally (they are not all equally important), and therefore we proposed a set of weight functions  $\Omega$ . On the basis of that, we assume that in our model the equivalent of order *OR* will be order *ORO*:

**Definition 4 (Value-extent-weight preference):** A total order  $ORO = (\geq; 2^{VO(X)})$  represents a preference relation between various values, their weight functions and various sets of situations. We assume that  $\Theta(VO^Z(x_n)) \geq \Theta(VO^Y(x_m)) \Rightarrow VO^Z(x_n) \geq VO^Y(x_m)$

### III. GOALS

The four kinds of goals defined in [1] remain the same. The only changes are caused by the fact that the level of promotion of values expressed in numbers, and therefore the threshold values: ( $v_n \min(ga)$  and  $v_n \min(gua)$ ) will also be numbers from the range  $(0; 1)$ . These values may be declared directly by the user or determined from function  $\Phi$  and the minimal values of particular physical values declared by the user.

### IV. INFERENCE RULES

The author of [1] introduces a number of the so-called argumentation schemes (in this work they will be treated as defeasible inference rules) allowing for the realization of value-based and teleological reasoning. Due to the length limitations, in this paper we will only present a model of three of them. A full model will be introduced in future works.

Below are presented three mechanisms from [1] which have been adapted to our reasoning model with a numeric representation of the level of value promotion (the names will correspond to the mechanisms from [1]):

**AS2 Generalized practical reasoning:** If in circumstances  $s_m$  performing an action  $a_t$  is preferred to remaining in  $s_m$  and  $as_{t,m} \in AS$ , then an action  $a_t$  should be performed:

$$\frac{\gamma(s_m) = 1 \quad as_{t,m} \in AS \quad VO^{as_{t,m}}(as_{t,m}) \geq VO^{s_m}(s_m)}{\mathcal{E}(as_{t,m})}$$

In the above example, relation  $gg$  from [1] (def. 9) is expressed by means of order *ORO* ( $\geq$ ) which takes into consideration the weight function.

**AS3 Reasoning with abstract goals:** If in the current circumstances  $s_m$  achieving an abstract goal  $ga_k$  is possible by a material goal  $gm_l$  and  $gm_l$  is an action at performed in  $s_m$ , then a goal  $gm_l$  becomes the practical goal  $gp$ :

$$\frac{\gamma(s_m) = 1 \quad gm_l = as_{t,m} \quad sat(gm_l, ga_k)}{gp = gm_l}$$

Interestingly, predicate  $sat(gm_l, ga_k)$  (see: def. ??) requires a determination (for goal  $ga_k$ ) of the minimal levels to which particular vales should be fulfilled  $v_i \min(ga_k)$ .

**AS5 Goal-driven practical reasoning:** In the current circumstances  $s_m$ , in order to achieve the practical goal  $gp$ , an action  $a_t$  should be performed:

$$\frac{\gamma(s_m) = 1 \quad gp = as_{t,m}}{\mathcal{E}(as_{t,m})}$$

### V. ARGUMENTATION FRAMEWORK

Since no argumentation framework on which to build the model has been pre assumed, we have to adapt a simple ad-hoc model from [1]. The model is presented in an informal way, the fully fledged formal model of the argumentation framework will appear in a future works:

- We assume that arguments are constructed on the basis of inference rules.
- There are two kinds of attack: undermining, which is an attack on the premise of the inference rule, and rebuttal, which is an attack on the conclusion of the inference rule.
- An attack on the premise occurs when there exists an argument whose conclusion is the negation of the premise.
- An attack on the conclusion of argument *arg1* occurs if: (1) There exists an argument whose conclusion is the negation of the conclusion of *arg1*, or (2) *arg1* concludes that  $\mathcal{E}(as_{t,m})$  and there exists argument *arg2* which concludes  $\mathcal{E}(as_{z,m})$ , where  $a_t \neq a_z$ , or (3) *arg1* concludes that  $gp = as_{t,m}$  and there exists argument *arg2* which concludes that  $gp = as_{z,m}$ , where  $a_t \neq a_z$ .
- We assume a partial ordering between arguments where if *arg1*  $>$  *arg2*, then it means that *arg1* is stronger than *arg2*.
- We assume that the basic grounds for determining order ( $>$ ) between arguments is the inference rule on the basis of which the argument is constructed. We assume that  $AS5 > AS3$ ,  $AS5 > AS2$ , and  $AS3 > AS2$ , meaning that if arguments *arg1* and *arg2* are in conflict and if *arg1* is built on the basis of  $AS3$  and *arg* is built on the basis of  $AS2$ , then *arg1*  $>$  *arg2*.
- Argument *arg1* defeats argument *arg2* when argument *arg1* undermines argument *arg2* or argument *arg1* rebuts argument *arg2* and *arg1*  $\not>$  *arg2*.
- Reasoning about priorities: we assume that priorities between arguments built on the basis of the same inference rule, depend on values whose application the argument promotes.
  - If both arguments (*arg1* and *arg2*) are built on the basis of inference rule  $AS2$ , argument *arg1* attacks argument *arg2* (or vice versa), the conclusion of

$arg1$  is  $\varepsilon(x_1)$ , the conclusion of  $arg2$  is  $\varepsilon(x_1)$ , and  $\Theta(VO^{x_1}(x_1)) > \Theta(VO^{x_2}(x_2))$ , then  $arg1 > arg2$ .

- If both arguments ( $arg1$  and  $arg2$ ) are built on the basis of inference rule AS3, argument  $arg1$  attacks argument  $arg2$  (or vice versa), the conclusion of  $arg1$  is  $gp = gm_l$ , where  $gm_l = x_1$ , the conclusion of  $arg2$  is  $\varepsilon(x_1)gp = gm_k$ , where  $gm_k = x_2$ , and  $\Theta(VO^{x_1}(x_1)) > \Theta(VO^{x_2}(x_2))$ , then  $arg1 > arg2$ .

- If one of the arguments concludes that  $\varepsilon(as_{t,m})$  and the argument is not defeated, it brings about performing action  $as_{t,m}$ .
- If one of the undefeated arguments concludes that  $\varepsilon(as_{t,m})$ , it results that action  $as_{t,m}$  cannot be performed and  $as_{t,m}$  is excluded from set AS.
- If the argument excluding  $as_{t,m}$  from set AS is defeated, then  $as_{t,m} \in AS$ .
- Argument  $arg1$  is not defeated if it is not attacked by any argument or all arguments which attack  $arg1$  are defeated.

Generally speaking, the argumentation framework used in the example is based on a simplified version of the ASPIC+ argumentation framework [10].

## VI. CONCLUSIONS

The framework included in [1] allows for the modeling of reasoning in autonomous systems. Regretfully, its practical implementation requires a declaration of a large number of orders describing relations between levels to which various situations promote various values and sets of values. With real decision-making problems, the declaration of such a high number of orderings is very challenging and can only be feasible in the case of a situation with relatively small sets of values and actions which are possible to perform. The main objective of our work is to propose modifications of the framework from [1] which would allow a facilitated implementation of the decision-making systems for autonomous agents.

While making a decision, a person intuitively evaluates available decision options, dividing them into better and worse ones (like it was presented in [1] and other works), but does not attach any numeric values to them. This paper introduces a modified approach, where the level to which particular situations promote various values is represented as a number from the range  $(0;1)$ . Though unlike a typical human approach, we believe it is much more natural for all kinds of technical devices. The proper definition of function  $\Phi$  allows for automatic evaluation of not only simple values (like the ones used in the example), but also more complex ones, e.g. degree of resemblance to the pattern (image, sound, etc.) or the level of risk evaluation. The modification we propose allows for a substantial reduction of the number of orderings (declarations of  $O$  and  $OR$  will not be necessary) because the level to which particular values are promoted can be easily compared; moreover, the lack of necessity to search large order sets may significantly accelerate the decision-making process. The proposed mechanism of determining the cumulative evaluation of particular situations (decision options), joined by the weight functions, makes it possible

to compare complex situations promoting various values to various levels.

Further work on the model will proceed in several directions: (1) development of a full argumentation model for our framework, (2) discussion of our model's formal properties (e.g. basing on one of the available proofcheckers [11]), (3) discussion of the issue of decision-making in a legally-regulated environment, including an analysis of various reasoning mechanisms ([12], [13]), conflict resolution ([14], [15]), interpretation ([16], [17]), and other.

# 7<sup>th</sup> International Workshop on Advances in Semantic Information Retrieval

**R**ECENT advances in semantic technologies form a solid basis for a variety of methods and instruments that support multimedia information retrieval, knowledge representation, discovery and analysis. They influence the way and form of representing documents in the memory of computers, approaches to analyze documents, techniques to mine and retrieve knowledge. The abundance of video, voice and speech data also raises new challenging problems to multimedia information retrieval systems.

We believe that our workshop will facilitate discussions of new research results in this area, and will serve as a meeting place for researchers from all over the world. Our aim is to create an atmosphere of friendship and cooperation for everyone, interested in computational linguistics and semantic information retrieval. The ASIR'17 workshop will continue to maintain high standards of quality and organization, set in the previous years. We welcome all the researchers, interested in semantic information retrieval, to join our event.

## TOPICS

The workshop addresses semantic information retrieval theory and important matters, related to practical Web tools. The topics and areas include but not limited to:

- Domain-specific semantic applications.
- Evaluation methodologies for semantic search and retrieval.
- Models for document representation.
- Natural language semantic processing.
- Ontology for semantic information retrieval.
- Ontology alignment, mapping and merging.
- Query interfaces.
- Searching and ranking.
- Semantic multimedia retrieval.
- Visualization of retrieved results.

**Abstract**—Keyword extraction is widely used for information indexing, compressing, summarizing, etc. Existing keyword extraction techniques apply various text-based algorithms and metrics to locate the keywords. At the same time, some types of audio and audiovisual content, e. g. lectures, talks, interviews and other speech-oriented information, allow to perform keyword search by prosodic accents made by a speaker. This paper presents *PitchKeywordExtractor* - an algorithm with its software prototype for prosody-based automatic keyword extraction in speech content. It operates together with a third-party automatic speech recognition system, handles speech prosody by a pitch detection algorithm and locates the keywords using pitch contour cross-correlation with four tone units taken from D. Brazil discourse intonation model.

## I. INTRODUCTION

**K**EYWORDS make the semantic backbone of a text. As keywords reflect the text ideas and convey text meaning they are used for text indexing, analysis, summarizing compression, etc. [1]. In modern world of on-line information abundance automatic keyword extraction techniques are extremely in-demand ([2], [3]).

There is a great number of research in the area of automatic keyword extraction either for individual documents e. g. [4], [5], or large document corpora [6], as well as for specific types of on-line content like e-newspapers [7] or micro-blogs on Twitter [8]. Content-based retrieval research [9] is also highly relied upon the keywords [10].

Some of these techniques use document corpora, while others do not. When a document corpus is used, a function which balances a measure of a keyword within a document (frequency, location or co-occurrence) with a similar measure from the corpus is applied. When corpus is unavailable, keyword extraction techniques use lexical or semantic analysis or keywords co-occurrences over an individual document. An excellent literature review on automatic keyword extraction techniques is presented in [11]. Automatic keyword extraction techniques for text compression and summarizing can be found in [3].

In comparison with text processing techniques specific audio and audio-visual speech content keyword extraction algorithms are less developed. Meladianos et al. [12] report

on a high demand for speech processing from the point of view of information mining. The actual research in this area is usually based on a preliminary audio-to-text conversion by means of automatic speech recognition system (ASR) and further application of content-sensitive text-based techniques (e. g. see Elakiya K. et al. [13] or G. Alharbi [14]).

At the same time, speech content has an inherent powerful feature, namely, speech prosody (i. e. intonation, rhythm, tempo, pausing, etc.) that can help to locate and extract keywords. We use the term "prosody" exactly in the sense of D. Brazil system of discourse intonation (DI) [15], [16], [17] and refer to his tone units to define the prosodic patterns for *PitchKeywordExtractor*. The working hypothesis of the present research is based on concept that keywords being the most informative parts of speech are prosodically highlighted by a speaker, and, therefore, they must have specific discernible prosodic characteristics.

Speech prosody is observable by measuring the fundamental frequency (pitch) and there exist a variety of speech processing tools e. g. see *Praat* or *Visi-Pitch* or *TarsosDSP* [18] to analyse prosodic characteristics as per pitch detection and estimation algorithms [19], [20]. A perfect guideline for special software operation can be found in [21].

There have been much research, discussion and critics on prosody-based methods applicability and limits. Now they go far beyond simple pitch measurement and exist as components for complex analytic frameworks: e. g. see P. Roach [22] or A. Meftah et al. in [23] for prosody-based systems of emotion recognition. A deep insight into the contribution of prosody-based techniques to corpus linguistics was made by M. Warren [24].

On the assumption that automatic keyword extraction can benefit from prosody-based analysis we propose to add processing of prosodic features to automatic keyword extraction algorithms as far as speech content is concerned. We present *PitchKeywordExtractor* - a prosody-based tool for automatic keyword extraction. Operating together with a third-party ASR and speech processing software *PitchKeywordExtractor* searches for keywords in speech content by matching their prosodic characteristics to ASR output text.

## II. METHODOLOGY AND MATERIALS

It is widely recognized that keywords in speech have not only statistically measurable features or occupy a certain sentence position, but are usually highlighted by intonation because they frequently act as speech signals for given and new information [25]. The way to make this tonal emphasis may be different depending upon the context and background of the speakers. For our analysis we have taken 4 tones from the tonal model of discourse intonation developed by D. Brazil [16] which is widely used in linguistics to describe the semantic aspect of speech prosody. This model comprises 5 principle tones of English speech: fall, rise, fall-rise, rise-fall and level. D. Brazil also defines the speech situations when each of these tones occurs.

Fall tone (p-tone) and rise-fall tone (p+-tone) are defined by Brazil as proclaiming tones, so they are used to mark new information introduced by a speaker, therefore, these tones may indicate the keywords entries. Among those the rise-fall tone is defined as "dominant proclaiming" and it highlights not only new, but important information, so it can be a strong keyword entry marker.

At the same time, fall-rise and rise tones are "referring", r-tone and r+-tone respectively. In speech they mark the already known information, i. e. the common ground of the speakers. These tones may also indicate keyword entries.

We consider four model tone units (fall, rise, fall-rise, rise-fall) to be searched for in speech. Strictly speaking, Brazil tones describe phrasal intonation and refer not to one word but to a whole semantic unit, i. e. a syntagm. A tone pattern has complex structure, namely, a pre-head, head, nucleus and tail and refers to a part of a phrase (or to a whole phrase, if it is short); while a keyword can be marked by the nucleus only. However, the entire tone pattern can be located more accurately with correlation, while nucleus is too short to provide a good correlation peak. Thus, we are looking for keywords inside a phrasal tone pattern provided corresponding phrase pitch contour is obtained, compare to model tone units and map it to ASR output to retrieve the keywords.

The architecture of *PitchKeywordExtractor* consists of 4 main parts (see Fig.1):

- 1) Pitch Detector
- 2) Tone Unit Detector
- 3) Speech Recognizer
- 4) Segment-to-word Mapper

### A. Pitch Detector

Pitch Detector obtains pitch series  $s[k]$  for a given speech record. We use a third-party YIN [26] pitch detection algorithm provided with *TarsosDSP* [18].

### B. Tone Unit Detector

Pitch series  $s[k]$  are subsequently processed by Tone Unit Detection Algorithm (see Sec. III for details). The output of Tone Unit Detector is a set of segments (time intervals) where model tone units were found.

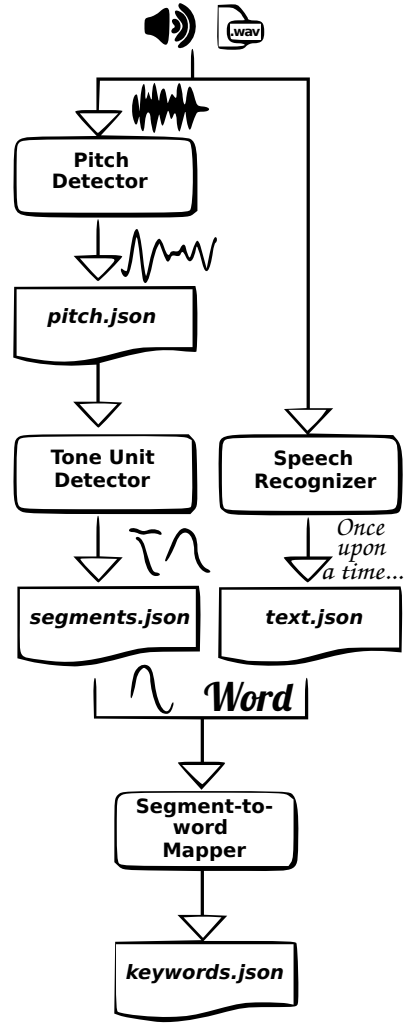

Fig. 1: *PitchKeywordExtractor* Flowchart

### C. Speech Recognizer

Speech Recognizer produces text for a given speech record to create the reference wordlist. Sphinx [27] is used in *PitchKeywordExtractor* prototype by now, while this block may be implemented with any alternative solution for speech recognition.

### D. Segment-to-word Mapper

The segments received from Tone Unit Detector and Speech Recognizer output file are mapped to each other to locate a word within a segment (see Sec.IV for details). Segment-to-word Mapper output is the final keyword list.

## III. TONE UNIT DETECTION ALGORITHM

Tone unit detection is based on the correspondence of a syntagm pitch contour and one or more model tone units.

### A. Preliminary Assumptions

Tone unit detection is performed on evenly distributed pitch series  $s[k]$  obtained as per pitch detection algorithm.

Fig. 2: Model tone units

Let us define 4 discrete-time limited basic functions:  $\phi_w^f(x)$ ,  $\phi_w^{rf}(x)$ ,  $\phi_w^{fr}(x)$ ,  $\phi_w^r(x)$  of  $w$  length,  $w \in [w_{min}, w_{max}]$ , where  $w_{min}$ ,  $w_{max}$  are the empirically chosen syntagm boundaries;  $x \in \mathbb{Z}$ ,  $0 \leq x \leq w$ . These functions correspond to Brazil tone model (see Fig. 2) as follows:

- $\phi_w^f(x)$  – "fall tone" p-tone
- $\phi_w^{rf}(x)$  – "rise-fall" p+-tone
- $\phi_w^{fr}(x)$  – "fall-rise" r-tone
- $\phi_w^r(x)$  – "rise" r+-tone

### B. Pre-Processing

- 1) Median filtering [28] is applied to remove single prominences in  $s[k]$ .
- 2)  $s[k]$  is divided into the datasets  $\{s_j[k]\}$ , bounded by natural pauses in speech (silence).
- 3) Too short datasets  $\{s_j[k]\}$  are not processed as statistically inconsistent.

### C. Processing

The following Algorithm 1 is subsequently applied to all datasets  $\{s_j[k]\}$  and all model tone units  $\phi_w(x)$ . Values of correlation coefficient  $r_\phi(k, w) \in [-1, 1]$  are used to estimate the similarity between the model tone unit  $\phi_w$  and the pitch contour of a segment, which starts at  $k$  and ends at  $k + w$ .  $r_\phi(k, w)$  is calculated only for full-size segments, i. e.  $k$  varies in the range of  $[0, K_j - w]$  that discards the edge issues. Eq.1 shows Algorithm 1 output.

$$\begin{array}{ccc}
 r_\phi(0, w_{min}) & \dots & r_\phi(k - w_{min}, w_{min}) \\
 r_\phi(0, w_{min} + 1) & \dots & r_\phi(k - (w_{min} + 1), w_{min} + 1) \\
 \vdots & \ddots & \vdots \\
 r_\phi(0, w_{max} - 1) & \dots & r_\phi(k - (w_{max} - 1), w_{max} - 1) \\
 r_\phi(0, w_{max}) & \dots & r_\phi(k - w_{max}, w_{max})
 \end{array} \quad (1)$$

### Algorithm 1 Tone Unit Detection (Search)

```

1:  $J \leftarrow \text{NUM\_OF\_DATASETS}(\{s_j[k]\})$ 
2:  $K_j \leftarrow \text{LENGTH}(s_j[k])$ 
3: for all  $0 \leq j \leq J - 1$  do
4:   for all  $w_{min} \leq w \leq w_{max}, w \in \mathbb{Z}$  do
5:     for all  $\phi_w(x) \in \{\phi_w^f, \phi_w^{rf}, \phi_w^{fr}, \phi_w^r\}$  do
6:       for all  $0 \leq k \leq K_j - w$  do
7:          $r_\phi(k, w) = \text{corrcoef}(s_j[k : k + w], \phi_w(0 : w))$ 
8:       end for
9:     end for
10:   end for
11: end for

```

(a) Horizontal overlap

(b) Vertical overlap

(c) Tone unit collision

Fig. 3: Cases for post-processing

Thus, each segment is defined by  $k$ ,  $w$ ,  $\phi_w$ , and  $r_\phi(k, w)$ .

### D. Post-Processing

Post-Processing (see Algorithm 2) is applied to all the segments and comprises 4 steps (see Fig. 3):

- 1) Thresholding
- 2) Resolving horizontal segment overlap for different  $k$  at fixed  $w$
- 3) Resolving vertical segment overlap for different  $w$
- 4) Resolving tone unit collision

The first three steps are applied to each group of segments referring to one tone unit  $\phi_w$ , while the last step is applied only to segments where several tone units were found.

Thresholding checks the statistical significance of correlation. Thresholding parameter,  $Q_{Threshold}$  sets the significance level, e. g. 0.95 or 0.98.

To locate model tone unit accurately  $k$  takes all the integer values in  $[0, K_j - 1]$ . For two neighbour values  $k_1, k_2$  the corresponding  $r_\phi(k_1, w)$ ,  $r_\phi(k_2, w)$  will be very close to each other, because they are calculated over almost identical datasets leading to a significant redundancy of the output data. We call this issue "horizontal overlap". It is resolved now by keeping the only one segment with the largest  $r_\phi(k, w)$

**Algorithm 2** Tone Unit Detection (Post-processing)

---

```

1: for all  $w_{min} \leq w \leq w_{max}$ ,  $w \in \mathbb{Z}$  do
2:   for all  $0 \leq k \leq K_j - w$  do
3:     if  $r_\phi(k, w) \geq Q_{Threshold}$  then
4:        $CREATE\_SEGMENT(tone, k, w, r_\phi)$ 
5:     end if
6:   end for
7: end for
8: for all  $SEGMENTS$  do
9:    $RESOLVE\_HOR\_OVERLAP(SEGMENT)$ 
10: end for
11: for all  $SEGMENTS$  do
12:    $RESOLVE\_VERT\_OVERLAP(SEGMENT)$ 
13: end for
14: for all  $SEGMENTS$  do
15:    $PRIORITIZE(SEGMENT)$ 
16: end for

```

---

for further processing among all the overlapping segments for given  $w$ , which are discarded.

"Vertical overlap", i. e. the overlap of segments with different  $k$  and  $w$ , is also possible. It is resolved in exactly the same manner. Again, only the segment with the largest  $r_\phi(k, w)$  is kept for further processing.

The last step processes tone unit collision, i. e. the overlapping segments which correspond to different model tone units. In this case, the priority is given to "complex" units (p+ and r).

#### IV. SEGMENT-TO-WORD MAPPER

Keyword search is performed by Segment-to-word Mapper, which operates with an ASR output text labelled with the timestamps and Tone Unit Detector output file containing the segments. The goal of Segment-to-word Mapper is to find a word that was pronounced during the given segment; this word is deemed to be a keyword. Partial coincidence between segments and word timestamps is allowed and can be set in Algorithm 3 by ratio parameter. Fig. 4 illustrates a fragment of Segment-to-word mapping results achieved for the online lecture The Great Reversal: The "Rise of Japan" and the "Fall of China" after 1895 as Historical Fables delivered by Benjamin Elman from Harvard University's Fairbank Center for Chinese Studies. Table I shows 35 keywords marked with proclaiming tones (fall and rise-fall) found by Segment-to-word Mapper in a 2-minute piece of lecture. The keywords are sorted in the same order as they are mentioned in the text; keywords given in boldface refer to Fig.4.

#### V. RESULTS AND DISCUSSION

To summarize, an algorithm to process ASR output text for keywords by their prosodic features is presented. The first prototype has custom Tone Unit Detector and Segment-to-word Mapper, it also operates with pitch detection and speech

Fig. 4: Example of Segment-to-word mapping: words "story-line" and "meiji" are deemed to be keywords

**Algorithm 3** Segment-to-word Mapping

---

```

1: for all  $SEGMENTS$  do
2:   for all  $ASR\_WORDS$  do
3:      $MAP(SEGMENT, ASR\_WORD)$ 
4:   end for
5: end for

```

---

recognition performed by third-party tools. As the result, a list of possible keywords is generated.

For our experiments we used a number of audio samples including academic lectures, presentation talks and news recordings. A particularly interesting case is the online lecture of B. Elman mentioned in Section IV and used for segment-to-word mapping evaluation. This use case refers to (not very common but still possible) situations when audio tracks are available with no explicit metadata describing the substance and the internal content of the recorded material. This, apart from obvious applications of the proposed algorithm and related tools, we can also consider solving a problem of mapping the processed recordings to a variety of external resources such as online encyclopedias, historical books, geographical maps, etc. In such a case the process of audio playback (together with prosody-based keyword extraction performed in background) can be enhanced by delivering additional visual and text information retrieved with using the extracted keywords.

#### ACKNOWLEDGMENT

This work is partially supported by the grant 17K00509 of Japan Society for the Promotion of Science (JSPS).

Authors would like to thank Karina Vylegzhanina, for if it was not for her we would not have taken up this research. Our discussions and work together have greatly influenced this paper.

**Abstract**—Semantic web technologies have gained some spotlight in recent years, mostly explained by the spread of mobile devices and broadband Internet access. As once envisioned by Tim Berners-Lee, semantic web technologies have fostered the development of standards that enable, in turn, the emergence of semantic search engines that give users the information they are looking for. This paper presents the results of a systematic literature review that focuses on understanding the proposals on the semantic search engines from an architectural point of view. From the results it is possible to say that most of the studies propose an integral solution for their users where their requirements, the context and the modules that comprise the search engine have a great role to play. Ontologies and knowledge also play an important role in these architectures as they evolve, enabling a great myriad of solutions that respond in a better way to the users' expectations.

**Index Terms**—Semantic web, semantic search engines, ontologies, knowledge, knowledge representation, software architecture, systematic literature review.

## I. INTRODUCTION

SEMANTIC search is one of the hottest fields in recent years that have gained attraction. This is explained because search is one of the most used features in the Internet<sup>1</sup> and it is evolving in ways that can give users more meaningful data than before. We have witnessed the arrival of digital assistants on smartphones, tablets and computers, the presence of suggestions in social media, when buying online or when interacting with other people. These are proofs that what we search for, what our intentions are and how we like this information to be presented are becoming more important every day.

This panorama was envisioned by Tim Berners-Lee in 2001 [1], when the web was different and was starting to evolve from static contents to dynamic ones. Since then the Word

Wide Web Consortium (W3C) has developed a myriad of standards in order to make that vision a reality. Several researches have been and are being carried out which demonstrate that semantics can be applied to search so that computer systems can understand the intentions, meanings and purpose of what the users want, and deliver the results they expect.

Nowadays we can see how search engines have improved their algorithms to make search results closer and useful to what users want to find. Google's Hummingbird algorithm, for instance, was developed to deal with the new needs of search, understanding the words typed by the user and returning meaningful results<sup>2</sup>. This kind of optimizations are also implemented in other search engines and products (e.g. Microsoft's Bing and Cortana digital assistant), and even traditional relational databases like SQL Server have some sort of semantic search capabilities built-in<sup>3</sup>.

In the light of this current situation, it is important to understand how these applications are built, how they connect each other, and how they work to deliver what users are looking for. That is the main motivation for this research: to know and understand the architectures of these semantic search engines, how they look like and how they are changing our present.

This paper is organized as follows. Section II presents the literature review methodology. Section III presents the identification of the need for this study. Section IV presents the review protocol that this study followed. Section V presents the results obtained after the execution of the review protocol. Section VI discusses the findings of this study in order to give answer to the research questions. Finally, in section VII the conclusions and future work are discussed.

## II. METHODOLOGY

A systematic literature review is conducted as the methodology for this research to obtain the evidence needed to understand how the architectures of semantic search engines are formulated and how they work, which is the main objective of this research. As mentioned by Kitchenham in [2], "a systematic literature review (often referred to as a systematic review) is a means of identifying, evaluating and interpreting all available research relevant to a particular research question, or topic area, or phenomenon of interest".

A systematic literature review has three main stages: planning the review, conducting the review and reporting the review [2]. There are several activities inside of those phases that involve iteration, especially those regarding the developing of the review protocol in the planning phase, or when conducting the review [2].

### III. IDENTIFICATION OF THE NEED FOR A REVIEW

As stated in the introduction of this research, the main purpose is to identify how the architectures of semantic search engines have been and are being proposed and, as a result, a background will be constructed to summarize existing knowledge in this field and future research activities can be suggested [2].

There were no previous researches in the architecture of semantic search engines, as it is presented in subsection IV-B1. Therefore, the need to carry out this research was justified.

### IV. REVIEW PROTOCOL

One of the most important steps in any systematic literature review is the development of the review protocol. This protocol specifies the context of the review, the research questions, the criteria to use in the study selection, the quality assessment of the studies, the data extraction strategy, as well as the strategy to use when reporting the results.

#### A. Research questions

The research questions are subject to change while the review protocol is being developed [2]. As a result, the following questions went through several changes during the development of this systematic review. These research questions cover the main point of interest: to understand how a semantic search engine works and what the main building blocks are that allow them to work. With this in mind, the research questions are as follows:

- RQ1: What modules of the architecture of a semantic search engine are the most used across implementations?
- RQ2: What are the evaluation methods for validating and/or verifying the architecture of a semantic search engine?
- RQ3: What are requirements that an architecture of a semantic search engine needs to comply with?
- RQ4: What role do ontologies play in the architecture of a semantic search engine?
- RQ5: What role does knowledge play in the architecture of a semantic search engine?

TABLE I  
KEYWORDS IDENTIFIED FROM RESEARCH QUESTIONS

<b>RQ1</b>	module, architecture, semantic search engine, implementation
<b>RQ2</b>	evaluation, method, validation, verification, architecture, semantic search engine
<b>RQ3</b>	requirement, architecture, semantic search engine
<b>RQ4</b>	role, ontology, architecture, semantic search engine
<b>RQ5</b>	role, knowledge, architecture, semantic search engine

#### B. Search strategy

First a preliminary search was carried out, its purpose and results are presented here. Then the search terms are listed, as well as the query strings to be used. The search resources and the search process are explained afterwards. Finally, the search process documentation is mentioned.

1) *Preliminary search*: The preliminary search was carried out in Scopus to identify what the current studies looked like, what subjects they were talking about, and if there was any new point of interest that can be added to the research. The search string was as follows: *TITLE-ABS-KEY (architecture) AND TITLE-ABS-KEY("semantic search")*. This search was carried out on June 8th 2016, and 219 articles were found.

The first 100 articles, ordered by publication year, were picked. From these 100 articles, 55 of them were found to be related to the main subject of this study, whereas 36 were somewhat related. The other 9 articles were not related to the main subject at all. In order to classify the articles as related, somewhat related or not related, titles, abstracts and keywords were analyzed and compared to the main subject and the research questions presented in subsection IV-A.

From those 55 articles found to be related to the main subject of this study, the following concepts were found to be mentioned constantly in their abstracts and were added to the research questions:

- Ontologies, either as part of the architecture of a semantic search engine or as the core of the proposed engine. 23 articles were found to be related to ontologies.
- Knowledge, either as part of the architecture as a knowledge base or as a knowledge technique to be used in the proposed semantic search engine. 25 articles were found to be related to this concept.

2) *Deriving search terms*: As a first step, the search terms are derived from the research questions. In table I the main keywords are listed per each question.

In table II the synonyms for the keywords found in table I are presented. These synonyms were taken from the Thesaurus of the Oxford Dictionaries <sup>4</sup>. There were also words that were added because they were related to the first keywords - these words were identified in the exploratory search that was explained in subsection IV-B1.

<sup>4</sup>Thesaurus of the Oxford Dictionaries: <http://www.oxforddictionaries.com/thesaurus/>. [Online; accessed 6-July-2016]

TABLE II  
SYNONYMS AND RELATED WORDS IDENTIFIED FOR KEYWORDS IN TABLE I

<b>module</b>	layer, component
<b>evaluation</b>	assessment, appraisal
<b>method</b>	procedure, technique, approach
<b>architecture</b>	system architecture
<b>semantic search engine</b>	semantic search system, semantic search platform, semantic search tool
<b>implementation</b>	implantation, application, approach
<b>requirement</b>	need, requisite

TABLE III  
EXPRESSIONS TO USE FOR QUERIES

<b>RQ1</b>	(module OR layer OR component) AND (architecture OR system architecture) AND (semantic search AND (engine OR system OR platform OR tool)) AND (implementation OR application OR approach)
<b>RQ2</b>	(evaluation OR assessment OR appraisal) AND (method OR procedure OR technique OR approach) AND (validation OR verification) AND (architecture OR system architecture) AND (semantic search AND (engine OR system OR platform OR tool))
<b>RQ3</b>	(requirement OR need OR requisite) AND (architecture OR system architecture) AND (semantic search AND (engine OR system OR platform OR tool))
<b>RQ4</b>	role AND ontology AND (architecture OR system architecture) AND (semantic search AND (engine OR system OR platform OR tool))
<b>RQ5</b>	role AND knowledge AND (architecture OR system architecture) AND (semantic search AND (engine OR system OR platform OR tool))

The expressions to use for querying the studies per each question are as stated in table III. These expressions were then customized according to the syntax of each search resource.

3) *Search resources*: The sources that are used for this research are the following: ACM Digital Library, IEEE Xplore, Scopus and ScienceDirect, as they have a broad set of articles in the computer science field.

4) *Search process*: Firstly, an initial, preliminary search was carried out in order to identify potential new terms that can enrich the keywords derived from the research questions. This also allows the identification of any new research question that can be of interest. This was presented and discussed in subsection IV-B1.

After that, a primary search phase is proposed to filter the articles found in the search resources. For this phase, duplicate articles are identified, and the inclusion and exclusion criteria are applied to the studies. These criteria will be applied to the title, abstract and keywords of each study. The criteria to be used for this phase are presented in subsection IV-C1. In case of ambiguity, the full text of the article is retrieved.

Lastly, a secondary search phase is proposed in order to identify the final articles that can answer the research questions. The full text of each article will be retrieved, the quality assessment criteria will be checked again, applying the inclusion/exclusion criteria as well as the quality assessment

checklist presented in subsection IV-C2, paying special attention to the introduction, the architecture modules if applied, and the conclusions of each study. After this phase, the final articles will have been identified, ready to answer the research questions.

### C. Study quality assessment criteria

The intention behind assessing study quality is to identify the primary studies that provide direct evidence about the research questions [2]. This quality assessment will be carried out to determine the relevance and identify reliable evidence of the selected studies to answer those questions.

In that way, the inclusion and exclusion criteria are presented in this section, as well as the quality assessment checklist to be used when selecting the studies in the search process. If the quality of a study does not satisfy the quality assessment criteria, it will be removed from the analysis given its weak evidence.

1) *Inclusion/exclusion criteria for study selection*: The inclusion and exclusion criteria, which can be refined during the search process, are defined in the systematic review protocol to minimize the bias effect that is likely to appear while conducting the review. For a study to be included in the systematic review, it will have to satisfy the first condition, and either the second, third or fourth conditions. In the case of studies for research questions 4 and 5, either the fifth or sixth condition must be fulfilled:

- 1) The study must be written in English.
- 2) The study proposes an architecture for a semantic search engine as a solution for a problem.
- 3) The study discusses about an architecture for a semantic search engine either in a conceptual or implemented way.
- 4) The study explains in greater or lesser detail the layers or modules the architecture includes.
- 5) In the case of a study that needs to answer RQ4, the study must provide an explanation of the role of the ontology within the architecture.
- 6) In the case of a study that needs to answer RQ5, the study must provide an explanation of the role of knowledge within the architecture.

The following exclusion criteria is meant to identify those studies that will not be included in the systematic review:

- 1) Those that do not focus on proposing an architecture of a semantic search engine, or where the semantic search engine is not the main subject in the study.
- 2) Those that do not include an explanation of the layers or modules that the architecture of a semantic search engine should have.
- 3) Those that are either books, conference proceedings, or secondary or tertiary studies.

2) *Quality assessment checklist*: Checklists are a way to assess the quality of the studies and therefore their importance as evidence to answer the research questions. They are also useful in order to decrease the effect of bias when reviewing

the studies [3]. Note that this assessment is in terms of relevance of evidence to answer the research questions and not to criticize the work of any researcher [3].

The questions for the following checklist are based on the ones presented in Zarour et al. [4] for their systematic review. Those were rephrased according to the needs of this research.

- QA1: Is the main subject of the study well defined?
- QA2: Is the presented architecture in the study clearly explained?
- QA3: Is the context where the study was carried out well described?
- QA4: Are the presented conclusions clearly stated?

QA1 is stated like this to identify whether the aims of the study are clearly defined. In QA2, the architecture of the semantic search engine explained by the study is analyzed to determine whether its purpose and components are presented clearly. QA3 is concerned with the background where the semantic search engine is working, so the architecture makes sense to the problem or situation that tries to solve or improve. Finally, QA4 considers the previous answers so the conclusions of the study are presented clearly and in line with the architecture and its context. Future work is also taken into account.

Each of the questions given in the checklist will be answered according to the following scale: Yes (1), No (0), Partially (0.5). In order to select a study, it needs to have a score greater than or equal to 3. This checklist will be applied to the results obtained after the primary search is carried out.

It is worth mentioning that the third question proposed by Zarour et al. about the threats to validity was not included because, from the preliminary search carried out before, there was no evidence of experimental or quantitative studies.

#### D. Data extraction strategy

After the primary studies have been selected and their quality assessed, the data will be extracted. The data extraction forms and the strategy to be adopted for recording the data are given in the sections below.

1) *Data extraction form*: Data extraction forms are meant to contain all the information that is necessary for answering the review questions and addressing the study quality criteria. The data extraction form for this systematic review is presented in table IV.

2) *Data extraction procedures*: In order to have a centralized storage for the execution of the review protocol and the extracted articles, a specialized software for systematic reviews was used. The name of this tool is StArt (State of the Art through Systematic Review), developed and maintained by the Laboratory of Research on Software Engineering (LaPES) that belongs to the Computing Department of the Federal University of São Carlos (DC/UFSCar) in Brazil<sup>5</sup>. It allows the management of the steps needed for carrying out a systematic review, giving a great support when executing the review protocol and searching for the articles.

<sup>5</sup>StArt (State of the Art through Systematic Review), available at: [http://lapes.dc.ufscar.br/tools/start\\_tool/](http://lapes.dc.ufscar.br/tools/start_tool/)

TABLE IV  
DATA EXTRACTION FORM

Field	Description	RQ
Id	Sequential number	General
Extraction date		General
Authors		General
Title		General
Study type	Journal article or a conference article	General
Search resource name	Name of the search resource where the study was found	General
Publication year		General
Institution	Researchers' institution or institutions	General
Country		General
Problem to be solved	Brief description of the main problem the architecture tries to solve	General
Architecture type	Whether is conceptual or concrete	General
Application field	Field where the architecture has been applied, or if it is a general purpose architecture	General
Architecture's modules	List of modules that the architecture is comprised	RQ1
Architecture's patterns applied	List of any pattern that the architecture applies	RQ1
Verification method	List of any methods used to verify the architecture	RQ2
Validation method	List of any methods used to validate the architecture	RQ2
Requirements	List of requirements the architecture fulfills	RQ3
Ontologies used	List of ontologies the architecture is using	RQ4
Ontology role	Brief description of the role the ontologies play within the architecture	RQ4
Knowledge role	Brief description of the role that knowledge plays within the architecture	RQ5

StArt allows the management of the articles found when retrieving them from the search resources. The review protocol is entered in this tool, including the inclusion and exclusion criteria, quality assessment checklist and the data extraction form fields provided in subsection IV-D1. With this information, and after the primary phase of the research is accomplished, the selected studies will be identified in the tool so that the secondary search phase can be carried out.

For the secondary search phase, the selected studies from the primary search phase are exported from StArt to an Excel file for further revision. As stated in subsection IV-B4, in this phase the inclusion/exclusion criteria and the quality assessment are applied, completing the respective columns in the Excel file. The resulting studies then will be used for answering the research questions. This way the data collected

TABLE V  
NUMBER OF STUDIES FOUND PER RESEARCH QUESTION AND DIGITAL SOURCE

Research question	ACM	IEEE	Scopus	Science Direct	Total
RQ1	3	5	24	4	36
RQ2	2	0	0	0	2
RQ3	11	22	48	3	84
RQ4	2	5	8	0	15
RQ5	0	2	8	0	10
Total	18	34	88	7	147

from the studies is consolidated in one place, gathering both the extraction form questions and the quality assessment checklist questions.

## V. EXECUTION

As mentioned in subsection IV-B4 about the search process, the first search phase comprises the identification of duplicates, as well as determine whether the articles found using the search queries presented in subsection IV-B2 can fulfill the inclusion and exclusion criteria. In this section, the documentation of the search process is presented, as well as any incidence or change that came up when executing the review protocol.

### A. Searches in the search resources

The searches in each of the search resources were carried out from September 17th to October 4th. The years covered by the searches were from 2002 to 2016. In table V the number of studies per each search resource and per each research question is listed. These studies were the input to start the primary search.

147 studies were found in the search resources. The results obtained were exported in the BibTeX format, taking special attention to the authors, title, abstract and keywords fields when exporting the results. Other data, such as journal title or country, were selected if available in the search resource.

### B. Primary search

In this phase, the studies found from the search resources are filtered based on the inclusion and exclusion criteria detailed in subsection IV-C1.

After being obtained from the search resources, the BibTeX files were imported into StArt and grouped by search resource. When a BibTeX file is imported, each of the studies specified in the file are analyzed by StArt in order to identify possible duplicates. Each duplicate found is then highlighted in blue across all of the previous results already imported in StArt. It is also possible to specify duplicates manually. This option was used after all BibTeX files were imported, ordered by title. 54 studies were found to be duplicates.

The next step after identifying duplicates was to read carefully the title, abstract and keywords of each of the studies, and apply the inclusion and exclusion criteria. This step took a while to accomplish because of the number of studies

TABLE VI  
SUMMARY OF THE PRIMARY SEARCH

Search resource	Duplicates	Rejected	Accepted	Total found
ACM	5	9	4	18
IEEE	8	7	19	34
ScienceDirect	6	1	0	7
Scopus	35	26	27	88
Total	54	43	50	147

TABLE VII  
SUMMARY OF THE SECONDARY SEARCH

Search resource	Accepted	Rejected	Unavailable	Total
ACM	3	1		4
IEEE	10	9		19
Scopus	16	5	6	27
Total	29	15	6	50

considered for the systematic review. 43 articles were rejected after applying the selection criteria. Table VI summarizes the previous steps.

### C. Secondary search

In this phase, the studies selected from the primary search phase are filtered out using the inclusion and exclusion criteria detailed in subsection IV-C1 and applying the quality assessment checklist presented on subsection IV-C2. This phase also helped modify the data extraction form fields in order to add or update them accordingly to any new point of interest that can help answer the research questions.

The 50 accepted studies found in the primary search, along with the duplicated and rejected studies, were exported to the Microsoft Excel format from StArt to continue with the secondary search phase. The duplicated studies were used to help identify the research question those studies had assigned, so that the selected studies can answer those research questions as well.

This phase took long to complete, starting from November 23rd 2016 to January 22nd 2017. This is because each study was reviewed thoroughly. Some studies were not available when this phase started until the authors kindly answered back with the full text of their studies after contacting them via email. Some authors were not available to contact and, as a result, their studies were not considered as part of this research. The results of this phase are presented in table VII.

The studies accepted after concluding the secondary search are presented in next list. Each study is presented with the research questions it needs to answer.

- [5], [6], [7], [8], [9] for answering RQ1 only
- [10], [11], [12] for answering RQ1, RQ3
- [13] for answering RQ1, RQ3, RQ4
- [14] for answering RQ1, RQ4
- [15] [16], [17], [18], [19], [20], [21], [22], [23], [24], [25], [26], [27] for answering RQ3 only

TABLE VIII  
QUALITY ASSESSMENT CHECKLIST RESULTS

Id	Quality question	Yes	No	Partially
QA1	Is the main subject of the research well defined?	29	0	0
QA2	Is the presented architecture in the study clearly explained?	21	0	8
QA3	Is the context where the study was carried out well described?	22	0	7
QA4	Are the presented conclusions clearly stated?	18	0	11

- [28] for answering RQ3, RQ4, RQ5
- [29] for answering RQ4 only
- [30] [31], [32] for answering RQ4, RQ5
- [33] for answering RQ5 only

## VI. SYNTHESIS AND ANALYSIS OF DATA

The following subsections present the most relevant data obtained from the selected studies. First, the general facts are analyzed, and then the research questions are answered.

### A. General facts from selected studies

1) *Quality assessment checklist results*: The quality assessment checklist results are presented in table VIII. These show that the main subject of each study was found to be clearly stated. The second question tries to identified if the architecture was clearly presented and explained in the study; in this case, 8 studies were found to have gaps while explaining the architecture of the semantic search engine, or whether the architecture's modules were not explained thoroughly.

Third quality question checks whether the context is clearly presented and described, so that the semantic search engine can be a solution or propose a solution to resolve the problem identified. 7 studies were found that gave some light on the context for their architecture proposal, without making a deeply explanation of it. For the last quality question, it can be seen that a high number of studies presented not so well defined conclusions, mostly due to simple or obvious statements, mentioning previous concepts or lacking future works recommendations.

2) *Application fields and problems to be solved*: From the semantic search engines revised it was found that:

- 7 studies propose general purpose engines, that is, that can be applied to any field: [5], [6], [23], [19], [18], [24], [31].
- 3 studies propose solutions for digital documents: [15], [16], [22].
- 2 for medicine: [26], [28].
- 1 study for each of the following fields: military [7], distance education [8], multimedia content [9], biology [10], biomechanics [11], audiovisual content repositories [12], source code control systems [13], culture [14], education [17], web services [21], reporting [20], Russian

museums [27], environment [25], transport services [29], academic library [30], innovation processes [32], and government to government cooperation [33].

Regarding the problems to be solved by the proposed semantic search engines, it can be mentioned, as the application fields, they are diverse in nature and they could not be categorized without discarding important details from them. However, most of the studies try to propose a solution for a previous unresolved problem, to propose a new alternative for users, or to improve search results.

3) *Architecture types*: The architecture type field is intended to identify whether the proposed architecture is conceptual or concrete. The former refers to the studies that formulates an architecture without implementing the actual semantic search engine whereas the latter refers to actual search engines implemented following the proposed architecture. From the results obtained, it can be mentioned that 21 studies proposed a concrete semantic search engine. The other 8 studies proposed a conceptual semantic search engine.

### B. Answering research questions

In the next subsections the research questions are answered, as well as some discussing is added where needed. The fields used in the data extraction form, presented in table IV, are explained better, according to the results obtained during the secondary search phase.

1) *RQ1: Modules most used by semantic search engines implementations*: The aim of this research question is to identify what modules are the most used in the proposed architectures of semantic search engines. Although the word "implementations" can be understood as something that needs to be built or constructed, for this research is also covering conceptual architectures.

For this question, two fields were proposed in order to retrieve the data from the studies:

- Architecture's modules**: this field aims to get the list of modules, components or tiers that the architecture has. If the study has an explanation of what the module is about, that is also taken into account.
- Architecture's patterns applied**: this field aims to identify what architectural patterns are presented in the proposed architecture.

There are 10 studies found to answer this question. There are several modules identified that are common across the proposed architectures. These are listed as follows, highlighting the most relevant studies on each module found:

- **Extractor components**, such as crawlers used by [9] and [11], or extraction systems in [6], which navigates within raw data and store it for further processing. These can also make some sort of filtering, based on system's needs or requirements [13].
- **Storage support**, such as a database used by [9] and [8], an indexer used in [13] and [7], or tables as mentioned by [5], that can store the data and knowledge of the system. These storage elements are related to other key components, such as ontologies.

- **Reasoning components**, for example ontologies or inference engines. These are responsible for generating the answers based on the user queries and the knowledge stored in the systems. As it can be seen, usually the ontologies are customized for the field or domain where they will be applied (e.g. [10] and [14]). It is worth mentioning the work of Çelik et al. [8] where inference rules based on ontologies are proposed for the reasoning component of their semantic search engine for a Learning Management System (LMS).
- **User interfaces**, usually as web forms (e.g. [8]) where users formulate their search query. It is worth noticing the case of [14], which proposes a guided user interface, whereas others are plug-ins that need to be installed in another application in order to be available to the user [13].

In the case of the architecture patterns identified, the majority of the studies reported that a multitier (N tier) architecture was applied in the proposed solution. This leads to design the modules as layers that are loosely coupled, customized for a specific functionality. There are two specialized cases: in [5] a peer-to-peer design is proposed because of the distributed nature of the engine, where each node has its indexer and processes documents that are available for other nodes through web services. In [13], a client application (i.e. a plug-in for a developer's integrated development environment - IDE) is designed to be used by users, which displays the search results (mainly source code files).

2) *RQ2: Evaluation methods for validating and/or verifying the architecture of a semantic search engine:* The aim of this research question is to identify what evaluation methods exist for validating and verifying an architecture. In this case, validation is related to whether the system fulfills its requirements; verification is related to whether the system was developed right [34].

For this question, two fields were proposed in order to retrieve the data from the studies:

- a **Verification method**: this field aims to get any verification method proposed by the study.
- b **Validation method**: this field aims to get any validation method proposed by the study.

For this research question unfortunately there was no study found that fulfilled the search criteria and the quality assessment checklist. Even though there was no study identified, it can be said that not finding studies for this research question constitutes an opportunity for a future work. This is discussed further in the conclusions.

3) *RQ3: Requirements an architecture of a semantic search engine complies with:* The aim of this research question is to identify what kind of requirements an architecture needs to comply with. Although requirements are closed to the field or domain where the semantic search engine is working, the purpose of this research question is to identify any common underlying requirement that an architecture of a semantic search engine needs to fulfill independent of that field or domain.

For this question, one field was proposed in order to retrieve the data from the studies:

- a **Requirements**: this field aims to get the list of requirements that the architecture of a semantic search engines needs to comply with. The requirements or needs were identified from the study, whether they were explicitly or implicitly mentioned.

This field is meant to gather both functional and non-functional requirements. This was done this way in order to understand the requirements in their context, and taking into account that usually requirements are not classified and presented in these two categories. That implied to read the full text of the selected studies thoroughly.

There are 18 studies found to answer this question. The following is a set of common requirements identified from those studies:

- a **Precision on results**, mentioned by [13], [15], [10], [16], and in some way it is also mentioned by [21], [11], [23], [24]. This requirement is related to find the most relevant results based on the user's search query. The purpose of the semantic search is to improve results based on the user's intention and the context of the search query, so it does not come as a surprise that an architecture of a semantic search engine must have precision on results as one of its requirements.
- b **Existence and maintenance of ontologies**, mentioned by [13], [16]. Although this is explicitly mentioned by few articles, it has a great impact because of the important role that ontologies play in an architecture (as it is described in subsection VI-B4). Almost all selected studies rely on ontologies to make the search engine work. Ontologies are the base to learn new concepts, share knowledge and make possible that search agents can retrieve information even when new concepts were not previously defined [35].
- c **Usability**, mentioned by [13], [17], [23], [27]. This is concerned with how user-friendly users find the search engine, how easy it is to use and if it is accessible through common ways, such as smartphones and tablets. In the case of [27], richer representation takes a special meaning because of data the search engines needs to display, i.e. Russian museum art collections.
- d **Evolution of knowledge base as new documents appears**, mentioned by [15], [16]. This is pretty close to the previous ontology-related requirement, as knowledge and ontologies are related. In this case, a knowledge base needs to accept new concepts as new information becomes available. In the case of [12], it is even proposed that the system should be able to cover various domain models.
- e **Handle structured, unstructured and heterogeneous data sources**, mentioned by [15], [10], [16], [25], [26], [27]. This requirement is related to the diverse sources a semantic search needs to deal with. As shown in the work of Fernandez et al. [36], heterogeneous sources,

heterogeneous knowledge bases and heterogeneous ontologies can help getting answers for natural language queries, which are used in [26]. For structured and unstructured data, such as what we can find in the Web, crawlers and annotation mechanisms help coping with those, so semantic search can be done on those kinds of data [36].

- f **Use of ontologies for suggesting or guiding the user search**, mentioned by [28], [18], [19], [11], [22], [23], [24]. This requirement is about having the help of ontologies while the user writes his/her query. This help can be presented as suggestions of additional or related terms [19], or it can use user's preferences in order to retrieve relevant results, as proposed by [24] or [18].
- g **Use of natural language**, mentioned by [20], [21], [26]. This requirement is related to the usage of natural language queries that can express users' intentions in a much freer way. This implies that the search engine needs to process and translate the user's query properly, using techniques such as word-sense disambiguation. Then the query can be consumed by the domain ontologies so a match can be found against the knowledge base.
- h **Handle large amount of data**, mentioned by [26]. This requirement, although mentioned by one study, is worth to be pointed out because new search engines will need to have a broader action range, such as in the Internet of Things as proposed in the work of Wang et al. [37]. However, the search engine proposed by Słezak et al. is oriented to the biomedical literature field, which is small when compared to other broader Internet-based solutions.

It is worth mentioning that, although is not stated literally on the previous requirements identified from the studies, for [12] having a decoupled system is important, as it keeps the engine core independent from the data and knowledge layers.

4) *RQ4: The role of ontologies in the architecture of a semantic search engine*: The aim of this research question is to identify what role ontologies play within the architecture of a semantic search engine. As it was seen in RQ1 and RQ3, ontologies have a strong presence in the proposed architectures. With this research question, what is sought is to unveil the functionalities ontologies perform.

For this question, two fields were proposed in order to retrieve the data from the studies:

- a **Ontologies used**: this field aims to identify what kind of ontologies are proposed in the study.
- b **Ontology role**: this field aims to get any description of the role that the ontologies perform within the proposed architecture.

There are 7 studies found to answer this question. The ontologies used and the ontology roles identified are as follows:

- a **Domain ontologies are mostly used**, which seems to be a pattern across architectures. That is an expected scenario because a domain ontology can give specialized

results and further customization, satisfying users' need in a better way. Even those that make use of general purpose ontologies (e.g. WordNet), as mentioned by Kerschberg et al. [31], at the end they resort to use domain ontologies in order to represent better user concepts, or to represent several domains within the same engine, as mentioned by [14].

- b **Ontology roles are diverse**, but most of the selected architecture use them as a way to classify and express relationships among key concepts - that is the case of [29], [28], [31] and [32]. Two cases are special: in [13], Durão et al. mention that the domain ontology is used for reasoning processing, in order to identify relevant source code documents and suggest related terms to improve future user queries. In [30], although it is not further discussed, Jamgade and Karale mention that the domain ontology is used for building ontotriples (or ontology triples), a way to express concepts by a subject, a property and an object [38]. These ontotriples are then used for queried the knowledge base to retrieve the relevant documents.

5) *RQ5: The role of knowledge in the architecture of a semantic search engine*: The aim of this research question is to identify what role knowledge plays within the architecture of a semantic search engine. As it was seen in RQ1, RQ3 and RQ4, knowledge has a relevant role in the proposed architecture, mostly by means of a knowledge base. Most of the studies have already answered RQ4 before.

For this question, one field was proposed in order to retrieve the data from the studies:

- a **Knowledge role**: this field aims to get any description of the role that knowledge performs within the proposed architecture.

There are 5 studies found to answer this question. The following are the aspects found in those studies:

- a **Knowledge sharing should be a key feature**, so that the semantic search engines proposed in these studies should allow knowledge sharing by means of the domain ontology they have implemented, such as a document ontology [33] or an innovation process ontology [32].
- b **Knowledge bases help getting better search results**, and in doing so ontologies play an important role. As it is already noted before, knowledge and ontologies usually work together in order to retrieve better and relevant results [30]. On the other hand, in [28], Mendonça et al. use a knowledge base to help on the document annotation process so that users can query those documents, and it can be used to help users creating their queries, which leads to get better search results.
- c **Knowledge is gathered from heterogeneous sources**, which enriches the results a user can get. In order to accomplish this, a set of agents were proposed by Kerschberg et al. so that those diverse sources can be queried [31]. This takes into account the set of general

and domain specific ontologies the system uses, as already mentioned by that study.

## VII. CONCLUSIONS AND FUTURE WORK

The goal of this review is to identify how the architectures of semantic search engines work, how the proposals are designed and what problems they were and are solving. Most of the studies, as depicted previously, propose a concrete implementation for their architectures, so those systems were and are working now in a myriad of application fields. As there was no previous study that summarized this subject, no time range filter was set when searching for the studies.

It can be seen that most of the studies try to propose a solution for a previous unresolved problem, to design a new alternative for users, or to improve search results. To measure whether those proposals represent an improvement, some studies present comparison results or performance benchmarks as is the case of the work of Amanqui et al. [10], Thangaraj and Sujatha [22] or Dong et al. [29]. However, as the purpose of this systematic review is not related to that kind of experiments, this can be considered as a good starting point for a future work.

As for the modules that a semantic search engine comprises, it can be said that reasoning components such as ontologies and inference engines constitute key modules present across the studies. Domain ontologies in particular are a fundamental piece in a semantic search engine as they allow addressing the needs of a specific domain and user requirements [31]. The use of ontologies fosters reusability, as new concepts are identified and added to the ontology, making its maintenance crucial as it evolves over time [38].

Likewise, it was identified that ontologies and knowledge play together a key role in the architectures reviewed. One of the key roles for knowledge is knowledge sharing that is achievable through the implementation of the ontologies that search engines rely on [39]. This brings benefits to search results, improving search engines' precision and recall which, along with usability and the ability to handle unstructured and heterogeneous sources, constitutes some of the most important requirements that the architecture of a semantic search engine needs to fulfill as it is designed and developed.

Finally, although there was no validation and verification methods identified for the architectures of semantic search engines, this can be seen as an opportunity for future work by proposing validation and verification mechanisms already in use in other software engineering application fields. As mentioned by Abowd et al. in [40], there are many benefits of architectural evaluation methods, such as a better understanding and documentation of the system, clarification and prioritization of requirements, and early detection of problems in the architecture, which boosts architecture quality.

## ACKNOWLEDGMENT

The authors of this review thank the support of the "Programa Nacional de Innovación para la Competitividad y Productividad", Peru, under the contract 124-PNCP-PIAP-2015.

**Abstract**—In this paper we examine a number of solutions used in developing multimedia guiding systems for travelers. We pay particular attention to existing mobile audioguide systems and the capabilities they provide for tour creators. The major contribution of this work is to propose a model that would be appropriate for better tour recommendation and playback automation of outdoor travel tours with using geo-positioning. Specifically, we make an effort to advance a *just walk* concept, and to resolve a number of client-server data synchronization issues in process of tour modification by both tour creators and its users.

## I. INTRODUCTION

WHILE traveling, people often want to learn more about the places they discover. Despite there are travelers who prefer careful forethought of a journey, sometimes tourists might not be well prepared for a journey: they believe that they are able to know everything in place, and not due to prior preparations. People often rely on support of professional guides and expect that will tell them all the important stories. However, for many possible reasons, professional guides are not always available:

- Guided excursions might take more time that a traveler expect to spend in a certain place;
- There might be no guide available right now;
- Excursions might be offered not in a language that a traveler can understand.

Rapid development of facilities provided by portable devices (such as smart phones or tablet computers) dramatically changed usage models that we would expect to get from digital solutions accessible virtually at any moment. Fusion of multimedia and mobile technology is one of tangible consequences of human-centric systems evolution [1] including the domain related to design and development of information systems for travelers.

Even those travelers who prefer not to spend much time in pre-journey cultural investigations and careful forethought of their outings, would not like to be passive customers listening to the stories told by a guide: they might want to control the process and to be able to select guiding services on the way. They would also expect to have some flexibility in changing possible itineraries and points of interest as well as in sending their feedback to tour creators and to

other travelers just in the moment when they are en route. A possibility of communication between different devices (directly or via special servers) opens totally new perspectives in arranging traveler collaboration by sending different kinds of notifications and hints aimed at actualizing current tour information and its conditions. The next obvious factor is a possibility to integrate tour information display with the geographical maps and geolocation features of present-day mobile devices. Thus, state-of-the-art information services for travelers are developing towards better user personalization, tour customization, extending possible usage scenarios, and improving tour suggestions on the way [2], [3], [4].

Variability of possible tours suggested to a user is especially important in big cities where a traveler might be lost in the ocean of possible sightseeing tracks with a big number of important attractions. We believe that improving travel-centric services may be considered as an excellent test case of digital transformation changing user activities for their greater interaction and collaboration [5].

## II. PROJECT VISION

With respect to a number of scenarios addressed by travel-centric systems [6], the focus of this work is on improving guiding tools providing multimedia assistance automation with a particular attention to audio guiding systems. In contrast to text and image based applications, audio guides have some important advantages. They do not draw attention much away from an object of interest, since the user needs interacting with a screen only in between times. For the same reason (less screen usage) such solutions are more energy efficient, since they drain mobile batteries less.

The objective of our work is to develop an approach to multimedia assistance of outdoor travel tours with using geo-positioning for tour recommendation and playback automation. Unlike to many existing on-demand audio guides created for using in a particular museum or sightseeing site, our idea is to develop a framework that would allow tour creators and tour user to collaborate indirectly.

## III. STATE-OF-THE-ART SOLUTIONS

In contrast to our previous work [7], within the scope of this contribution we pay particular attention to the solutions

integrated with geographical maps and providing facilities to define a tour as a route connecting selected POIs with associated audio tracks and other relevant annotations. There is a number of good examples of such solutions including such popular applications as *Izi.travel*<sup>1</sup>, *PocketGuide*<sup>2</sup>, and *Azbo*<sup>3</sup>.

#### A. Story Telling Platform: *Izi.travel*

The *Izi.Travel* application is marketed as a storyteller platform for indoor and outdoor audioguiding with a possibility to display other multimedia data such as texts, links or images. Audio track playback starts automatically as soon as a user enters a so called trigger zone (as Figure 1 (left) shows). There is a free walking mode, and a user may select stories from the story base. The application supports both online audio streaming and offline playback of the downloaded tours.

We can particularly mention the following strong points of this application:

- Despite the application recommends to follow a desired order of POIs, the tours are more or less flexible: it is not prohibited to visit POIs in user's own order.
- There are useful features supporting tour timing and distance.
- Registered tour creators use a special interface and an access to the content management system for uploading their own tours.
- There is a sandbox mode: in order to test a just defined tour, the system allows giving an access to this tour only to a limited number of users.
- There is a feature for nearby object recommendations which is particularly important for a free walking mode.

Fig. 1. Visibility area usage (left) and definition (right) in *Izi.Travel*

Thus, there are significant strong points. However, there are issues to consider while improving possible use cases and underlying data models:

- Since trigger zone definition is a tour creator's responsibility, there could be inconsistent zones (as Figure 1 (right) shows). As a result, audio track playback might not always begin in the most appropriate moment.
- Audio playback begins from scratch if a user quits a trigger zone for a while and enters it again. In such a case the user has to adjust the playback manually.

- Nearby object recommendation facility doesn't differentiate users according their movement speed (recommendations would be more helpful if we would be able to distinguish between walkers, biker and car drivers).
- Audio tracks are played by the application itself, not in background.

#### B. Travelling in Big Cities: *PocketGuide*

The *PocketGuide* application is oriented to those users who travel in big cities. Basically, the audioguide collection contains numerous must-see style tours featured with the access to information about dining and shopping facilities displayed on the map. Such approach is particularly suitable for business visitors having not much time for detailed tours and for prior preparations. User can create travel diaries and sync them with user's *Facebook* account). The *PocketGuide* provides also a ticketing platform for the partner companies selling regular (non-electronic) tours. A user can sync audio with others (a certain fee required) but we did not find any possibility for creating and sharing user's own routes. Thus, the *PocketGuide* is rather a consumer-centric (not creator-centric) platform.

Summarizing obvious advantages of this application, we can emphasize the following important points:

- For each tour there is information about its distance and required time; for some tours the best and the worst visiting time periods are provided.
- It is possible to download the offered tours for the selected city all-at-once.
- By using device orientation and geo-positioning, the application computes the current user's field of vision automatically.
- The application provides public transportation information for accessing the POIs.
- There are tours offered in many languages, and the application provides a convenient interface for selecting a tour in your language.

There are some issues which are not completely resolved in the *PocketGuide* and provide foundation for future work:

- Tours are classified only by cities.
- The application straightforwardly follows the model "see the most in the shortest time". However, though information about tour distance and required time is available, a user is unable to search a tour for a given period of time.
- Despite significant efforts to compute a user's field of vision, sometimes playback begins even if an object is overlapped by another objects.
- Similar to *Izi.Travel*, the recommended nearby objects might be very distant from the actual user's position.
- It is expected that a user permanently holds a mobile device and interacts with it. All the information (where to go, which object is worth looking at, etc.) is shown on the screen. So, the application is rather not much battery-friendly: it exploits very actively the most energy consuming device features (such as screen, GPS, wi-fi, positioning sensors, etc.)

<sup>1</sup><https://izi.travel/en>

<sup>2</sup><http://pocketguideapp.com>

<sup>3</sup><https://azboguide.com/en>

- Tour search and classification facilities are very limited.
- No platform for tour creators is provided: the standard option is to contact the *PocketGuide* team.

### C. Up to a City District: Azbo

In the *Azbo* guiding application the available audioguides are classified by cities and city districts. In contrast to the *PocketGuide* and the *Izi.Travel*, a user selects and launches the audio tracks manually. For the cities included to the *Azbo* list, there is a possibility to create a new tour; however, a tour creator is limited by only those points which already exist on the *Azbo* map (this feature requires user authorization). Local user itinerary construction is possible with using points defined in the system.

Among other significant advantages we could mention the following capabilities:

- The *Azbo* supports tour search by a desired time and duration.
- There is a nearby excursion searcher (in this mode, the tours can be offered in 1 km area close to the actual user position).
- All the itineraries available for a certain city district can be downloaded. Available district itineraries are shown on the map. This simplifies tour selection.
- Registration is required only for new public itinerary creation.

There are several drawbacks which could be a rationale for further improvements:

- Currently the *Azbo* does not support automated audio display. Apparently, a user has to permanently hold a device in his or her hands.
- We did not find an option to create a tour in a city which is currently not included to the *Azbo* list. We think that it could stand in the way of gaining more popularity among those users who would like to share their own experience in new places.
- User itineraries are saved only to a mobile device. The only way to create your tours is to use the mobile application. There is no any platform for tour creators and for collaboration of travellers.
- The route between the existing points is created automatically. In reality, such an automatically constructed route might be far from being optimal, especially if the goal is not to construct the shortest route, but to offer the most interesting connection from creator's point of view.
- Excursion online streaming is not supported. Every excursion has to be downloaded to a user device.

### D. Lessons Learned

We admit that developers of the above examined applications had their own views on the features they decided to implement. So, it is extremely important to note that our analysis **does not tend to criticize existing solutions** (which are excellent examples of very successful and popular products), **but to summarize possible areas where concepts,**

**data models, use cases and application organization can be rethought, improved or advanced.**

In particular, our investigations showed that most existing applications are limited on selecting a tour to follow: there is no support for postponed or suspended tours; there are few features allowing tour adjustments or recommendations according to traveler's movements.

Many applications target the travelers who did preliminary preparations, so such travelers (more or less) know the places that they would like to visit. However, there are situations when the primary plans of a journey are not connected to sightseeing (for example, in a case of business trips). In such a case, there could be spontaneous walks within the limited period of time: it means that a traveler might not have time and/or wish to carefully select the possible tours. The same situation might happen if a traveler has to overstay in some area due to such reasons as flight delay, missing the train, business program extension, etc.

Current systems have very limited support for tour combinations and/or for using fragments from different tours during one walk without forcing users to explicitly select these fragments.

Attempts to define traveler's field of vision automatically requires using device orientation facilities. Thus, a user has to constantly hold the device in hands in proper orientation: in such a way, the user has to interact with a device instead of directing attention to the tourist attractions. Most interactions with a user require screen operations. Again, it does not help in focusing user's attention on the excursion, not on the device. Furthermore, an active screen might quickly drain device battery.

We also believe that it is very important to combine online streaming facilities with the support for following the tours when the user device is not connected to the Internet.

## IV. INTERACTIVE AUDIO GUIDING SYSTEM: OBJECT MODEL AND INTERFACES

Our focus is on creating flexible tours with paying attention to actual traveler walk using geolocation and other features of mobile devices.

We define two major *user roles*: a tour creator (*expert*) and a tour user (*traveler*). Hereafter we describe the object model of interactive audioguiding system.

### A. Object Model

A *tour* is a sequence of *point of interests* (POIs) where for each point a *zone of vision* is defined. A zone of vision (which is also a trigger zone used to decide at what moment the corresponding audio track playback should start) is a geometric shape corresponding to a certain area associated to a geographic map. Trigger zone definition is based on polygon geometry types from "OGC Simple Features Specification for SQL OpenGIS" [8].

A set of entities (POI, POI zone of vision, POI multimedia) forms a *standard location model*. Location multimedia may include audio tracks (particularly, for a case of creating tours

the traveler gets a notification. The traveler is able to see all the points of vision on the map and their areas of vision. As soon as the traveler enters such an area, playback begins for a certain point of vision.

One of objectives of our approach is to extend the standard audio guide organization with the abilities to create and modify tours with using information of current guide or traveler position and with respect to such device features as geopositioning, photo/video camera, voice recorder, etc.

### C. Databases

In accordance to the object model and the usage modes described in Sections IV-A and IV-B, we designed the server-side and client-side databases. Figures 3 and 4 represent the excerpts with only core database entities included. These core entities are required in order to examine synchronization issues discussed in Section IV-D. Database schema was designed with *dbdesigner.net* [9].

### D. Synchronization Issues

With respect to indirect collaboration of tour creators and tour users, the important aspect is how to sync tour contents in the case when a tour is modified by a tour creator or by an authorized moderator. If the tour is currently playing, its modification on the fly might unpleasantly interrupt the excursion: it is highly unlikely that users would be satisfied with such an interruption. So we propose the following algorithm in order to assure proper synchronization of client device contents with the changes on the server:

- 1) As soon as an expert decides to modify a tour, and saves the changes in the mobile or web client application, all the update information is sent to the server by using PUT (for a tour update operation) or DELETE (for a tour removal operation) method <sup>5</sup>.
- 2) On the server side, the records corresponding to the tour (to be modified) are deleted together with all the records from the linked tables (places, translations, etc.) as well as from the tables containing user modified data (such as accessibility marks and passed points information). After deletion, on update, the new tour record is added to the database.
- 3) On successful server database modification, PUSH-notifications are sent to all the users. Every notification contains the following data:
  - a) "Operation" – "Update" or "Delete";
  - b) "Outdated tour id" – a removed tour id; and
  - c) "City of outdated tour" – a city id.
- 4) As soon as a client device gets the notification, the application checks whether a tour exists in the local database. If such a tour exists, the application checks whether it is active (being played) right now.

<sup>5</sup>According to the REST (REpresentational State Transfer) architectural style for distributed hypermedia systems [10]. HTTP-based web-service APIs adhering to the REST architectural constraints typically use a set of standard HTTP-methods: GET, PUT, POST, and DELETE. See [11] for details.

- 5) If the client is in the single guide mode and the outdated tour is being played, the application changed status of playing tour to "Outdated". This status change prevents from interrupting the tour, but prepares its further update. If the tour is outdated, the application continues playing the tour, but stops sending requests for updating user-provided information (such as POI accessibility marks, passed points information, etc.). The recent information (i.e. information before the update) stored in the local database is displayed to the user. As soon as a user decides to stop this tour, the tour is completely deleted from the local database. The new version is downloaded upon further selection of this tour.
- 6) If the client is in the just walk mode (it means that there is no tour which is currently playing), the application checks the update notification parameter "City of outdated tour". If the user is in this city, all the information in device memory (e.g. points on the map) is reloaded again.
- 7) If currently there is no specific mode, but a user interacts with one of tour information screens, the application suggests to update data. The outdated tours are now blocked for usage.
- 8) In all other cases, the outdated tours are removed from the device.

Thus, an active tour is not interrupted even if a tour creator modifies it. The application proceeds with an update only if a tour is completed or cancelled by the user. Despite some records might require being downloaded from the database while the tour is playing, this is only a minor synchronization overhead. Finally, the outdated tours are completely deleted from the server database, hence frequent GET requests (required, for example, in just walk mode) do not imply the analysis of many outdated database records.

At the same time, we admit that such an approach is not free from several drawbacks. The above described algorithm is not incremental: partial updates are not possible. So, for example, a tour creator can not change only some location attribute, and update only this small part of data. In such a case, the whole tour has to be updated. The server file system might become obstructed by a lot of outdated information. So, some garbage collection scripts might be periodically required, and this process might temporarily block the system for accessing by mobile clients. In this work we did not consider this issue.

## V. CONCLUSION

Based on our analysis of solutions offered on the digital market, we introduced an approach to developing an audio-guiding recommendation and journey assistance systems with particular attention to system usage scenario definitions, its architecture and data models. In addition to using necessary standard features of present-day mobile devices (such as geolocation sensors and multimedia facilities), our solution follows an idea of implementing a collaboration framework and exploits a concept of mobility in a broader sense: users may complement the contents of a tour they follow, and,

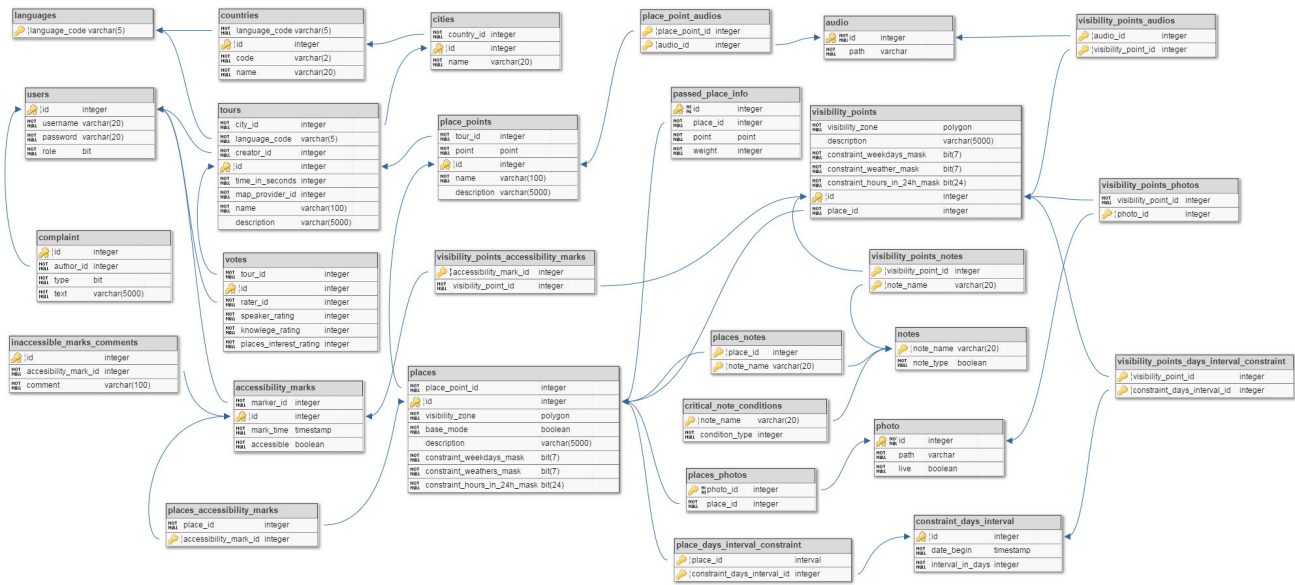

Fig. 3. Server database: core entities

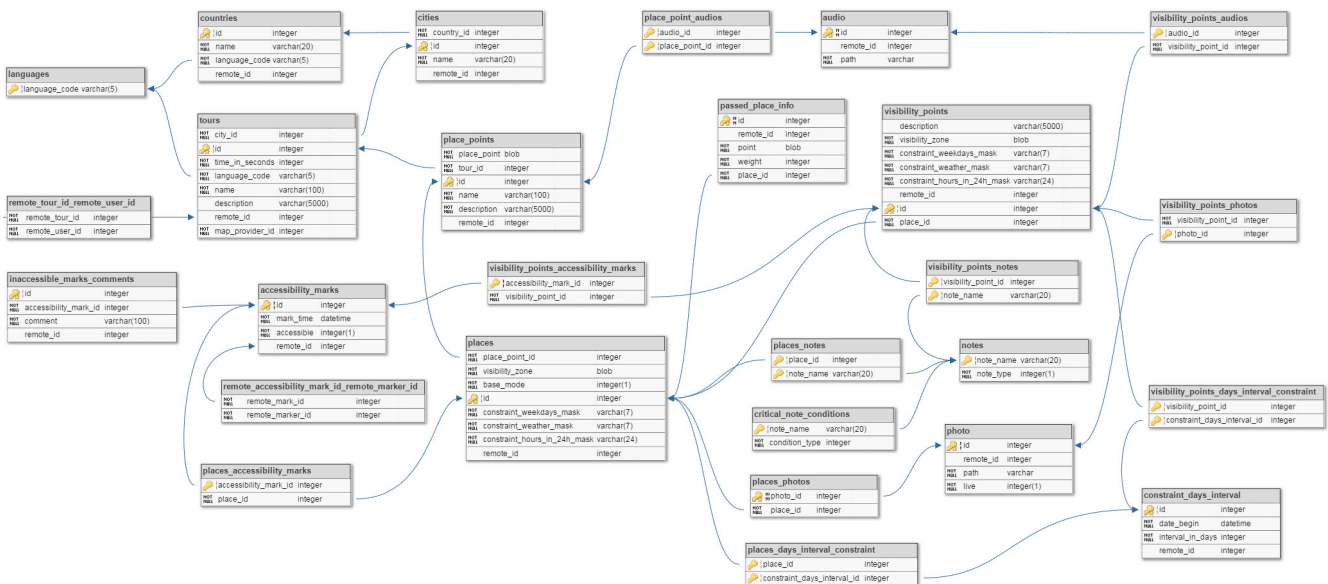

Fig. 4. Client database: core entities

conversely, tour creators can leverage customers' experience while creating or modifying travel tours.

We particularly address a just walk scenario where the system does not force concrete activities upon users, but suggests possible options on the base of available tour information, actual conditions and existing recommendations.

A tour creation model fits both professional guides and (even more) amateurs willing to share their knowledge and experience with others in the form of authored audio excursions integrated with geolocation features and geographical maps accessible from a mobile device (currently we rely on

Google Maps as a map service).

We believe that our approach can expand opportunities of present-day audioguiding applications and increase the number of potential stakeholders interested in using such systems. The obverse case is the eventual complexity of tour creator's user interface required in order to support all the capabilities of the proposed architecture. Our future work is on improving user interfaces, increasing the system's flexibility by using a number of different map providers as well as advancing a concept of automated tour and track selection and recommendation.

# 11<sup>th</sup> Joint Agent-oriented Workshops in Synergy

**M**ULTI-AGENT systems (MASs) provide powerful models for representing both real-world systems and applications with an appropriate degree of complexity and dynamics. Several research and industrial experiences have already shown that the use of MASs offers advantages in a wide range of application domains (e.g. financial, economic, social, logistic, chemical, engineering). When MASs represent software applications to be effectively delivered, they need to be validated and evaluated before their deployment and execution, thus methodologies that support validation and evaluation through simulation of the MAS under development are highly required. In other emerging areas (e.g. ACE, ACF), MASs are designed for representing systems at different levels of complexity through the use of autonomous, goal-driven and interacting entities organized into societies which exhibit emergent properties. The agent-based model of a system can then be executed to simulate the behavior of the complete system so that knowledge of the behaviors of the entities (micro-level) produce an understanding of the overall outcome at the system-level (macro-level). In both cases (MASs as software applications and MASs as models for the analysis of complex systems), simulation plays a crucial role that needs to be further investigated.

## TOPICS

JAWS'17 aims at providing a forum for discussing recent advances in Engineering Complex Systems by exploiting Agent-Based Modeling and Simulation. In particular, the areas of interest are the following (although this list should not be considered as exclusive):

- Agent-based simulation techniques and methodologies
- Discrete-event simulation of Multi-Agent Systems
- Simulation as validation tool for the development process of MAS
- Agent-oriented methodologies incorporating simulation tools
- MAS simulation driven by formal models
- MAS simulation toolkits and frameworks
- Testing vs. simulation of MAS
- Industrial case studies based on MAS and simulation/testing
- Agent-based Modeling and Simulation (ABMS)
- Agent Computational Economics (ACE)
- Agent Computational Finance (ACF)
- Agent-based simulation of networked systems
- Scalability in agent-based simulation

## STEERING COMMITTEE

- **Cossentino, Massimo**, ICAR-CNR, Italy
- **Fortino, Giancarlo**, Università della Calabria, Italy
- **Gleizes, Marie-Pierre**, Université Paul Sabatier, France
- **Pavon, Juan**, Universidad Complutense de Madrid, Spain

## I. INTRODUCTION

**J**AWS are the Joint Agent-oriented Workshops in Sinergy at the annual FedCSIS conference. This section presents the events and papers of the 7th edition in this series, which includes the 11th edition of the Multi-Agent Systems and Simulation (MAS&S) and the 9th Agent-Based Computing - from Model to Implementation (ABC:MI) workshops, the longest standing in the series. The JAWS event provides researchers on agent-based systems and their applications from all over the world the opportunity to meet together. Since its first edition (Szczecin, Poland, 2011), the JAWS workshops have been expanded their scope to become well-recognized international events in their fields. Their papers have been published in English by prestigious publishing houses (this year by IEEE Press).

The organizational structure of JAWS 2017 is similar to other international scientific workshops. The backbone is the scientific program and the open debates on the main topics about agents.

The scientific program of the event is organized by the different workshops under the umbrella of JAWS, with common guidelines to guarantee an homogeneous quality level. Each submitted paper has been reviewed by three members of the Program Committee (PC), coordinated by the corresponding Workshop Chairs. In case of potential conflicts of interest, reviewers from FedCSIS but outside those of JAWS were recruited to write the reviews. The PC consisted of 25

researchers from 7 different countries. The full list of chairs, PC members, and reviewers can be found in the pages of these FedCSIS proceedings.

JAWS 2017 has received 12 papers from all over Europe, attesting to the truly international nature of the event. After review by the international PC, 6 papers have been accepted for presentation and published in this volume. These numbers are similar to those of the last edition.

## ACKNOWLEDGMENT

We would like to express our sincere gratitude to all the people who helped to bring about JAWS 2017. First of all, thanks to the contributing authors, for ensuring the richness of the workshops and for their cooperation in the preparation of this volume. Special thanks are due to the members of the program committee and reviewers for their professionalism and their dedication in selecting the best papers for the event. Thanks also to the JAWS Steering Committees for its guidance and continuous support.

Nothing would have been possible without the initiative and dedication of the Organizing Committee from the Faculty of Information Technology, Czech Technical University in Prague. We are very grateful to all the people who helped in the large variety of organizing tasks.

Also, we thank you the FedCSIS Organizing Committee and Secretariat for their continuous support in administrative matters, as well as Maria Ganzha, Leszek A. Maciaszek, and Marcin Paprzycki and the teams from their Polish universities.

# Failure Analysis for Adaptive Autonomous Agents using Petri Nets

Mirgita Frasheri, Lan Anh Trinh, Baran Cürüklü, Mikael Ekström

**Abstract**—Adaptive autonomous (AA) agents are able to make their own decisions on when and with whom to share their autonomy based on their states. Whereas dependability gives evidence on whether a system, (e.g. an agent team), and its provided services are to be trusted. In this paper, an initial analysis on AA agents with respect to dependability is conducted. Firstly, AA is modeled through a pairwise relationship called willingness of agents to interact, i.e. to ask for and give assistance. Secondly, dependability is evaluated by considering solely the reliability attribute, which presents the continuity of correct services. The failure analysis is realized by modeling the agents through Petri Nets. Simulation results indicate that agents drop slightly more tasks when they are more willing to interact than otherwise, especially when the fail-rate of individual agents increases. Conclusively, the willingness should be tweaked such that there is compromise between performance and helpfulness.

## I. INTRODUCTION

**D**EPENDABILITY IS, and has been for a decade, a promising research direction for researchers and is considered central in designing systems that are intended to work closely with and for humans (e.g. automotive, airborne, and service robots). Originally, it was devised from software development areas and can be stated by Avizienis *et al.* [1] as "*the ability to deliver service that can justifiably be trusted*". The dependability of a system is evaluated by one, several or all of the attributes including availability, reliability, safety, integrity, and maintainability. The implementation of dependability starts with the understanding of the threats to the system dependability: The threats consists of failures, errors, and faults. The link between the three is known as fault-error-failure chain. A failure happens when the services provided by a system do not comply with its specification. An error affects the services and leads to the failure of the system. The hypothesized cause of an error is a fault. Therefore, there are four means that have been developed to protect the system dependability which are fault prevention, fault removal, fault forecasting, and fault tolerance, whereof fault tolerance is discussed in this work. It is deducible that the fault is the root of every failure appearing inside and outside of the system. The most pressing challenge is how to predict the frequency of faults and the moment a fault occurs, thus fault analysis is utilized to minimize the probability of faults and fault prediction is applied to give an estimate of when faults happen in the system. Thereafter, other means are developed to protect the dependability with respect to the analysis of the

fault. In order to conduct fault analysis, various approaches such as Petri Net (PN), fault tree analysis (FTA), failures modes effects and criticality analysis (FMECA), and hazard operability (HAZOP) have been introduced in the work of Bernardi *et al.* [2]. However, in this work PN is chosen because this framework provides a probability approach for fault analysis and fault prevention in both development and operational stages of designing a system. For instance as an extension of PN, a stochastic Petri net could be combined with Markovian models to evaluate the probability of the current state and the probability of future fault events for a fault prognosis process. In this work, a Colored Time PN (CTPN) is utilized for fault analysis in a system of adaptive autonomous agents.

On the other hand, agent autonomy represents a widely discussed topic in the literature. It can be described in two dimensions: self-directedness, i.e. autonomy in determining one's own goals, and self-sufficiency, i.e. autonomy in carrying out a task or goal without outside help [3]. Autonomy is also a relational concept [4]. There is autonomy from the environment, which is defined by how much an agent is independent from the stimuli coming from outside. Moreover, there is autonomy from other agents – social autonomy – that is defined by how much an agent is independent from the influences of those other agents. Castelfranchi [4] grounds the concept of autonomy on dependence theory. Consequently, an agent *A* doing a task might realize that it needs a resource, know-how, a plan, or an action that it does not have in order to achieve its goal. If there is an agent *B* that can provide *A* with what it needs, then *A* will depend on *B* for that specific need. As a result *A* is not autonomous from *B*. When the dependencies change, so does the autonomy of the parties involved. Adaptive autonomy specifically enables the agent to decide on its own autonomy [5]. In this work, it means that agents can choose when to depend on others, or when to be depended upon based on their current circumstances.

The aim of this paper is to analyze an initial concept of an adaptive autonomous agent developed previously [6] with respect to fault tolerance by using Petri Nets. The following sections are organized as follows. First related work both on Petri Nets and adaptive autonomy is discussed. Thereafter, the initial agent model is described and it is shown how the willingness to interact shapes the agent's autonomy. Next, the failure analysis is conducted. Simulations are run in order to

show how the willingness to interact, failure frequency and the number of tasks dropped by the agents relate to each other. Finally results are described and discussed.

## II. RELATED WORK

### A. Dependability

The assessment of system dependability, as aforementioned, is based on the basic attributes. Depending on the specific applications, different attributes are used to measure the dependability of a system. In the development of robotics application, with regards to the reliability, a group of researchers from India [7] proposed an approach to assess various parameters that make a multi-robot system more reliable. The proposed method is a combination of PN and fuzzy lambda-tau. Another model and analysis for multi-robot based on stochastic PN is introduced by Sheng *et al.* [8]. However, the former research focused on reliability analysis for a navigation system, the latter one studied of a reliable model for multi-robot exploration. These researches are limited to these particular systems.

In the study of fault tolerance analysis for a group of agents, there are some researches on modeling and analyzing a distributed system of agents using PN and extended PN. For instance, Ammour *et al.* [9] introduced a stochastic Petri net combined with Markovian models to evaluate the probability of the current state and the probability of future fault events for a fault prognosis process in discrete event systems. In the work of Sun Chen *et al.*, [10] an adaptive consensus of fault tolerance for a multi-agent system was proposed. Another automated analysis of fault tolerance for a reliable communication system is introduced by Stoller and Schneider [11]. A model, analysis of fault tolerance for a distributed multi-agent system using Time Colored Petri Nets are provided by Boukredera *et al.* [12]. In the work of Kristan *et al.* [13], based on PN tool, the activities of agent in a complex multi-agents system are analyzed. Recently, a combination of a fuzzy method and PN introduced in [14] is proposed to analyze a sequential failure in complex industrial systems. Although some effective techniques for faults analysis have been developed, there are lacks of works focusing on the analysis of faults for adaptive autonomous multi-agent systems. Therefore, a method based on CTPN is proposed for failure analysis in the context of autonomous adaptive agents.

### B. Agent Autonomy

Alongside adaptive autonomy, there are several other similar concepts such as adjustable autonomy, collaborative control, mixed-initiative interaction, and sliding autonomy. Adjustable autonomy refers to a system in which the human operator is the one to decide on the levels of autonomy of the agent [5]. Mixed-initiative interaction makes it possible for either the human or the agent to decide on autonomy levels [5]. Collaborative control allows the human and agent to resolve their inconsistencies through dialogue [15]. Sliding autonomy refers to a system which can switch between full tele-operation and autonomy on a task level, i.e. the agent can be tele-operated with respect to a task  $T_1$  whilst executing autonomously a task

$T_2$  [16]. While this list is not exhaustive, it still represents the most encountered terminology in the literature and serves to build a general picture of the landscape in the field. Worth noting is that there has been a paradigm shift in how dynamic autonomy is handled, from the 10 levels of autonomy [17] to team-work approaches in which autonomy is not fixed but rather changes depending on the interdependencies between agents [18]. Moreover, the authors have proposed a design methodology which identifies possible interdependencies in a system, and thus helps the designer provide support for them in the implementation phase.

Several works aim at providing comparison between systems with and without adaptive autonomy [19], and between systems with different approaches to autonomy [5] [20]. Systems such as RIAACT [21] are oriented toward meeting real-time requirements of adjustable autonomous agents. Whereas, STEAM [22] is an agent architecture which adds support for teamwork. Specifically, team operators, i.e. reactive team plans, are introduced. The agents also have their individual plans which do not require teamwork. Kaa [23] is a system developed on top of the KAoS policy system [24]. KAoS implements policies to orchestrate multi-agent behavior, and Kaa allows for their modification on run-time. This solution is centralized.

In this paper, the willingness to interact is used to shape agent autonomy. Additionally, the decision of whether to interact, i.e. whether to ask or to give assistance, is considered as internal to the agent. There is no hierarchy between them, nor fixed levels of autonomy.

## III. BACKGROUND ON PETRI NETS

A Petri net (PN), from a mathematical perspective, is a bipartite graph built from a set of tuples  $(U, V, W)$ , where  $U$  and  $V$  are a set of places and set of transitions respectively. Meanwhile,  $W$  is a set of arcs used to link from a place to transition and vice versa. Noting that there is no any connections between places as well as between transitions. The arcs running out from a place to a transition are known as input places of transitions, whereas the contrary arcs, i.e. running out from a transition to place, are called output places of transitions. PN, therefore, with regards to two types of flows from a transition, is described as a set of five tuples  $(U, V, W, W^-, W^+)$ , in which  $W^-$  defines the output weights and  $W^+$  for the input weights from a transition. The number of tokens inside a place is named marks. The stage of PN is completely determined based on the marks of all places, therefore a marking  $M$  is used to present the current state of PN. The marking  $M$  is expressed by a vector  $[M(p_1), M(p_2), \dots, M(p_i), \dots, M(p_n)]$ , in which  $n$  is the number of places and  $M(p_i)$  is the mark of place  $p_i$ . Let  $W^-$  is expressed by a two dimensional matrix of weights where each element  $W^-(p_i, t_j)$  is determined as the number of tokens allowed to move from the place  $p_i$  to the transition  $t_j$ . Similarly,  $W^+$  is formulated by the weight  $W^+(t_j, p_i)$  from the transition  $t_j$  to the place  $p_i$ . It is noted

that  $1 \leq j \leq m$ , in which  $m$  is the number of transitions. Thus, the marking is updated by the following equation.

$$M'(p) = M(p) + W^+(t, p) - W^-(p, t), \forall p. \quad (1)$$

Let  $M_0$  being an initial marking, the tuple  $(U, V, W, W^+, W^-)$  is extended to  $(U, V, W, W^+, W^-, M_0)$ . The marking  $M$  is reachable if  $M'$  is the result of applying a sequence of update equation (1), starting from  $M$ . The state-space analysis of PN shows a full graph of all possible markings that are reachable from  $M_0$  and all possible paths of transition from a marking to another. However, the complexity of the state-space analysis dramatically increases with respect to the number of places and transitions of a PN network. Thus, the state-space analysis is completely suitable for the small PN network.

There are various types of extension of PN. The colored PN (CPN) is one of them, in which CPN utilizes different color to mark tokens [25]. Additionally, each type of token separately fires with the transition. The transition behavior for different colors is decided by the arc expressions which are built from operators and functions. Another extension type is the stochastic PN in which a time delay is added to each transition, and a random variable is used to estimate the firing rate. A probabilistic inference, therefore, is utilized to analyze the state-space of the PN network. In this work, a hybrid PN called colored time PN (CTPN) is applied to deal with both non-deterministic and deterministic variables of the time delay. CPNTools [25] are utilized to model the proposed system and perform the failure analysis.

Figure 1. Agent Model

#### IV. AGENT MODEL

The agent is realized as a state machine with 5 operational states which are *idle*, *execute*, *interact*, *regenerate* and *out\_of\_order* (Figure 1). An agent starts its operation in the *idle* state, in which it will generate a task with a probability  $P$ . As long as it is in *idle* the agent has not committed to any task. A change of state occurs either if a request for help is received, or if the agent has generated a task. In the former, the agent switches to the *interact* state and decides whether it will give assistance or not (not interruptible process). This decision will depend on the agent's willingness to give assistance (defined probabilistically). In the positive case the agent will put the task in a queue and switch to *execute*, otherwise it will discard the request and resume what it was doing (either back in *idle* or *execute*). In the latter, the agent will put its own generated

task into a queue and will change its state to *execute*. At the beginning of the execution of a task the agent decides on whether it needs outside assistance or not. This is based on the agent's willingness to ask for assistance. If it does, it will select the agent which was perceived as most helpful in the past and make a help request. This is a blocking operation. Nonetheless, the agent waits for a reply for a finite amount of time, after which it will return to idle regardless of the outcome. In principle, the agent could receive a request while being in the execute state as well. If the agent reaches critical levels of battery, i.e. lower than some predefined threshold, it will switch to *out\_of\_order*. As of now, the agent will immediately switch to *regenerate*, in which the recharge takes place, and into *idle* right after. The willingness to ask and give assistance make up the agent's willingness to interact, i.e. they are like the two sides of a coin. Modeling these elements mathematically is part of the research for adaptive autonomous agents. Nonetheless, for the purposes of this work, they are expressed through probabilistic distributions, as is explained in the next section.

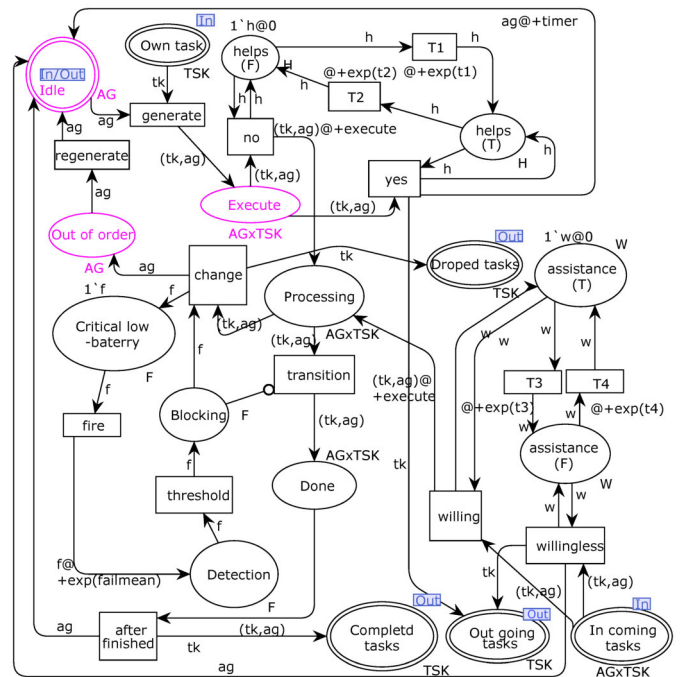

Figure 2. Design of the *agent module*

## V. FAILURE ANALYSIS

Based on the description given in the previous section the agent module is designed. Moreover, all agents share the same structure which is represented by PN (Figure 2). All tasks are generated by the agents. The agent once completing the task will put the completed tasks in a submodule known as *completed tasks*. Otherwise, the task will be put on a submodule called *dropped tasks*. The agent, right after, will send a helping request. If there is an available agent which is willing to give assistance, the agent will take the task from a

willingness to interact when the fail mean is low induces a slightly higher number of dropped tasks. It is possible to conclude that, while being willing to interact and collaborate is a desired characteristic for an agent, it will not always result in higher performance. Consequently, the agents need proper reasoning mechanisms that will allow them to make the best of any situation they are in. In some cases this might mean being helpful, and in others it might mean focusing on one's own tasks/goals.

In the future, the proposed approach will be extended to deal with a more complex agent architecture in which relevant factors that should shape the willingness to interact will be identified and analyzed. Consequently, appropriate models will be developed so as to reflect the impact of these factors and will replace the distributions used in this work. Ultimately, agents should be able to find a balance between helping each other, completing their tasks and face failures of different frequencies. Another concern relates to the potential scalability of such approach by considering a bigger population of agents in ranges of 10, 20, 50 etc. Finally, the actual communication between the agents will be addressed as well in future PN models, as it is central to the adaptive autonomous agent model described in this paper.

#### VIII. ACKNOWLEDGMENTS

The research leading to the presented results has been funded by the EUROWEB+ project (1<sup>st</sup> author) and the research profile DPAC - Dependable Platforms for Autonomous Systems and Control project, funded by the Swedish Knowledge Foundation (2<sup>nd</sup>, 3<sup>rd</sup>, and 4<sup>th</sup> author).

**Abstract**—Ambient Assisted Living (AAL) pursues providing an autonomous and satisfactory life to people through technology, independently of their actual conditions. Its developments usually require testing prototypes with real users in Living Labs (LL). This makes projects expensive. Virtual LLs (VLLs) try to address these issues by using simulations for requirements elicitation and the initial testing of solutions. These simulations frequently require considering social aspects, e.g. relationships, culture, or decision making. These are recurrent and quite application-independent aspects for AAL. Our work proposes *social properties* as patterns that represent these aspects and that can be plugged-in in simulations. The knowledge for these properties is extracted following the Activity Theory (AT) paradigm from Social Sciences. Their specification uses models and transformations (e.g. to generate other models or code) following Model-Driven Engineering (MDE) practices. This facilitates their understanding and use in simulation development. A case study on AAL for ageing illustrates the approach.

## I. INTRODUCTION

AMBIENT Assisted Living (AAL) [1] pursues the development of socio-technical solutions that facilitate to people carrying out an independent and satisfactory life, regardless their particular conditions, both physical and mental. Its solutions are intended to support a variety of needs, like those of elderly people, support for temporal or permanent impairment, or home safety and security.

AAL solutions are socio-technical systems [2], which depend on human, social, and organisational factors, technical features, and their interplay. The design of such systems fall beyond traditional practices of system development, as it needs to take a closer, holistic, and pluri-disciplinary look to all these elements [3]. In the case of AAL, design needs to consider human aspects such as what assistive technologies people accept, the takecarers' involvement, or the users' self-image.

The discovering and testing of these requirements frequently demands the use of Living Labs (LLs). A LL [4] is an open research and innovation ecosystem. It gathers the different stakeholders (e.g. user communities, developers, researchers, policy makers, and investors), and the resources needed for their interaction. In particular, it usually includes the settings and devices to analyze needs and technologies, and to evaluate and test hypotheses, technologies, and solutions. The main issues with these facilities are that they are expensive (to set

up and keep updated, and therefore to use), and that they strongly constrain tests (e.g. only with available devices, in real time, and controlling potential damages). In turn, this highly increases the cost of AAL solutions.

The research on Virtual LLs (VLLs) [5] addresses these issues through the development of very accurate software simulations of LL. The AAL system is deployed in the VLL as it would be in a LL. The VLL receives its outputs and actions and provides the relevant inputs. From the perspective of the AAL system, there is no difference between deployment in a LL and a VLL. The VLLs can replace physical LLs in the early stages of the development of solutions, mainly regarding requirements elicitation and early prototyping. Of course, VLLs have limitations. It is difficult to consider any potential event and interaction that can appear in the real world, but a VLL can still consider a wide variety of them.

Social aspects have a pervasive impact on AAL system, that frequently affects them in quite abstract aspects, like acceptance, interaction with devices and other users, or concerns on privacy. This high level of abstraction facilitates its reuse in different contexts. At the same time, it frequently puts them far beyond the usual background of researchers and developers from technical-oriented fields.

The previous considerations took our research to consider the need for VLL, and for extension in AAL, of ready-to-use knowledge on social aspects for the design of these systems. This knowledge should alleviate the workload on eliciting and applying these aspects in the development of AAL solutions.

Our work proposes the use of *social properties* [6] and Model-Driven Engineering (MDE) [7] to address these issues. Social properties crystallize knowledge from Social Sciences in forms useful for development, that MDE techniques can quickly incorporate to simulations models and code.

*Social properties* [6] are similar to design patterns [8] in Software Engineering, i.e. they are templates of general solutions to problems that repeatedly appear in the development of systems, and are described at different abstraction levels (from graphical specifications to code). When available, engineers use and combine them to address well-identified issues of their systems. The application of patterns is usually a manual task, i.e. engineers design / write how the pattern is applied.

However, in the context of MDE [7] this application can be semi-automated.

MDE [7] is an approach to system development organized around *models* and *transformations*. It formally defines Modelling Languages (MLs) that are domain-specific. Engineers specify their systems using *models* that conform to these MLs. *Transformations* [9] allow generating models from models (M2M) (e.g. addition of platform-oriented information and refactoring.), text from models (M2T) (e.g. documentation and code generation), or models from text (T2M) (e.g. reverse engineering). The development process is then conceived as an iterative refinement of model specifications through the manual addition of information and the semi-automated transformation of models.

In a MDE context, social properties are defined using models and transformations. Having specifications at different level of abstraction allows addressing the need of high-level design with domain expert, but also of developers in late design. Moreover, making explicit all this information facilitates the traceability of all the artefact in development. Therefore, it helps to guarantee that the simulation corresponds to the initial requirements.

The last element of the approach is related to how to obtain useful knowledge from Social Sciences to design AAL simulations in VLLs. Our work resorts to Activity Theory. The Activity Theory (AT) [10] is a paradigm for interdisciplinary research based on a socio-cultural approach. Previous works [11], [12] have proven the advantages of AT in the development of Multi-Agent Systems (MAS) as a source of expertise about intentional and social aspects. In particular, this knowledge has been used in requirements elicitation to study interactions among systems and their users in an integrated way [12].

The paper illustrates the application of the approach with a case study about the development of an AAL solution with different types of users. These users experience some problems when moving (e.g. falls, blockades, or inability to grasp objects). However, their features regarding age, gender, cultural background, or familiar relationships are different. The simulation needs to consider these variations to study the feasibility of a surveillance and help request system for these people at their homes. This case study shows how social properties consider these features and introduce them in the simulation running in a VLL.

The remainder of the paper is organized as follows. Section II presents AT. Section III describes *social properties* and section IV the process to use them in simulations, which section V applies in the case study. Section VI compares the presented approach with existing AAL works. Finally, section VII discusses some conclusions and future work.

## II. ACTIVITY THEORY

The Activity Theory (AT) [10] is a socio-psychological framework for the study of human behaviour. It focuses on the dialectics between people and their physical and social environment. The environment shapes human actions and their

Fig. 1. AT depiction of an activity system [13].

execution, but at the same time, these actions also partially define and change the environment. This interaction occurs over time. Since these perspectives are inherently interleaved, AT advocates for their holistic analysis. These acts in context constitute the minimal meaningful unit of analysis and are called *activities*. AT makes no distinction between physical and mental activities.

An *activity* [13] is a transformation process driven by people's needs. The *outcome* of the activity is a product able to satisfy those needs. The activity produces the outcome through the transformation of the initial *objects*. The *subject* is the active element that carries out the activity. Any resource the subject uses is a *tool*.

Subjects with a set of common social artefacts constitute a *community*. It characterizes the socio-historical context. The relationships in the community and of this with other elements are mediated by two types of artefacts: *rules* and *division of labour*. They include elements such as norms, tacit knowledge, or learned behaviours. The key difference is the focus. The division of labour is related to the organization of the community in the activity. It includes aspects such as goals, hierarchies, collaborations, or responsibilities. Rules represent the context that comes from outside the scope of the activity but affects it. They include, for instance, religious beliefs, state laws, or socially acceptable behaviours.

All these elements make up the *activity system*, i.e. the context of an activity. Fig. 1 shows its traditional depiction as introduced in [13].

Activity systems do not appear isolated. They are always interconnected with neighbour activity systems through shared artefacts. For instance, the execution of an activity produces outcomes that become the artefacts (e.g. subject, object, or division of labour) of other activities.

AT also considers the hierarchy of subjects' motives, based on their relevance and how conscious subjects are about them. *Activities* are linked to the high-level *objectives* that they are potentially able to satisfy. *Objectives* meet people needs. *Activities* are executed through networks of *actions*, i.e. sequences of *actions* with alternatives. *Actions* pursue low-level *goals*, which decompose the *objectives*. Subjects are

also conscious about goals. At the lowest level, *actions* are implemented through *operations*. These depend on the specific state of the *environment*. Operations are frequently internalized by subjects, so they are unconscious about the actual steps to execute them.

The evolution of activity systems over time depends on their inner *contradictions*. These contradictions are conflicts between the elements in the networks of activity systems. There are four levels of contradictions according to where they appear. Primary and secondary contradictions appear inside an activity system. Primary ones happen in an artefact, or between artefacts of the same type. For instance, because some tools are not designed to work together. Secondary contradictions appear between artefacts of different types. For instance, because tools are not suitable to transform the object. Tertiary contradictions appear between different states of the historical evolution of an activity system. For instance, the care systems for elderly people based on the family and the more recent ones based on technology and hired assistance. Finally quaternary contradictions appear among different activity systems. For instance, a system produces an outcome that is not a suitable tool for another system.

Subjects try to remove contradictions through the evolution of the involved activity systems. This usually generates other contradictions, which produce further evolution of systems.

### III. SOCIAL PROPERTIES

The specification of AAL solutions to analyse their human and social aspects is a demanding task. In order to reduce this effort, our work tries to take advantage on the similarities between different scenarios. For instance, the attitudes towards privacy, surveillance, and technological skills can be common to multiple scenarios. The concept of *social property* aims at describing these reusable partial specifications.

A *social property* specifies a human aspect recurrent in different scenarios of socio-technical systems. The use of these properties in AAL pursues multiple goals: to document a social aspect; to facilitate communication among stakeholders; and to support the development of solutions. To meet all these objectives, social properties are described with the structure represented in Fig. 2.

A *social property* has a unique identifier and a description. The description is a general explanation of its meaning, the context where it can be applied, and its effects.

The *settings* provide the detailed specification of the property. A *setting* is a specific application of a property in a type of context, i.e. a kind of social group and environment. For instance, a social property describes a structure that relates caretakers and caregivers when the later are hired staff, and its settings account for the differences between organizations with these people in the same premises or caregivers using systems for remote monitoring.

The description of a *setting* includes text and models. UML-AT [11] is the ML used to describe these models. It is a Unified Modelling Language (UML) [14] profile that represents the main concepts of AT (see Section II) with extensions like

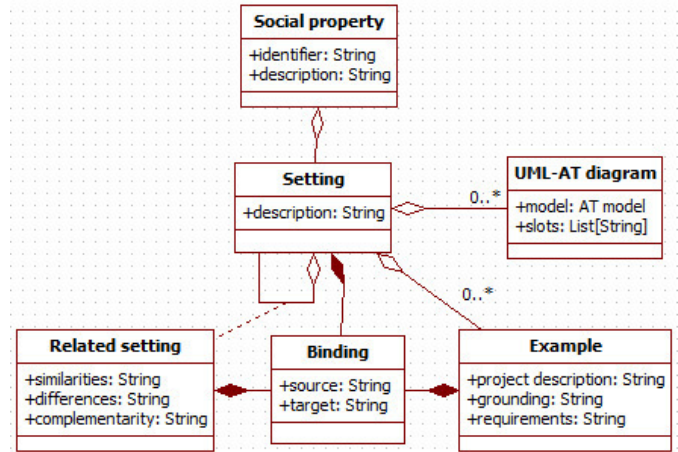

Fig. 2. Structure to describe social properties.

inheritance and decomposition relationships, constraint expressions, and the concept of *artefact*. The properties in models can be constant or variables to ground when the setting is applied in a simulation. Settings may have *examples* that help to understand their application.

The *related settings* link settings from different *social properties* whose contexts or artefacts are related. For instance, settings about family, care organization, and normative frameworks can be related. The *related settings* also discuss similarities and differences among linked settings.

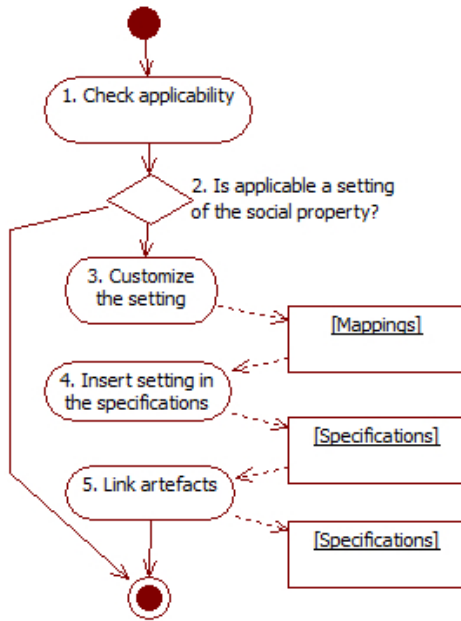

Finally, the *bindings* are pairs of names that associate *settings* or *settings* with *examples*. They indicate which pairs of variables or variable-value must be mapped between the settings or with the example. For instance, they indicate that the outcome of an activity is the tool in a related setting.

As the introduction discussed (see Section I, the settings of a social property can correspond to different levels of detail (e.g. abstract requirements or target simulation platform), contexts (e.g. cultures or countries), and targeted to different transformations (e.g. simulation platforms or documentation). These properties assist in the specification of AAL simulations with predefined parts of models and suggest potential alternatives for model refinement.

### IV. USING SOCIAL PROPERTIES

The *social properties* of the previous section provide the reusable social knowledge to add new information to AAL specifications in a semi-automated way. The activity diagram in Fig. 5 depict this process.

Task 1 *Check applicability* considers whether a social property can be applied in a given context through its *settings*. The specification of a setting includes a description, models, and transformations that can be checked against the current specifications. Usually, a setting can be applied to some specifications to introduce a complete set of new entities. If the setting is going to be connected to some elements already existing in the specifications, some additional checkings are needed, considering that variables can match any value.

Fig. 3. Process to apply the *social properties*.

In task 3 *Customize the setting*, the engineer chooses the values to instantiate the non-grounded variables. These values can already appear in the specifications or the user can directly provide them.

Task 4 *Insert setting in the specifications* adds the customized setting to the AAL specification. This is usually done through the setting transformations, modified for the specific context.

In task 5 *Link artefacts*, engineers can introduce additional relationships to connect artefacts. For instance, they can specify that an added artefact is a subtype of an existing one.

Transformations are not only used to add information to specifications. Some social properties represent features to keep or avoid in specifications. For instance, properties can represent AT contradictions (see section II). In that case, running setting transformations over specifications helps to check them.

## V. CASE STUDY: AAL FOR PEOPLE WITH MOTOR PROBLEMS

The attitude towards technology depends on many factors. The level of adoption of mobile technologies regarding age is a classical one [15], [16]. The design of AAL systems must consider these variations in order to provide effective solutions. This case study considers a monitoring system and how it can be adapted to the age of its final users using social properties.

The proposed monitoring system has two main functionalities: monitor and ask for assistance. The first one watches the caretaker user and tries to determine when the caretaker may need assistance. In this last case, it uses some communication device to call the caregiver.

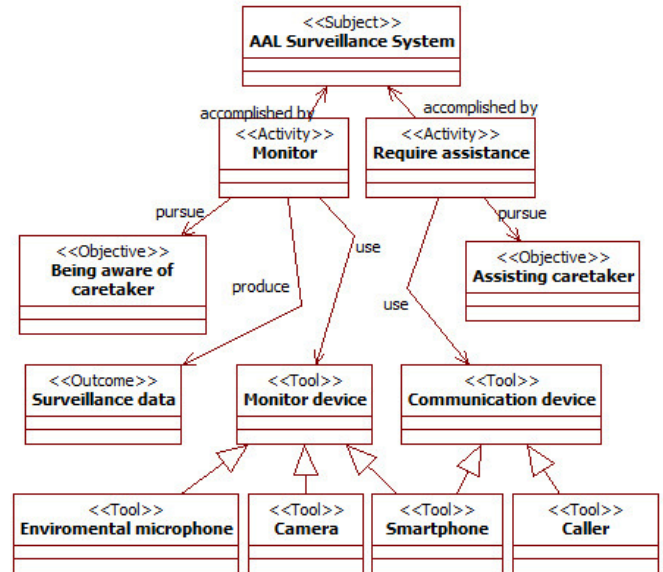

Fig. 4. Enviroment of the AAL system.

In order to support the previous functionality, the system has several devices. It can run a specific app in the caretaker's smartphone. The sensors in the smartphone can provide information on the state of its user. Alternatively, it can use some environmental microphones and cameras to gather information. Microphones are sometimes less reliable, particularly in noisy situations. Cameras require a higher computational capacity than the other devices to process their video.

Regarding users, elderly people are less prone to use smartphones, while youngsters always keep them close and use them continuously. Moreover, youngsters are usually more comfortable with being under video surveillance than elders, that perceive it as highly intrusive. The attitude towards microphones is worse in youngsters than in elder, as the first group is more conscious about the capabilities of modern devices.

This case study is going to use the UML-AT language (see Section II) to model all these elements. The interested reader can find a more complete description of the language in [6], [11].

Let start modelling the AAL solution. From the point of view of AT, the *AAL Surveillance System* is a *subject* able to carry out two *activities*: *monitor* and *require assistance*. The purpose of executing these *activities* is represented with the *objectives being aware of caretaker* and *assisting caretaker*. In these *activities*, it uses two types of device that are *tools*: some *monitor devices* to watch the caretaker, and *communication devices* when it needs to call the caregiver. Given its capabilities, the smartphone is the only device that belongs to both categories. Fig. 4 shows this information.

In this case, the *social properties* report the information on the usual preferences of users. For the sake of simplicity,

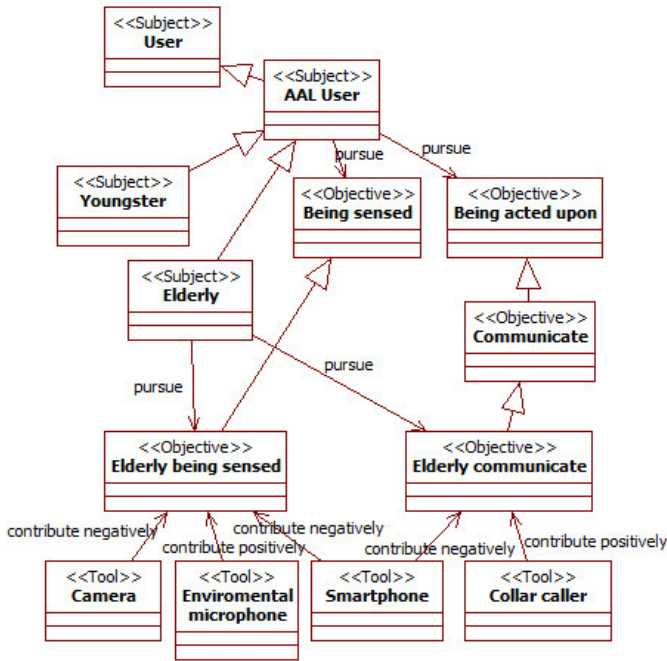

Fig. 5. Social property for AAL users: models of settings.

the case study considers one *social property* with two *settings* that summarize the usual preferences of elderly and youngster users. In UML-AT, both *users*, *elderlies*, and *youngsters* are *subjects*. In relation to AAL solutions, these users have two main objectives: *being sensed* and *being acted upon*. *Communicate* is modelled as an *objective* sub-type of *being acted upon*. Fig. 5 shows this information.

The preferences of users on devices are represented using contribution relationships on *objectives* (see Section II). These relationships allow specifying when an artefact (i.e. any AT element) helps or damages the possibilities of achieving the purpose of other artefacts. Fig. 5 describes how users prefer interacting with different devices according to their age. The models of both settings for elderly and youngster are combined to simplify their discussion.

The objectives *being sensed* and *being acted upon* are sub-typed in order to acknowledge how different *subjects* have different preferences regarding their satisfaction. In the case of *elderly subjects*, they prefer trying to achieve the *objective elderly being sensed* using the *tool environmental microphone* (relationship *contribute positively*) instead of the *tools camera* or *smartphone* (relationship *contribute negatively*). In the same way, for the *objective elderly communicate*, it is preferred to use a *collar caller* that they usually carry with them, instead of the *smartphone*, that they take with them less and find more difficult to use.

The diagram does not include the preferences of the *youngster subject*. That part of the model is similar to the one discussed for the *elderly subject*.

The application of the *social property* in Fig. 5 to the AAL solution in Fig. 4 follows the process described in section IV.

The three steps are as follows for the elderly setting.

Task 1 *Check applicability* consider whether the social property can be used in the context of the current specifications. Here it is used to add information on the users' preferences as new model elements. There is no constraint that precludes its application.

In task 2 *Customize the setting*, engineers decide how to map those elements that are common to the specifications and the property. The mapping here just indicates that the *tools* that appear with the same name in the specifications and the property are the same artefacts, e.g. *camera* and *smartphone*.

Task 4 just merges both models using transformations. This adds the entities and relationships from the setting to the specification of the AAL system.

Finally, task 5 *Link artefacts*, adds additional relationships among artefacts. In this case, they need to indicate how to meet the users' objectives, so that their experience with the AAL system is positive and they use it. The specifications model this information with new contribution relationships. The user's *objectives elderly being sensed* and *elderly communicate* respectively contributes positively to the AAL system *objectives being aware of caretaker* and *assisting caretaker*.

After introducing this information, engineers can perform an automated analysis of the specifications. Navigating relationships from objectives, they can discover the user preferences. Changing the *setting* to use that for youngster, changes the preferences. This indicates that the AAL system needs to be aware of the age of the user.

## VI. RELATED WORK

This work is related to several areas of research: studies on people, their features and behaviour linked to socio-technical systems; and the development and simulation of AAL solutions. The first group of works is related to sources of knowledge for *social properties*, and how to model it. The second group is linked to the tradeoffs of using these properties in development.

Studies with actual people provide information on the relevant attributes and processes to consider when designing AAL solutions. Some of them (e.g. [17]) are focused on the problems that appear in the daily life of certain population groups and are useful to characterize them. There are also works related to the attitudes of people towards certain aspects of socio-technical solutions, like design issues [15] or technologies [16].

Those studies are useful sources of information to design AAL solutions. However, engineers must perform an important work to extract that knowledge, adapt it to their context, and transform it to requirements. There are already works intended to provide some design knowledge as reusable patterns, mainly in the wider context of Ambient Intelligence [18], [19]. However, these are more at the level of system design, like traditional design patterns [8].

In this context, social properties are means to reuse social knowledge, and are at a higher level of abstraction than available patterns. Both types of pattern can be used in a

complementary way. The use of patterns facilitates reuse and communication, and thus reduces the effort on these development aspects.

Currently, most of AAL developments follow traditional practices (e.g. [1], [20], [21]). Experts and engineers design the solution, then the code and relevant hardware is produced, and finally it is tested. Research [5] has already discussed the problems regarding the high costs and failures of projects following these approaches. The use of VLLs tries to mitigate them. Both with and without VLLs, some works propose the use of MDE techniques [22]. Working with models facilitates the automated generation of systems using MDE techniques.

Social properties support all these alternative ways of development. Settings can be defined at different levels of abstraction and for different targets. For instance, there can be transformations for several target simulation platforms. Nevertheless, the effort to adapt the property to a specific development can largely vary.

## VII. CONCLUSION

This paper has introduced *social properties* as means to deal with social knowledge in AAL developments, particularly in the context of VLLs. They support works by providing ready-to-use knowledge and ways to integrate it in the technical design.

The knowledge can be extracted from different studies following the paradigm of AT [10]. The paradigm offers the tools to study settings, and previous works help to specify [6] them as properties.

This work also proposes a process to apply the properties. It is based on the use of MDE transformations. These transformations support checking the appearance of properties and adding their information to specifications.

The case study has shown how the simulation of an AAL solution can be tailored to consider different features of its user or their social context. Social properties allowed the quick change of the simulation in order to distinguish elder and young users, and the modifications this brings to the environment of the system.

The previous work is still ongoing. The effective application of social properties requires a relevant number of them to model complex contexts. Moreover, transformations need to be adapted to the MLs of the specifications where they are applied and the target simulation platforms. Work in this line was reported in [11] for UML-AT and MLs for MASs. Second, the definition of complex social structures requires being able to provide more information on the properties of artefacts. The current language for constraints is based on the Object Constraint Language (OCL) [23], and limited regarding social issues. A tailored domain-specific language is currently being designed. Third, further validation and assessment of the utility of properties in AAL development is needed. Experiments until now correspond to research projects in AAL.

## ACKNOWLEDGMENT

This work has been done in the context of the projects “Fostering a Transition towards Responsible Research and

Innovation Systems (FoTRRIS)” (grant 665906) supported by the European Commission in the Horizon 2020 programme, “Collaborative Ambient Assisted Living Design (ColoSAAL)” (grant TIN2014-57028-R) supported by the Spanish Ministry for Economy and Competitiveness, the research programme MOSI-AGIL-CM (grant S2013/ICE-3019) supported by the Autonomous Region of Madrid and co-funded by EU Structural Funds FSE and FEDER, and the “Programa de Creación y Consolidación de Grupos de Investigación” (UCM-BSCH GR35/10-A).

**Abstract**—Demand peaks in electrical power system cause serious challenges for energy providers as these events are typically difficult to foresee and require the grid to support extraordinary consumption levels. Accurate peak forecasting enables utility providers to plan the resources and also to take control actions to balance electricity supply and demand. However, this is difficult in practice as it requires precision in prediction of peaks in advance. In this paper, our contribution is the proposal of data mining scheme to detect the peak load in the electricity system at country level. For this purpose we undertake the approach different from time series forecasting and represent it as pattern recognition problem. We utilize set of artificial neural networks to benefit from accurate detection of the peaks in the Polish power system. The key finding is that the algorithms can accurately detect 96.2% of the electricity peaks up to 24 hours ahead.

### I. INTRODUCTION

ELECTRICITY consumption peaks appear in the electricity system as a consequence of collective behavior of end users which is influenced by many external factors [1]–[3]. An example of an aggregate behavior may happen when relatively large group of consumers is turning on their home air conditioners within a short time span, as a consequence of a hot weather. This aggregated behavior is easy to notice since temperature increase affects a large population which might cause the peak. However, there are other factors that are likely to influence users' electrical consumption and therefore, it is not trivial to foresee what will be the consumption level and, in turn, to detect high loads in advance.

Consumption peaks may cause serious challenges to electricity providers because they need to over-dimension the grid in order to support the abnormally high consumption load. Managing these peaks is crucial for the providers since energy scarcity can lead to severe consequences such as power outages. An alternative approach to overreach these peaks and to reduce the costs of over-dimensioning and enormity is to balance the grid with the introduction of intelligent methods for controlling them. Controlling the peaks can be done in several ways, such as performing load balancing and developing dynamic and intelligent pricing strategies taking into account that end

users are sensitive to price and they may reduce the consumption whenever the electricity price is high.

The proposed paper is focused on detection of electrical power consumption peaks in the Polish power system by relying on historical data for both: electricity and weather conditions including temperature and humidity. The contribution to the research is twofold. First, we deal with peak detection as binary classification problem unlike to most legacy studies formulating the problem as time-series forecasting. Second, we propose a wide set of artificial neural network parameters to assure the problem is thoroughly tested for the benefit of precise classification. We further experimented with data from Polish power system, and were able to prove the high accuracy in peaks detection.

The rest of this paper is organized as follows. In the second section the literature review on similar problems is presented. The data characteristics and their mapping into binary classification problem is presented in section three. The fourth section deals with the experiments carried out and their results. The paper ends with concluding remarks in the last section.

### II. LITERATURE REVIEW ON SIMILAR PROBLEMS

Forecasting the energy consumption and load demand peak has been intensively studied. In recent years, the extensive research stream of forecasting models was based on traditional algorithms including time series analysis, regression and grey models, as well as soft computing algorithms including genetic algorithms, fuzzy logic and other machine learning methods.

Time series models represent the future values based on previous observations. The models which are based on time series have many forms adequate for forecasting electricity consumption volume and peak demand load in the electrical grid. For instance, the problem of forecasting the monthly peak demand of electricity in north India was studied by Ghosh [4] who combined two different time series: a multiplicative Seasonal Auto-Regression Integrated Moving Average (SARIMA) and Holt-Winters multiplicative exponential smoothing. In turn, Mati et al. [5] used time

series to forecast the electricity demand in Nigeria. Garcia-Ascanio and Mate [6] used the interval time series to forecast the monthly electricity consumption per hour in Spain.

Another way to predict the energy consumption is to use statistical regression models that correlate the power consumption with a number of influencing variables. Energy distribution companies often use regression analysis to forecast the variable (dependent) values based on one or more independent (predictor) variables. The relationship can be described using simple linear functions (e.g. linear regression) or large non parametric models like Gaussian and neural network. Simple linear, multiple linear, quadratic and exponential regression models are typically used to forecast short term load demand (usually five minutes to one week ahead) with hour by hour load data. The quantile regression is recommended to predict the peak electricity demand as well. Gibbons and Faruqi [7] developed a method that used quantile regression to model the daily peak demand, and subsequently used a loss function to estimate a quantile for annual peak prediction. In order to model system uncertainty, inexactness and random daily 15-minutes peak power demand at distribution trans-formers, Nazarko and Zalewski [8] used a fuzzy regression model expressing the correlation between substation peak load and other customer explanatory variables.

Lack of detailed data or limited dataset make difficulties in predicting future peak demand value which is critical for the dispatching center to handle current operations (short-term forecasting) or to plan development and modernization of the power system (long-term forecasting). In such circumstances artificial neural networks (ANN) appear to be excellent technique to deal with noisy and incomplete data. ANN has been used to predict the hourly electricity consumption prediction model in Saudi Arabia [9], Nigerian Electrical Power System [10], the long-term demand of electricity in Turkey [11] and in Iran [12]. The multilayer perception model (MLP) to forecast the long-term energy consumption in Greece was applied by Ekonomou [13]. He compared the results of the model with those resulting from the support vector machine and the linear regression model. The applied model occurred very promising. Another comparative study among ARIMA, ANN and multiple linear regression (MLR) models was performed by Kandananond [14] who predicted long-term electricity demand in Thailand.

Lastly, it is worth mentioning that analysis of the last decade of electricity demand data in European countries shows trend that the peak demand (largest daily demand) throughout the year usually occurs in the winter, during the weeks before Christmas or in the summer [15]. Factors causing this increase in electricity demand include the cold weather (increased use of electrical heating devices) or prolonged period of abnormally hot weather (increased use air conditioners).

### III. DATASET CHARACTERISTICS

#### A. Load data

This study was performed based on historical data representing energy consumption in Polish power system [16]. The data set included 70128 observations (hourly data) covering time span between January 1<sup>st</sup>, 2008 and December 31<sup>st</sup>, 2015. Time series of the power system load exhibit annual, weekly and daily seasonal cycles as shown in Fig. 1. The daily curves differ in shape depending on the day type (workday, Saturday, Sunday) and season. Fig. 2 shows a smooth profile shape with relatively little electricity consumption in the early morning, a clearly defined peak in the evening and a slightly smaller defined peak in the late morning.

Changes in the daily load shape and load level during the year are influenced by weather conditions including temperature, wind speed, cloud cover, humidity, precipitation and daylight hours. The weekly cycles are determined by workdays and holidays. The multiple seasonal cycles in the load time series as well as trend and nonstationarity in mean and variance have to be captured by a forecasting model. Electricity load when it is considered as time series cannot be modeled directly and additional treatments such as detrending, or decomposition are needed.

Fig. 1. Weekly load data covering time span between 1st October 2015 and 30th November 2015

Fig. 2. Daily load data on October 23th (Friday) and 24<sup>th</sup> (Saturday), 2015.

### B. Weather data

Weather is one of the most important independent variables for load forecasting, often described by temperature and humidity as presented in Fig. 3. The effect of weather is most prominent for domestic and agricultural consumers, but it can also alter the load profile of industrial consumers. Unexpected weather conditions are often cited as the tipping point that can cause unreliability in the system by decreasing the efficient supply of power. For instance, unpredicted thunderstorms in the middle of sunny day are one of the environmental factor that can decrease the temperature and thus causing overestimated load forecast [17], resulting in producing more power than required.

Temperature can also alter the conductivity of the transmission lines. Thus, it can affect the overall carrying capability of the transmission lines. High temperature can increase not only the resistance of the transmission lines, but also it can influence the reactance of line, as well as induced expansion of transmission line length [18].

There is a high positive correlation between temperature

Fig. 3. Weekly average weather data in Warsaw in 2015

and load during summer season and there is a negative correlation between temperature and load during winter. This means that in the summer an increase in temperature will result in load increase whilst decrease in temperature will result in decrease in average daily load and also lowering the peak demand. In winter, the opposite trend is observed as decrease in per degree temperature will results in increase of electric load. This is because in summer increase in temperature affects consumers who use electricity for cooling purposes (air conditioners and fans), whereas in winter electricity is used for heating purposes. Hence, in winter there is negative or inverse relation between temperature and consumption volume [18].

Another weather factor influencing overall load is humidity. Formally, humid air was called not just the moist air but was referred as the mixture of water vapors and other constituents of air and humidity was defined in terms of water contents of this mixture called the absolute humidity [18]. In everyday life it is called relative humidity and is expressed in percentage. It is common observation that

humidity can increase apparent temperature while it has no effect on the real temperature. This means humidity can make a 30 °C temperature to be felt say 35 °C.

Although humidity has no effect on real temperature it can intensify the severity of hot climate. Therefore for the prediction of daily load at domestic consumers it is recommended to consider apparent temperature instead of real temperature. When dealing with mixed consumers, e.g. including industrial, agricultural and domestic, temperature humidity index can be employed as the factor influencing the load forecasting.

Finally, due to the high redundancy between weather and load data, a proper features selection approach in this research has to be considered.

### C. Determining peak values

In order to determine peak load values, the generic function quantile was used [19]. The function produces sample quantiles corresponding to the given probabilities by the weighted averaging of order statistics  $z_g$ :

$$Q_p = (1 - \gamma)z_g + \gamma z_{g+1}, \quad (1)$$

where  $\gamma = np + m - g$ ,  $n$  is number of observations,  $g = \text{floor}(np + m)$  and  $m = 1 - p$ .

In this study, peak load was determined as the load value equal or above 99th percentile for a given load distribution when grouping load in each week, as presented in Fig. 4.

Black curve reflects real hourly electricity consumption observed in November 2015. Blue line shows average load within particular week, red line shows the behavior of threshold values above which the loads are recognized as peak values. Finally, green dots stand for peak load.

## IV. NUMERICAL EXPERIMENT

### A. Implementation and classification technique

In our case, all the numerical calculations were performed

Fig. 4. Weekly peaks identification in the load data based on the 99th quantile of the load distribution (November 2015 data)

on personal computer with the following parameters: Ubuntu 16.04 LTS operating system and Intel Core i5-2430M 2.4 GHz, 2 CPU\*2 cores, 8 GB RAM. R-CRAN [20], which is an advanced statistical package, as well as an interpreted programming language, was used as the computing environment. For training neural networks we used the BFGS algorithm, available in the *nnet* library [20]. A logistic function was used to activate all of the neurons in the neural network and initial vector with weights was chosen randomly using uniform distribution.

To compare the neural networks obtained for different number of hidden neurons we used the following measures: (1) AUC (area under the Receiver operating characteristic (ROC) curve), (2) classification accuracy, (3) Sensitivity (true positive rate), (4) Specificity (true negative rate). Those measures are related to efficiency and effectiveness of the ANN and they have been often used for evaluation of classification models in the context of various practical problems such as credit scoring, income and poverty determinants or customer insolvency and churn [21]-[24].

The dataset was split into three parts which corresponded to the training, validation and testing samples with the following proportion. The training sample consisted of 6 years between January 1<sup>st</sup> 2008, and December 31<sup>st</sup> 2013; the validation sample consisted of one year between January 1<sup>st</sup> 2014, and December 31<sup>st</sup> 2014; and finally, the testing sample consisted also one year between January 1<sup>st</sup> 2015, and December 31<sup>st</sup> 2015.

The main criterion taken into account while learning the models is to gain good generalization of knowledge with the least error. The most commonly used measure to assess the

quality of binary classification problem is AUC. Therefore, to find the best parameters for all models and to assure their generalization, the following function was maximized:

$$f(AUC_T, AUC_V) = -\frac{1}{2}|AUC_T - AUC_V| + \frac{1}{2}AUC_V \quad (2)$$

where  $AUC_T$  and  $AUC_V$  stand for the training and validation errors, respectively.

In contrast to other machine learning algorithms, ANN required special preparation of the input data. The vector of continuous variables has been standardized, while the binary variables were converted in a way that the value of 0 was transformed into -1.

In the experiment we tried several neural network structures to get the best result. The number of neurons in hidden layer was proposed as a result of numerical procedure. We started neural network learning with small number of hidden units and then, successively, we increased number of neurons until no significant improvement in terms of models performance was observed (the number of neurons considered in the hidden layer was from 5 to 15). To avoid overfitting, after the completion of each learning iteration (with a maximum of 50 iterations - because already after 20 iterations the difference in terms of AUC between the learning and validation set began to increase), the models were checked for the error measure defined in equation (2). At the end, the ANN characterized by the smallest error was chosen as the best model. In order to achieve robust estimation of models' error, for each number of hidden neurons, ten different ANN were learned with different initial weights vector. Final estimation of the error was

TABLE 1.  
FEATURE VECTOR USED FOR MODEL ESTIMATION

Attribute No.	Description	Formula
1-5	Hour indicator (bits encoding)	$G_i, i = 1, \dots, 24$
6-10	Day of the month indicator (bits encoding)	$D_i, i = 1, \dots, 31$
11-13	Day of the week indicator (bits encoding)	$T_i, i = 1, \dots, 7$
14-17	Month indicator (bits encoding)	$M_i, i = 1, \dots, 12$
18	Holiday indicator (dummy variable)	$S$
19	Sunset indicator (dummy variable)	$N$
20-43	Load of previous 24 hours	$Z_{g-i}, i = 1, \dots, 24$
44-51	Average load observed over previous hourly intervals	$avg\{W_{g-i}, \dots, W_{g-i+[+1]}\}, i = 3, 6, 9, 12, 15, 18, 21, 24$
52-57	Load in the same hour of the previous week	$Z_{g,d-i}, i = 2, \dots, 7$
58-65	Linear trend of the load observed over previous hourly periods	$Trend\{W_{g-1}, \dots, W_{g-i}\}, i = 3, 6, 9, 12, 15, 18, 21, 24$
66-73	Average temperature observed over previous hours	$avg\{T_{g-1}, \dots, T_{g-i}\}, i = 3, 6, 9, 12, 15, 18, 21, 24$
74-81	Average temperature observed over previous hourly intervals	$avg\{T_{g-i}, \dots, T_{g-i+[+1]}\}, i = 3, 6, 9, 12, 15, 18, 21, 24$
82-89	Average humidity observed over previous hours	$avg\{H_{g-1}, \dots, H_{g-i}\}, i = 3, 6, 9, 12, 15, 18, 21, 24$
90-97	Average humidity observed over previous hourly intervals	$avg\{H_{g-i}, \dots, H_{g-i+[+1]}\}, i = 3, 6, 9, 12, 15, 18, 21, 24$

Notation [+1] stands for the next element from the set of indices  $i \in \{1, 3, 6, 12, 24\}$  e.g.  $avg\{T_{g-1}, \dots, T_{g-3}\}$  or  $avg\{T_{g-6}, \dots, T_{g-9}\}$ . Source: own preparation.

computed as the average value over ten models and for each number of hidden neurons.

### B. Feature vector

We focused on the next-day peak power demand detection. To forecast the peak, we constructed a feature vector with attributes as presented in Table 1. The attributes were constructed based on time series with hourly electricity demand. Additionally, other features were collected, including temperature, humidity, and calendar variables.

Electricity demand varies over time depending on the time of day (daily cycles), day of the week (weekly cycles), day of the month (monthly cycles), season (seasonal cycles) and occurrence of holidays. Therefore, we enriched the analysis with additional 18 variables including 5 variables describing the hour, 5 variables associated with the day of the month, 3 variables associated with the day of the week, 4 variables associated with the month, 1 variable indicating a holiday and 1 variable indicating the sunset in a particular hour. All above variables were derived in the following manner (bits encoding instead standard dummy encoding): first the categories were encoded as ordinal, then those integers were converted into binary code, then the digits from the binary string were split into separate columns. This encodes the data in fewer dimensions than standard dummy encoding.

The main variables taken into account in the forecasting process are those derived directly from the time series. The features were created by the decomposition of the time series, and they define, among others, linear trend and actual demand at certain intervals, taking into account up to 7 days of the history.

### C. Feature selection

In order to identify dependence between observed peak load and explanatory variables Kolmogorov–Smirnov statistics was applied as presented in Table 2.

The Kolmogorov–Smirnov statistic quantifies a distance between the empirical distribution function of the sample and the cumulative distribution function of the reference distribution, or between the empirical distribution functions of two samples. In our case we derived two samples, i.e. distribution for peak cases and distribution for non-peak cases. Based on the obtained p-values it was identified that most of the considered features have different distributions within positive and negative cases. The only exceptions are observed for the following variables (0.05 statistical significance assumed): temp\_1\_15, temp\_1\_18, hum\_1\_21, hum\_1\_24 and hum\_avg\_19\_21.

Next, the Chi2 ( $\chi^2$ ) test was used to determine whether there is a significant difference between the expected and the observed frequencies in one or more categories of each independent variable and dependent variable. Each independent variable was divided into 10 disjoint groups based on the quantiles values of the particular distribution (based on deciles). Then each feature and dependent variable have created a contingency table  $2 \times 10$ . Finally, based on the aforementioned table, Chi2 test was applied.

Proposed test showed that there is statistically significant dependence between independent variable and all dependent variables. On the other hand, in case of the categorical features, variables indicating holiday days and day of the month were not statistically significant (please refer to Table 3 for details).

The third approach to determine appropriate set of

independent variables was Area Under the ROC curve (AUC). In this case discriminatory power of each variable was checked out in the following manner:

- quantitative and ordinal variable were sorted in ascending order; categorical variables were sorted in ascending order based on the conditional probability of belonging into positive cases.
- ROC curve was determined. The actual values of the sorted variable served as the score values of the classification model.
- AUC measure was computed using trapezoidal integration.

Final AUC values for all the features are presented in Table 4 (quantitative variables) or Table 5 (categorical variables).

In the case of quantitative variables, the greatest discriminatory power can be assigned to: d\_6, d\_5, trend\_1\_18, trend\_1\_15, d\_7, trend\_1\_3 and t\_1 attributes. Out of categorical variables, two of them – hour and week\_days – have the best performance.

Obviously, there is a strictly linear dependence between

some features, which means that the redundancy in the data could be observed. There is no need to include for instance variable t\_4 and t\_5 in final input vector, due to collinearity. Therefore, from the best set of attributes, the variables having Spearman correlation coefficient greater than 0.6 were removed. Eventually, the final set of attributes is presented in Table 6.

#### D. Results

In order to benefit from the optimal score threshold which determine the peak (score above the threshold) or normal load (score below the threshold), Youden's J statistic [25] was employed. The optimal cut-off is the threshold that maximizes the distance to the identity (diagonal) line. The optimality criterion is defined as:

$$\max(\text{sensitivities} + \text{specificities}) \quad (3)$$

In this research optimal cut-off was identified at 0.1111.

The classification results obtained on training, validation and testing datasets are presented in Table 7 (upper and lower part). Importantly, the models exhibited stable performance in terms of the classification quality on all three datasets. For the testing sample the accuracy, which measures of how many correct forecasts the model makes, is up to 90.5%, and this is observed for the neural networks with six and eleven hidden neurons. The AUC measure for the models is ranging between 0.947 and 0.967. In terms of the sensitivity, which is proportion of peaks that are correctly identified as such, the results are ranging between 0.915 and 0.962. Finally, specificity which measures the proportion of non-peaks that are correctly identified as such is ranging from 0.855 to 0.904.

Taking into account that simpler model should be preferred over the complex one, the neural network with 9

hidden neurons represents fair tradeoff between the complexity and the classification quality.

Additionally, to give also a graphical view on the performance of the proposed model with 9 neurons, one day-ahead peak forecast obtained for the randomly drawn test period (five weeks in October 2015) is shown in Fig. 5. From the figure we can observe that the peak loads are correctly predicted in seven cases – green dots represent true positive classification. Three peak loads, marked as red dots, are incorrectly classified as a normal loads (false negative classification). Finally, in some cases (yellow dots), neural network claims that there will be peak load in one day ahead, but actually there was no peak (false positive classification). For the clarity of the Fig. 5 True negative class was not provided as it constitutes for the overwhelming majority.

The results of the numerical experiments can be summarized as follows:

- Peak demands in Poland are mostly affected by such features as day of the week, temperature, humidity, load in previous hours and the load trend observed in previous hours;
- The best results were obtained for the neural network with 9 hidden neurons;
- Predictive power of the model is considered to be excellent what was confirmed by AUC, accuracy, sensitivity and specificity measures;
- High true positive rate confirms the models ability to correctly classify the real peaks in the system.

## V. SUMMARY AND CONCLUDING REMARKS

The research addresses the problem of predicting electrical consumption peaks as an input into load balancing and smart pricing strategies. This was done by mapping the problem into a binary classification task aimed to detect the peaks using the features based on previous consumption and the weather data.

The contribution of this study provides the proof that models can capture the complex nonlinear effects of historical load, temperature, humidity and calendar effects. The classification results demonstrate that neural networks models perform remarkably well on the historical data.

The most promising results were produced by applying artificial neural network with 9 hidden neurons what led to predicting 96.2% of the true peaks (sensitivity) as observed on the testing dataset. It is worth mentioning that the algorithm was to favor false positives over false negatives as the latter are having less impact on electrical power grids. This is because a false positive, which is predicting a peak that is not present, has significantly fewer consequences than not predicting peaks which are present. Thus, high true positive rate is much more favored after than high precision of the model.

There are number of practical applications to make use of next-day peak power demand identification. Forecasts of the peak demand are useful for both, network capacity planning and investment decisions. In addition, the knowledge on the timing of the peak demand is important for network maintenance planning. An accurate classification can be used to improve decision making and the correct classification can reduce both costs and risks for the entities operating on the electricity markets.

## ACKNOWLEDGMENT

The study was cofounded by the National Science Centre, Poland, Grant No. 2016/21/N/ST8/02435.

**Abstract**—In the context of European climate goals municipalities have an increasing interest in an accurate estimation of current and future energy demand in buildings, as the domestic energy consumption is one of the major adjusting screws for the reduction of electrical and thermal energy consumption, whereas the demand for space heating has the highest impact. As part of the ongoing GEWISS project it is planned to create a geographical information system (GIS) to visualize domestic and industrial heat consumption in the city of Hamburg (Germany) to support political decision making by linking the development of urban areas and the district heating grid. Additionally, it is planned to provide simulation capabilities to offer planning assistance for future development. This paper will present the underlying agent-based simulation system that is used to simulate the development of the building stock. Thereby, the simulation approach and first results regarding the development of the renovation state of the building stock based on a study about the renovation behavior of different types of home-owners of detached and terraced houses will be presented.

## I. INTRODUCTION

IN THE context of European climate goals as well as the Energy Transition in Germany, municipalities have an increased interest in an accurate estimation of current and future energy demands in the building and traffic sector. The domestic energy consumption is one of the major parameter for the reduction of both electrical and thermal energy consumption, whereas the demand for space heating plays the biggest role [1]. Thus, profound knowledge about the building stock and its consumption is needed to tackle the challenge of energy transition towards non-fossil sources and their efficient integration into the energy mix. Future energy planning needs concepts like Smart Cities, a collective term for holistic development concepts that aim at constructing cities that are more efficient, technological advanced and environmentally sustainable [2]. This includes the knowledge of spatial distribution of energy consumption in an urban context.

For this purpose the ongoing *GEWISS* (Geographical Information and Simulation System for Urban Heat Flows, 2014-2018) project [3]<sup>1</sup> creates a tool based on geographical information systems (GIS) to visualize domestic and industrial heat consumption in the city of Hamburg, Germany. The tool supports political decision making by linking the development

of urban areas and the district heating grid. The grid-based heat supply needs to be planned with respect to the existing as well as future building stock. Aspects such as the conversion of urban areas, redensification, redevelopment or demolition as well as renovation of buildings should be aligned to locally available heat sources. Therefore, it is necessary to collect and analyze the required data with respect to the spatial location in a GIS. The goal of the *GEWISS* project is to provide such a GIS with information about heat demand and supply as well as simulation capabilities to offer planning assistance for future development [4].

This paper will present the agent-based simulation system of the *GEWISS* project that is going to be used to simulate the development of the building stock in Hamburg. Currently, it focuses on the renovation behavior of different types of home-owners of detached and terraced houses. Thereby, it simulates how the renovation level of the buildings and depending on that their heat energy demand could develop from 2016 to 2050. Future versions of the simulation system will support other types of residential buildings like apartment houses as well as non-residential buildings like factories or administration buildings. Apart from the renovation of buildings their demolition and reconstruction as well as aspects like redensification are also planned to be supported by the simulation system. In order to simulate the renovation behavior of different types of detached and terraced house owners, a study about motivations, barriers and target groups for energetic building renovation in Germany [5]<sup>2</sup> is taken as a basis to develop different types of home-owner agents implementing different renovation behavior. The agent-based simulation system is realized using *Repast Symphony* [6]. Figure 1 illustrates the types of buildings that are part of the current version of the simulation system (as these types are covered by the study from [5]) by showing a map extract from a residential area in the City of Hamburg where the building stock mainly consists of detached and terraced houses.

The remainder of this paper is structured as follows: The next section will give a brief overview about related work. Section III will describe the simulation approach before Section IV describes the developed simulation system in detail.

<sup>1</sup>German publication

<sup>2</sup>German publication

Fig. 1. Map extract from Hamburg showing a residential area with detached, terraced and apartment houses in the district of Othmarschen.

Afterwards, the simulation results are presented in Section V. Finally, Section VI concludes the paper and gives an overview about future work.

## II. RELATED WORK

The simulation conducted in this paper is related to the work done in [7] where the building typology designed by the German Institute for Housing and Environment (IWU)<sup>3</sup> was assigned to every building in the digital cadastre of Hamburg (ALKIS) in order to produce estimates for heat demand of individual buildings. The study conducted in [7] took into account the difficulties associated with a typology-based heat demand calculation approach like e.g. assumptions about building shell, incomplete data in digital cadastres, lack of data on renovation levels or lack of data on heating systems, and validated the results against a data-set of building energy certificates and the consumption values therein. Thereby, the authors found that while using the consumption-corrected heat demand values of the IWU-typology for individual buildings is rather difficult, using these values for groups of buildings, taking advantage of averaging-out-effects, does produce good results with average differences of 6% to 10% for different groups of buildings. This suggests that the typology-based heat demand calculation approach is plausible for large-scale studies or simulations like the one being conducted in this paper.

In [8] a procedure for creating a spatially referenced building stock with the population living therein in term of a

*synthetic city* for Germany is presented. The authors used data from the German microcensus (2010) [9] which contains detailed sociodemographic characteristics of individuals and details information on the type of buildings in which these individual live. Based on this data a synthetic population and building stock was created. Records from the microcensus about the construction year and number of dwelling units of buildings were used to classify buildings by their estimated heat demand. Contrasting to the approach presented in this paper, the authors of [8] developed a micro-simulation model to estimate the heat demand of synthetic building stocks, while focusing on the dweller's influence on the heat demand instead of the dweller's renovation behavior like considered in this paper.

A different approach for the calculation of building heat energy demand based on 3D building models instead of a building typology is presented in [10]–[12]. There *SimStadt* [13], a workflow-driven urban energy simulation platform, is used to calculate the heat demand based on *Open Geospatial Consortium* (OGC) standard compliant *CityGML* [14] models. CityGML is an an open, multi-functional model that can be used for geospatial transactions, data storage and for the modeling of 3D buildings. Based on the surface of the 3D building models, information about their usage and climate data the heat energy demand of the examined building stock is calculated by *SimStadt* by also considering aspects like solar irradiance and shadowing. While this results in a sophisticated simulation model and a good estimation of the buildings heat energy demand, the approach is not suitable for the Hamburg

<sup>3</sup><http://www.iwu.de/1/home/>, accessed September 11, 2017.

scenario with more than a hundred thousand buildings due to its complexity and resulting scalability issues.

### III. SIMULATION APPROACH

The main goal of the simulation is to simulate the development of the building stock in the City of Hamburg from 2016 to 2050. Therefore, aspects like renovation, demolition, reconstruction as well as redensification have to be considered for residential and non-residential buildings. Arguably, different types of owners for various types of buildings will behave differently in terms of the aforementioned aspects. Thus, the simulation system is realized as a Multi-Agent based Simulation (MABS) [15], where the various owner types are mapped to different agents. The current version of the simulation system maps five particular types of homeowners of either detached or terraced houses. These five types were identified in a study on the renovation behavior of such house owners in Germany [5]. Therefore, in its current state the simulation system focuses on the renovation behavior of these special types of residential buildings. Future versions aim at supporting the renovation behavior of other types of residential buildings like apartment houses as well as non-residential buildings like factories or administration buildings. Also aforementioned aspects like demolition, reconstruction and redensification are part of the objective.

The simulation is realized using *Repast Symphony* [6] an open source agent-based modelling environment that builds on the *Repast 3* library [16]. One key feature of *Repast Symphony* with particular interest for this project is its GIS support. *Repast Symphony* provides geographic referencing through geography projections that correlate the agents to positions in space. An agent's representation in a geography projection corresponds to a specific geographical feature, such as points, lines or polygons. *Repast Symphony* uses *GeoTools*<sup>4</sup>, an open source Java GIS toolkit that is an OGC compliant library, to provide support for the feature types described above, along with additional GIS data types and functions. *Repast Symphony*'s GIS capabilities also include support for *Environmental Systems Research Institute* (ESRI) Shapefiles [17] and a range of raster data files.

The geography projection is associated with a coordinate referencing system (CRS), which is based on the OGC standards and can be used to execute geographical queries on the topology of the agent features in the geography. Agents can query the geography to determine whether agent features overlap or are within a certain distance of, intersect with or border other agent features in the geography. Also of interest are *Repast Symphony*'s 2D and 3D GIS visualization modules, that provide tools to view running models interactively.

Another agent-based simulation tool with GIS capabilities similar to *Repast Symphony* is *GAMA* [18]. The reason for using *Repast Symphony* as part of the *GEWISS* project is that it, unlike *GAMA*, allows to model agents in Java therefore supports Java's rich ecosystem. This makes *Repast Symphony*

more suitable for the complex models and behaviors required in the *GEWISS* project. *GAMA*, on the other hand, is better suited for rapid prototyping because of its simple and easy to learn modeling language (*GAML* - *GAMA* Modeling Language [19]).

### IV. SIMULATION SYSTEM

The developed simulation system will be described in more detail below. Thereby, the structure of the simulation, its individual phases and the underlying data sources will be presented. The first part of this section will describe the data sources and initialization phase, followed by a discussion about the buildings heat energy demand calculation within the simulation. Afterwards, the different building owner agents are going to be described. Finally, the result handling of the developed system is going to be presented. The architecture of the simulation system is shown in Figure 2 in order to illustrate the interaction of the different components and the execution order of the simulation.

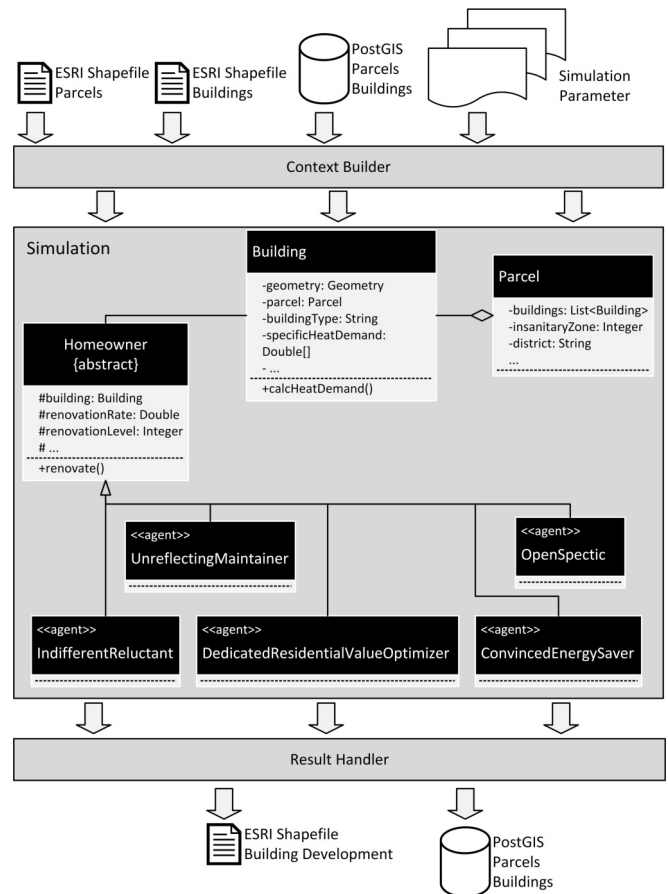

Fig. 2. Architecture of the developed simulation system.

#### A. Initialization and Data Sources

The *Context Builder* shown in Figure 2 processes various input parameters and data sources in order to create and configure the corresponding simulation objects. The buildings

<sup>4</sup><http://www.geotools.org/>, accessed September 11, 2017

whose development (with regard to the renovation) should be simulated can be imported either from an ESRI Shapefile or a PostGIS<sup>5</sup> database. The parcels on which the buildings were built can also be read from an ESRI Shapefile or a PostGIS database. On the basis of the parcels, it can be determined whether the building is located within a redevelopment zone and which development limits have to be adhered to in case of a refurbishment. The data sources of the buildings contain, among other things, information about the building's geometry, a reference to the parcel on which the building is located, the buildings type (detached or terraced house) and the specific heat energy demand.

The specific heat energy demand was determined in a study by the German Institute for Housing and Environment (IWU) for different types of buildings from different eras of construction [20]. Table I gives an overview about how the buildings are cataloged accordingly to the IWU study. Three different renovation levels have been taken into account, therefore a 3-tuple is obtained which includes the specific heat demand for the building type and era of construction in different renovation levels. Thereby, a renovation level of 0 means that the building has never been renovated since it was built, a renovation level of 1 means that the building has been renovated conventional accordingly to the German *Energy Saving Ordinance* (EnEV 2014<sup>6</sup>) and a renovation level of 2 means that the building has been renovated according to the German *Passive House Standard* which is also defined in the EnEV 2014.

TABLE I  
DIFFERENT TYPES OF BUILDINGS FROM DIFFERENT ERAS OF  
CONSTRUCTION CLASSIFIED ACCORDING TO THE IWU STUDY [20]  
(EXTRACT FROM THE ORIGINAL TABLE SHOWING ONLY DETACHED AND  
TERRACED HOUSES).

L 2016 ...	DH_L	TH_L

All information about the buildings and the underlying parcels have been extracted from the Hamburg digital cadastre. It is part of a standardized cadastral system used throughout Germany to store information about the geometry of the objects as well as additional information like building use, construction year and construction type etc. The interpretation of these attributes and the logic used for assigning an IWU

energetic building type to each building object based on its attributed is described in [7] (cf. Section II). As part of a joint work in the *GEWISS* project, the authors of [7] provided the data sources for the simulation so that each building is assigned with the according IWU energetic building type.

### B. Heat Demand Calculation

When considering heat demand calculation it is crucial to differentiate between the terms *demand*, the calculated theoretical amount of energy needed, and *consumption*, the energy actually used by the building and its inhabitants, measured by devices. The consumption usually differs from the demand due to the building user's influence and seasonal climate conditions. Within the simulation, the heat energy demand is considered. The heat energy demand ( $E_{HD}$  in  $\frac{kWh}{a}$ ) of a building is calculated by multiplying the specific thermal energy demand ( $E_{SED}$  in  $\frac{kWh}{m^2 \cdot a}$ ) for the building type according to the IWU typology ( $I_T$ ), taking into account the current renovation level ( $R_L$ ), with the gross floor area of the building ( $A_{GF}$  in  $m^2$ ) and a so-called living space factor ( $F_L$ ). This factor indicates how much of the gross floor area is used for residential purposes which is the reference area for the specific heat demand (cf. [21, p. 18] and [20, p. 40]). The total gross floor area is computed based on the cadastre as footprint area multiplied by the number of full storeys (this is a simplification that could, to some extent, under- or overestimate the gross floor area but this is neglected for the purpose of the simulation). The specific building heat demand  $E_{SED}$  is taken as computed useful heat demand for space heating (without domestic hot water) in  $kWh$  per square meter of the building's residential floor area. The climate zone is Hamburg. Additionally, a correction for typical consumptions levels is applied, see [20, p. 76-77]. This results in the following equation:

$$E_{HD} = E_{SED}[I_T, R_L] \cdot A_{GF} \cdot F_L$$

### C. Home-owner Agents

Currently, the simulation system focuses on simulating the renovation behavior of owners of detached and terraced houses. Thereby, it relies on the previously mentioned study about the renovation behavior of such owner types in Germany (cf. [5]). According to the study, there are five different types of home-owners with regards to their renovation behavior. These types and their ratio are shown in Table II. During the initialization phase the *Context Builder* creates a home-owner agent for each building read either from the ESRI shapefile or the PostGIS database and randomly maps the agent to one of the five renovator types with a probability matching the ratio shown in Table II.

Figure 2 shows that for each of these five types a specific agent class is implemented that extends the abstract *Homeowner* super-class. Thereby, the sub classes implement the super class by specifying the renovation behavior of the owner type. In fact, this is done by providing a general renovation rate for the owner type and the level of the renovation (cf. Section IV-A). The *Homeowner* super-class

<sup>5</sup><http://postgis.net/>, accessed September 11, 2017

<sup>6</sup>[http://www.enev-online.com/enev\\_2014\\_volltext/](http://www.enev-online.com/enev_2014_volltext/), accessed September 11, 2017 (German source).

TABLE II  
RATIO AND RENOVATION LEVEL OF DIFFERENT HOME-OWNER TYPES  
(DETACHED AND TERRACED HOUSES) ACCORDING TO [5].

Type	Ratio	Renovation Level
Unreflecting Maintainer	12%	1
Indifferent Reluctant	14%	1
Dedicated Residential Value Optimizer	20%	1
Convinced Energy Saver	25%	2
Open Sceptic	29%	2

provides common behavior that determines whether or not a home-owner agent renovates its building in the current simulation step. The simulation is carried out in discrete steps, where each simulation step corresponds to one year. Thus, a simulation of the development of the building stock from 2016 to 2050 corresponds to 34 simulation steps. The common agent behavior defined by the *Homeowner* super-class consists out of three steps:

- 1) Checking the renovation condition.
- 2) If the renovation condition is met, calculating the renovation probability.
- 3) Performing the actual renovation depending on the probability.

This behaviour is described in more detail below.

1) *Renovation Condition*: For an owner agent to renovate its building, the following two renovation conditions must be met:

1)

$$R_L = 0,$$

with  $R_L$  as the renovation level of the building. A renovation level of 0 means the building has never been renovated before.

- 2) The building has not been renovated within the *minimal renovation interval* ( $R_I$ ) which is a configurable parameter of the simulation:

$$R_Y \leq (C_Y - R_I),$$

where  $R_Y$  indicates the last year of renovation for the building and  $C_Y$  is current year.

2) *Renovation Probability*: The renovation probability  $R_P$  expresses the probability that a home-owner agent will renovate its building within the current simulation step. The probability is composed of the global renovation rate of the owner type ( $R_T$ ), a redevelopment area multiplier ( $M_{Ra}$ ) if the building is located in a redevelopment area and the so called neighborhood multiplier ( $M_N$ ). The redevelopment area multiplier ( $M_{Ra}$ ) is determined by increasing the redevelopment area level by 1. Accordingly, a value of 1 is obtained for a non-existent redevelopment area. In the case of an area with maximum redevelopment promotion, a multiplier of 4 is obtained. The neighborhood multiplier as well as the according neighborhood radius ( $N_R$ ) are configurable parameters of the simulation. The neighborhood radius  $N_R$  narrows the area that is considered as the neighborhood of the building. This results

in the following renovation probability:

$$R_P = R_T \cdot M_{Ra} \cdot M_N,$$

with

$$M_N = \begin{cases} 1 & \text{if no renovated buildings within } N_R \\ \gamma & \text{min 1 renovated building within } N_R, \end{cases}$$

where  $\gamma$  is a configurable parameter of the simulation.

Figure 3 shows an extract from the map of Hamburg, where redevelopment areas have been defined by the city in order to stimulate the renovation of buildings in the district Billstedt. In the case of the simulation, buildings within one of these redevelopment areas have a higher probability to be renovated than buildings outside these areas (compare equation above).

3) *Renovation Behavior*: The renovation behavior of the building owner agents is determined by their type. As a simplification for the sake of simulation, the renovation behavior is realized by setting the owned building to the according renovation level with the renovation probability calculated in the previous step. Thereby, home-owner agents of the type of *Unreflecting Maintainer*, *Indifferent Reluctant* and *Dedicated Residential Value Optimizer* renovate their building accordingly to the German *Energy Saving Ordinance* (renovation level 1). Home-owner agents of the type of *Convinced Energy Saver* and *Open Sceptic* renovate their building according to the German *Passive House Standard* (renovation level 2). In summary, the ratio and the renovation level of the different owner types are shown in Table II. The original study [5] distinguishes between renovation as a simple act of maintenance (e.g. repainting facades and fixing damages) and energetic retrofitting (e.g. adding insulation materials or changing heat supply systems), which different owner types are more or less likely to undertake. For the simulation however, we only consider renovations in terms of a energetic retrofitting with two levels of quality.

#### D. Result Handling

Result handling is done by the *Result Handler* a specialized agent responsible for collecting result data in each discrete simulation step by observing the set of buildings. In each step, it stores information about the renovation level and the dependent heat demand of the buildings. These result series are stored in the PostGIS database, so they can be linked to be building tables where the corresponding geometries are stored in order to visualize the results in form of a GIS. In addition, the *Result Handler* agent creates an ESRI Shapefile that stores the renovation level and heat demand for each building for each year, making it possible to directly load the results to a GIS tool such as *QGIS*<sup>7</sup> where they can be processed and visualized further (cf. Figure 2).

<sup>7</sup>Open Source Geographic Information System, <https://www.qgis.org>, accessed September 11, 2017

Fig. 3. Map extract from Hamburg showing detached and terraced houses in different levels of redevelopment areas in the district Billstedt.

## V. RESULTS

This section will describe first results of the simulation system with regard to the advancement of building renovation in Hamburg from 2016 to 2050 and depending on that, how the simulated renovation behavior affects the overall heat demand of residential buildings (detached and terraced houses) in the city. Table III lists the simulation parameters for a default reference scenario. It shows the global renovation rates of the five renovator types according to [5], which were allocated to the house owners according to the distribution shown in Table II. The values for the renovation rates shown in the table are estimated from the description in [5]. The minimal renovation interval states the minimum age of a building so that an owner would consider renovating it, while the vicinity range narrows the area that is defined as the neighborhood of the owner's building and the vicinity factor states the value the renovation rate is multiplied by, if a building in the neighborhood has already been renovated (cf. Section IV-C).

All detached and terraced houses in Hamburg, as identified by [7] were considered in the simulation. Thus, a home-owner agent was created for each building and configured as one of the five renovator types identified in [5] according to the ratio depicted in Table II. This resulted in a total of 151.636 buildings<sup>8</sup> respectively agents being simulated. The results of the above-mentioned simulation parameter configuration is depicted in Figure 4. There the x-axis depicts the simulated year, the primary y-axis on the left shows the overall heat demand in  $\frac{GWh}{a}$  and the secondary y-axis on the right gives information

<sup>8</sup>This is more than half of all residential buildings in Hamburg.

TABLE III  
SIMULATION PARAMETERS FOR THE *default* SCENARIO.

Parameter	Value
<i>Renovation Rates</i>	
Unreflecting Maintainer	3%
Indifferent Reluctant	1%
Dedicated Residential Value Optimizer	5%
Convinced Energy Saver	5%
Open Sceptic	2.5%
Minimal renovation Interval (year)	10
<i>Vicinity</i>	
Range (m)	100
Factor ( $\gamma$ )	2

about the number of buildings in a specific renovation level. The figure shows two aspects, first the development of the overall heat demand (sum of the heat demand of all 151.636 buildings) is depicted by the orange bars, second the progression of the renovation level. Thereby, the black curve shows the number of buildings that have not been renovated yet (renovation level 0), the blue curve shows the number of buildings that have been renovated according to the German Energy Saving Ordinance (renovation level 1) either by an *Unreflecting Maintainer*, an *Indifferent Reluctant* or a *Dedicated Residential Value Optimizer*. Finally, the green curve depicts the number of buildings that have been renovated according to the German Passive House Standard either by a *Convinced Energy Saver* or an *Open Sceptic*. Figure 4 shows how the overall heat demand of the considered buildings can be reduced by a third from about  $1500 \frac{GWh}{a}$  in 2016 to about  $1000 \frac{GWh}{a}$  in 2050 if the buildings would be renovated with the assumed rates.

Fig. 4. Simulation results of the scenario depicted in Table III. The x-axis shows the simulated year, the primary y-axis on the left the overall heat demand in  $\frac{GWh}{a}$  and the secondary y-axis on the right the number of detached and terraced houses in a specific renovation level.

The figure also shows that in order to achieve such a reduction of heat energy demand the number of non-renovated buildings has to be reduced significantly from around 150.000 to around 20.000.

The Hamburg digital cadastre does not contain information about construction materials or renovation status. Hence, all buildings were assumed to be in their initial (*baseline*) condition without any refurbishments. Although most buildings do not include the original windows or heating system from when they were constructed, but more recent ones. Nevertheless their overall efficiency is a lot lower than the *EnEV 2014* or *German Passive House* standards. Since some buildings with better than baseline renovation level are most likely present, the initial heat demand in the simulation might be higher than the demand of the actual building stock. Different qualities in regard to the buildings' conditions and thermal insulation are mapped by the construction year of the building and the linked IWU-type (cf. Table I).

Figure 5 shows a cartographic representation of the calculated heat demand in 2050 as it would be provided by a GIS. The gray buildings in the figure show either non-residential buildings or residential buildings which are neither detached nor terraced houses, so that no heat demand was calculated in the simulation for these buildings. The calculated heat demand is depicted as  $\frac{MWh}{a}$ . This means that the absolute heat demand of the buildings is represented and not the heat demand per square meter. Larger buildings therefore have a higher heat demand than small buildings. In this representation, the heat demand does not allow any conclusions on the state of the thermal insulation of the building. In contrast, Figure 6 shows the renovation level of the buildings in 2050. Thereby, it

becomes clear that only a few buildings remain in a non-renovated state (see also Figure 4).

## VI. CONCLUSION AND FUTURE WORK

In this paper we presented an agent-based simulation system that aims at simulating the building stock development in the city of Hamburg. In its current version it focuses on simulating the renovation behavior of detached and terraced house owners. Thereby, it implements different behaviors for the five renovator types identified in a study about the renovation behavior of detached and terraced house owners in Germany [5] by mapping these types to different agents and assigning them as home-owners to the building stock. The resulting simulation system uses data about the buildings and parcels from Hamburg's digital cadastre and uses the approach presented in [7] to assign an energetic building type according to the IWU-typology about different buildings types in Germany [20]. The IWU building typology also contains information about the specific thermal energy consumption of the different building types for different renovation levels. This is used to calculate the heat energy demand of the buildings. This paper leaves new construction, redensification, or change in usage/mix-usage or rebound effects out of scope. This would be required for a more realistic simulation of the heat energy demand of residential buildings in the city of Hamburg. Furthermore this work assumes fixed fractions of owner-types (cf. Table II), a socioeconomic approach could use adjusted fractions on the basis of the German microcensus [9].

The simulation system simulates in discrete steps the development of the renovation levels of the buildings from 2016 to 2050 (one step equals one year). Thereby, it determines the

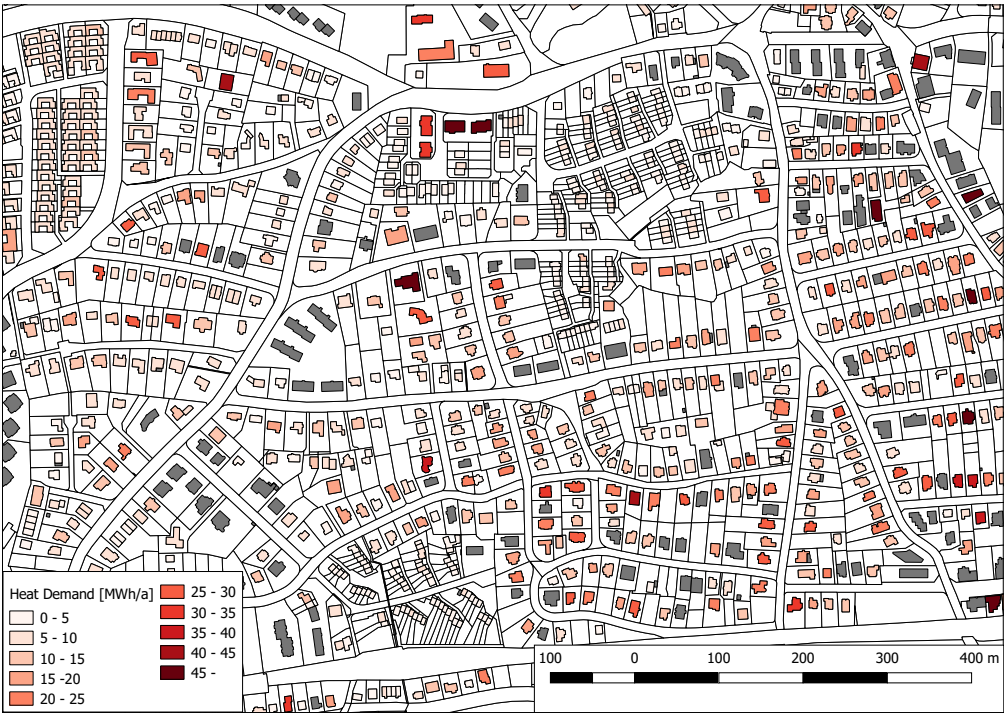

Fig. 5. Cartographic representation of the calculated heat demand for detached and terraced houses according to the IWU-typology in the district Othmarschen for the year 2050 based on the simulation scenario depict in Table III.

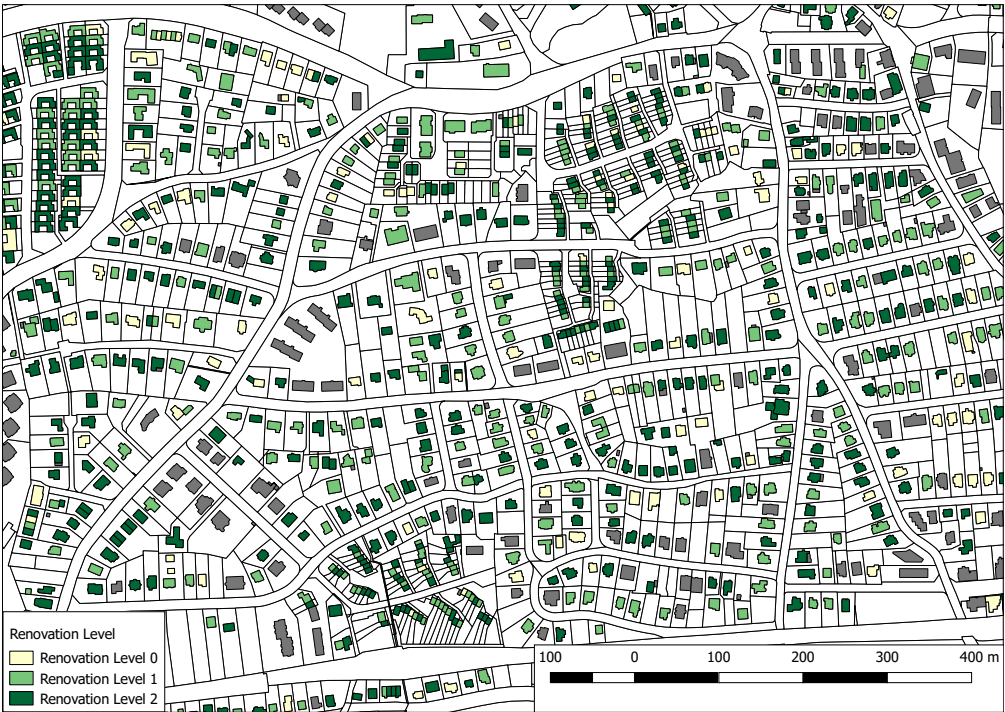

Fig. 6. Cartographic representation of the renovation level for detached and terraced houses in the district Othmarschen for the year 2050 based on the simulation scenario depict in Table III.

renovation probability for each building in each year by incorporating factors like the building's age, possible redevelopment zones, the renovation willingness of the owner type according to the study from [5] and possible neighborhood effects, where an owner is more willing to renovate his building, if he witnesses a renovation in his neighborhood. Based on this, first simulation results showed that the heat demand for detached and terraced houses in Hamburg can be significantly reduced if the owners behave according to the assumed simulation parameters. However, these simulation parameters still harbor a series of uncertainties and assumptions which have a significant influence on the renovation behavior and thus the resulting development of the heat demand. Therefore, we want to provide an exploratory tool with the simulation system to be used by interested stakeholders to investigate the influence of different measures, parameters and assumptions on the renovation behavior and thus the development of the heat demand.

Future work will focus on two different aspects. The first aspect considers the improvement of the simulation model. Here it is planned to simulate the renovation behavior of other types of building owners apart from the reviewed owners of detached and terraced houses. This includes different owner types for apartment houses, like residential building cooperatives that own multiple buildings and follow a non-profit interest, housing societies also owning multiple buildings but focusing on commercial profit or individual persons owning a block of flats also with a commercial interest.

The second aspect considers the interoperability of the proposed simulation system as well as the provision of a web visualization and user interface. Here it is envisioned to encapsulate the simulation system as a web-service following the approach presented in [22]. This is to enable the simulation system to be called from other systems in a standardized way in order to possibly be integrated in the context of a co-simulation system. Furthermore, it is planned to provide the simulation system as a data-adaptive simulation service following the concept described in [23]. Data-adaptivity in this context means that the system is adaptive with regards to its data, resulting in a data/knowledge space that is filled on demand. If the required data for a simulation request already exists it is returned directly, if not the required simulation is performed and the data/knowledge space is enriched with this information. Especially in the context of an exploratory tool, this approach allows to build up an increasingly extensive knowledge space, which allows repetitive queries to be answered very quickly, which then allows to provide an interactive web-based user interface where interested stakeholders can explore different simulation scenarios. For first-time simulation queries with no preexisting results, it is planned to develop an asynchronous solution based on *MQTT* [24], [25], which asynchronously sends intermediate simulation results to the client so that it can visualize first partial results and thus be more responsive.

## ACKNOWLEDGEMENT

This paper was developed within the *GEWISS* project, which is funded by the German Federal Ministry for Economic Affairs and Energy (BMWi) as part of the *EnEff:Stadt* program.

# 2<sup>nd</sup> International Workshop on Language Technologies and Applications

**D**EVELOPMENT of new technologies and various intelligent systems creates new possibilities for intelligent data processing. Natural Language Processing (NLP) addresses problems of automated understanding, processing and generation of natural human languages. LTA workshop provides a venue for presenting innovative research in NLP related, but not restricted, to: computational and mathematical modeling, analysis and processing of any forms (spoken, handwritten or text) of human language and various applications in decision support systems. The LTA workshop will provide an opportunity for researchers and professionals working in the domain of NLP to discuss present and future challenges as well as potential collaboration for future progress in the field of NLP.

## TOPICS

The submitted papers shall cover research and developments in all NLP aspects, such as (however this list is not exhaustive):

- computational intelligence methods applied to language & text processing
- text analysis
- language networks
- text classification
- document clustering
- various forms of text recognition
- machine translation
- intelligent text-to-speech (TTS) and speech-to-text (STT) methods
- authorship identification and verification
- author profiling
- plagiarism detection
- knowledge extraction and retrieval from text and natural language structures
- multi-modal and natural language interfaces
- sentiment analysis
- language-oriented applications and tools
- NLP applications in education
- language networks, resources and corpora

**Abstract**—In text mining, document clustering describes the efforts to assign unstructured documents to clusters, which in turn usually refer to topics. Clustering is widely used in science for data retrieval and organisation. In this paper we present a new graph theoretical approach to document clustering and its application on a real-world data set. We will show that the well-known graph partition to stable sets or cliques can be generalized to pseudostable sets or pseudocliques. This allows to make a soft clustering as well as a hard clustering. We will present an integer linear programming and a greedy approach for this NP-complete problem and discuss some results on random instances and some real world data for different similarity measures.

## I. INTRODUCTION

**D**OCUMENT Clustering is usually not perceived as a graph problem. But following [1] we would like to split the process in two steps. At first we need to define a similarity measure appropriate to the data domain. Then the technical clustering process can be done using a graph theoretical approach. Jain et al. also suggested a last step called "assessment of output" and we will show that this can also be solved using graph theory and building the graph visualization proposed in this paper.

We will now define the problem. For technical terms we refer to [2]. The Cluster Hypotheses is essential: "Documents in the same cluster behave similarly with respect to relevance to information needs." We are not trying to do  $K$ -Clustering, where we have a given number of  $K$  clusters. Thus we define the document clustering as follows:

Given a similarity function for the Document Space  $D$  as  $sim : D \times D \rightarrow \mathbb{R}^+$  and an  $\epsilon \in \mathbb{R}^+$ . We search for a minimal number of clusters, so that every two documents  $x, y$  in one cluster have  $sim(x, y) \geq \epsilon$ . We will use this approach as definition II.1.

A *hard clustering* defines, that every document belongs to only one cluster, whereas *soft clustering* allows documents to be belong to one or more clusters, even with a distinct probability. We will introduce a novel new graph structure that can also handle soft clustering.

A lot of research to the topic of document clustering in the last years focused on methods and heuristics. The authors of [3] for example try to cluster documents from MEDLINE by using evolutionary algorithms, whereas [4] use machine learning approaches. Only few authors like [5] use graph-based approaches. Some authors, like [6] cover related problems like

clustering in the context of search queries, whereas [7] work on the field of hierarchical clusterings.

This paper tries to use a novel reformulation of document clustering as a graph partition problem to get new insights to the problem itself. We hope that this leads to new heuristics and a deeper understanding of the problem. Thus, after considering some preliminaries we will introduce pseudostable sets and pseudocliques which are deeply related to graph coloring and stable sets. We will reformulate soft document clustering as a graph problem, where we seek a minimal partition in pseudostable sets. After introducing a greedy and integer linear programming approach we will make a proof of concept on some real world data.

## II. PRELIMINARIES

### A. Document Clustering

Using a Graph Partition for Clustering has been widely discussed in literature. Schaeffer points out that "the field of graph clustering has grown quite popular and the number of published proposals for clustering algorithms as well as reported applications is high" [8]. Usually directed or weighted graphs are subject of research. But we would like to point out that for problem complexity reasons it is suitable to focus on simple graphs. The work reported in [9] explains that a graph partition in cliques or stable sets is most common.

But we could also imagine – and find in literature – approaches that discuss somehow defined subgraphs or other partitions. As [8] points out unfortunately, "no single definition of a cluster in graphs is universally accepted, and the variants used in the literature are numerous". We will start with this definition:

**Definition II.1.** (*Hard Document Clustering*) Given a set of documents  $D = \{d_1, \dots, d_N\}$  and a similarity measure  $sim : D \times D \rightarrow \mathbb{R}^+$  as well as a bound  $\epsilon \in \mathbb{R}^+$ . We search for a minimal number of clusters, so that for every two documents  $x, y$  sharing the same cluster  $sim(x, y) \geq \epsilon$  holds.

We would like to suggest a slightly different approach to cover both hard as well as soft clustering. A graph partition into stable sets or cliques can be generalized to be universal in such a way that it can handle hard clustering as well as soft clustering.

We argue that a simple graph for a representation of documents for the purpose of document clustering is not a

limitation. The graph does not need to be directed, since for two documents  $d_i, d_j$  always  $\text{sim}(d_i, d_j) = \text{sim}(d_j, d_i)$ . Since every clustering algorithm needs to decide, if two documents are in one cluster there is no need to assign a weight to the edge. If a previous measurement algorithm decides that two documents cannot be in the same cluster, the value should be set that way that there is an edge.

### B. Graph Theory

Given a Graph  $G = (V, E)$  with nodes or vertices in a set  $V$  and a set of edges  $E$ . Two nodes  $u, v \in V$  are adjacent, if an edge  $(u, v) \in E$  exists. The graph coloring problem is to assign a color to each node so that every two nodes that are adjacent have a different color. The minimal number of colors needed to color a graph is called chromatic number and denoted with  $\chi(G)$ .

This problem has many applications and has been studied extensively. It is on most graphs NP-complete, see [10].

For every feasible coloring of  $G$  all nodes sharing the same color imply a stable set in  $G$ .  $S$  is a *stable set* in  $G$  if  $(u, v) \notin E \forall u, v \in S$ . Thus we have a partition of  $G$  in stable sets.

But it is also possible to use a set covering approach, where the set of vertices has to be covered by a minimum number of stable sets, see [11]. This is very useful in the context of linear programming. As Hansen et al. mentioned this approach involves an exponential number of variables which makes the problem complex. Many optimization problems on graphs can be formulated as set covering problems.

## III. PSEUDOSTABLE SETS AND PSEUDOCLIQUES

We will now discuss novel graph structures. Pseudostable sets were first introduced in [12] as a graph partition problem in the context of the Train Marshalling Problem covering the rearrangement of cars of an incoming train in a hump yard. They are still under research in several contexts. In this paper we will apply pseudostable sets in a total new context and also introduce pseudocliques and the corresponding graph covering problem. Thus the whole approach presented in this paper is novel.

We now consider a simple Graph  $G = (V, E)$  with a subgraph  $B \subset G$  of so called blue nodes and edges.  $B$  can be chosen absolutely arbitrary. For example it is also possible that  $B = \emptyset$  or  $B = G$ .

### A. A set covering approach

At first we need to define two different subsets of the graph  $G$  to create a set covering:

**Definition III.1.** (*Pseudostable Tuple*)  $T \subset G$  is a pseudostable Tuple, if it is the union of two stable sets  $D_1$  and  $D_2$  and a path  $p$  such that

$$T = D_1 \cup p \cup D_2$$

The intersection of  $D_1$  and  $p$  as well as  $p$  and  $D_2$  consists of one node. The set  $p$  is pairwise disjoint and consists of three nodes and two edges in  $B$ . That means,  $p_j \subset B(G)$ ,

$|V(p_j)| = 3$  and  $p_j$  is connected and circle-free.  $T$  can also be stable if  $D_1$  is stable and  $p = D_2 = \emptyset$ . Then the value of  $T$  is  $\zeta(T) = 1$ , otherwise  $\zeta(T) = 2$ .

It is also possible to allow more than one path between  $D_1$  and  $D_2$ , see figure 1 for an illustration.

**Definition III.2.** (*Multiple pseudostable Tuple*)  $M \subset G$  is a Multiple pseudostable Tuple, if it is the union of two stable sets  $D_1$  and  $D_2$  and paths  $p_1, \dots, p_i$  such that

$$M = D_1 \cup p_1 \cup \dots \cup p_i \cup D_2$$

The intersection of  $D_1$  and  $p_j$  as well as  $p_j$  and  $D_2$  ( $j \in \{1, \dots, i\}$ ) consists of one node. The sets  $p_i$  are pairwise disjoint and consist of three nodes and two edges in  $B$ . That means,  $p_j \subset B(G)$ ,  $|V(p_j)| = 3$  and  $p_j$  connected and circle-free.  $T$  can also be stable if  $D_1$  is stable and  $i = 0$  and  $D_2 = \emptyset$ . Then the value of  $T$  is  $\zeta(M) = 1$ , otherwise  $\zeta(M) = 2$ .

Since we usually have more than one  $M$  or  $T$  we will use indices to denote them. In the following,  $M_i$  or  $T_i$  are an arbitrary chosen  $M$  or  $T$ . We denote for  $M_i$  or  $T_i$  both stable sets with  $D_1^i$  or  $D_2^i$ .

It is possible that  $D_2^i = \emptyset$ , but it is always  $D_1^i \neq \emptyset$ . We define that  $Pf(T)$  or  $Pf(M)$  is the union of all paths in  $T$  or  $M$ .  $Pf(T_i) = \emptyset$  or  $Pf(M_i) = \emptyset$  if, and only if  $D_2^i = \emptyset$ . Every pseudostable Tuple is a multiple pseudostable Tuple. We usually search for a minimal set cover  $S$  of  $G$  with  $S = \{T_1, \dots, T_n\}$  or  $S = \{M_1, \dots, M_n\}$ . We define the weight  $w$  as

$$w(S) = \sum_{i=1}^n \zeta(S_i) + \sum_{i=1}^n \sum_{j \in \{1, \dots, n\} \setminus \{i\}} w_{i,j} \quad (\text{EQ})$$

$$w_{i,j} = \begin{cases} -1 & M_i \cap S_j = D_1^i = D_2^j \\ 0 & \text{otherwise} \end{cases}$$

The first condition ensures that two stable sets  $D$  in two different tuples which are identical are not weighted two times. All other cases can be ignored. This weight holds for multiple pseudostable tuples as well as pseudostable tuples. With a weight we can define a minimization problem.

For a given Graph  $G = (V, E)$  with a blue subgraph  $B \subset G$  we define  $\mathfrak{T} = \{T_1, \dots, T_n\}$  as the subset of all pseudostable tuples in  $G$  with  $B$ .

With  $\mathfrak{P}(T)$  we denote all inner nodes of paths within  $T$ , which means

$$\mathfrak{P}(T_i) = T_i \setminus \{D_1^i \cup D_2^i\}$$

Or, it is also possible to define it according to  $Pf(T_i)$  as  $Pf(T_i) \setminus \{D_1^i \cup D_2^i\}$  which is the same.

Fig. 1: A pseudostable tuple  $T_i$  in (a) and a multiple pseudostable tuple  $M_i$  in (b). Both sets  $D_1$  and  $D_2$  are stable and some blue paths of length 3 exist between both. The sets  $\mathfrak{P}(T_i)$  and  $\mathfrak{P}(M_i)$  consist of all blue nodes which are neither in  $D_1$  nor in  $D_2$ .

The Definition of the optimization problem can now be written as:

$$\begin{aligned}
 & \text{minimize} && \sum_{i=1}^n t_i \zeta(T_i) + \sum_{i=1}^n t_i \sum_{j=1}^n t_j w_{i,j} \\
 & \text{subject to} && \sum_{T \in \mathfrak{T}: v \in Pf(T)} t_i = 1, \forall v \in V \\
 & && \sum_{T \in \mathfrak{T}: v \in T} t_i \geq 1, \forall v \in V \\
 & && t_i \in \{0, 1\}
 \end{aligned} \tag{IP1}$$

The variable  $t_i$  indicates, if set  $T_i$  is chosen for this set covering. The minimization term refers to the weight given in equation EQ. The next line ensures that every node  $v \in V$  is assigned to exactly one node within a path of a pseudostable tuple. The last condition ensures that every node  $v \in V$  is covered by at least one set.

If we want to allow intersections between inner nodes of paths  $p$  we can simply skip the second condition. Thus our minimization problem is as follows:

$$\begin{aligned}
 & \text{minimize} && \sum_{i=1}^n t_i \zeta(T_i) + \sum_{i=1}^n t_i \sum_{j=1}^n t_j w_{i,j} \\
 & \text{subject to} && \sum_{T \in \mathfrak{T}: v \in T} t_i \geq 1, \forall v \in V \\
 & && t_i \in \{0, 1\}
 \end{aligned} \tag{IP2}$$

Both IP1 and IP2 hold for pseudostable tuples  $T$  as well as multiple pseudostable tuples  $M$ .

A set covering of a graph  $G = (V, E)$  with a subset  $B \subset G$  of blue nodes and edges with a set of  $T$  or  $M$  also induces the Graph of this set covering. In this graph every stable set  $D$  within the covering of  $G$  induces a node and every path an edge:

**Definition III.3.** (Graph of a set covering) Given a set covering  $S = \{S_1, \dots, S_n\}$  of a graph  $G = (V, E)$  with a subset  $B \subset G$  of blue nodes and edges with pseudostable tuples  $T_1, \dots, T_n$  or multiple pseudostable tuples  $M_1, \dots, M_n$ . Then we define  $G_S = (V, E)$  as the Graph of the set covering with

$$\begin{aligned}
 V &= \{D \subset S_1, \dots, S_n\} \\
 E &= \{(D_1^i, D_2^i) \mid i \in \{1, \dots, n\} \text{ if } D_2^i \neq \emptyset\}
 \end{aligned}$$

Now we can define the minimization problem as follows. We will continue using the naming introduced in [12].

**Definition III.4.** (minPS) We search for a minimal set covering  $S$  of the graph  $G = (V, E)$  with a subset  $B \subset G$  of blue nodes and edges with pseudostable tuples  $T$  according to IP1 where  $G_s$  is acyclic and  $\delta(v) \in \{0, 1, 2\}$  for all  $v \in V(G_S)$ .

**Definition III.5.** (minMPS) We search for a minimal set covering  $S$  of the graph  $G = (V, E)$  with a subset  $B \subset G$  of blue nodes and edges with multiple pseudostable tuples  $M$  according to IP1 where  $G_s$  is acyclic and  $\delta(v) \in \{0, 1, 2\}$  for all  $v \in V(G_S)$ .

We denote minPS' and minMPS' as the corresponding minimization problem according to IP2. minPS-a and minMPS-a are the corresponding minimization problems without restrictions on the graph  $G_S$ . This means

**Definition III.6.** (minPS'-a) We search for a minimal set covering  $S$  of the graph  $G = (V, E)$  with a subset  $B \subset G$  of blue nodes and edges with pseudostable tuples  $T$  according to IP2.

**Definition III.7.** (minMPS'-a) We search for a minimal set covering  $S$  of the graph  $G = (V, E)$  with a subset  $B \subset G$  of blue nodes and edges with multiple pseudostable tuples  $M$  according to IP2.

Now we have a definition as set covering problem. This is also useful to proof the NP-completeness of this problem. Now we will make a definition using a graph partition approach.

### B. A graph partition approach

The formulation of minPS or minMPS as graph partition problem is very clear and concrete but it gets unhandy when handling the variants minMPS-a or minMPS'. But since we need to proof that our new approach using set covering is equivalent to the work described in [12], we will introduce the graph partition approach.

Given a simple Graph  $G = (V, E)$  and a subgraph  $B \subset G$  of blue edges and nodes. We name a subset of  $G$  with  $i \in \mathbb{N}^+$  as  $P_i \subset G$ . See figure 2 for an illustration of the following definitions.

Fig. 2: Example partition  $D_1, p_{1,1}, p_{1,2}, D_2, p_{2,1}, p_{2,2}, p_{2,3}, \dots, p_{m-1}, D_m$  in multiple pseudostable sets.

**Definition III.8.**  $P_i$  is called a pseudostable set if and only if  $P_i = D_i$  is stable or there exist stable sets  $D_j^i$  so that  $P_i$  is partitioned in

$$D_1^i, p_{1,1}^i, D_2^i, p_{2,1}^i, D_3^i, \dots, p_{m_i-1}^i, D_{m_i}^i$$

with  $m_i \geq 2$ . The intersection of following stable sets  $D_j$  and sets  $p_{j+1}$  as well as  $p_j$  and  $D_{j+1}$  consist only of one node. The sets  $p_j$  are pairwise disjoint and consist of three nodes and two edges in  $B$ . That means,  $p_j \subset B(G)$ ,  $|V(p_j)| = 3$  and  $p_j$  connected and circle-free. The value of this set  $P_i$  is  $m_i$ .

Now again we have some nodes that are not in stable sets, but in pseudostable sets. This means, we allow documents to lie in between clusters. To allow more than one node in between stable sets, we define multiple pseudostable sets:

**Definition III.9.**  $P_i$  is called a multiple pseudostable set if and only if  $P_i = D_i$  is stable or there exist stable sets  $D_j^i$  so that  $P_i$  is partitioned in

$$D_1^i, p_{1,1}^i, \dots, p_{1,n_1}^i, D_2^i, p_{2,1}^i, \dots, p_{2,n_2}^i, \\ D_3^i, \dots, p_{m_i-1,1}^i, \dots, p_{m_i-1,n_{m_i-1}}^i, D_{m_i}^i$$

with  $m_i \geq 2$ . The intersection of following stable sets  $D_j$  and sets  $p_{j+1}$  as well as  $p_j$  and  $D_{j+1,n}$  consists only of one node. The sets  $p_{j,n}$  are pairwise disjoint and consist of three nodes and two edges in  $B$ . That means,  $p_j \subset B(G)$ ,  $|V(p_j)| = 3$  and  $p_j$  is connected and circle-free. The value of this set  $P_i$  is  $m_i$ .

Without loss of generality it is of course possible to store the possible paths in a list and not as a subset of the graph  $G$ . Both formulations are equivalent and searching for a minimum set covering of  $G$  will provide a minimum graph partition. We will show exemplarily the following lemma. All other proofs can be done the same way.

**Lemma III.10.** Every set covering  $S$  of a graph  $G = (V, E)$  with a subgraph  $B \subset G$  of blue edges and nodes with multiple pseudostable tuples according to definition III.5 is equivalent to a graph partition of  $G$  in multiple pseudostable sets according to definition III.9.

*Proof.* " $\Rightarrow$ " Given a minimal set covering  $S$  of the graph  $G = (V, E)$  with a subset  $B \subset G$  of blue nodes and edges with multiple pseudostable tuples  $M$  according to IP1 where  $G_s$  is acyclic and  $\delta(v) \in \{0, 1, 2\}$  for all  $v \in V(G_s)$ .

Since  $G_s$  is acyclic we can handle each connected component  $Z \subset G_s$ . This either has only one node and is thus equivalent to a stable set  $D^i$ . We then create a stable set  $D^i$ . Or it has at least two nodes  $v_1$  and  $v_j$  with  $\delta(v) = 1$ . Then we consider each stable set in sequence  $v_1$  till  $v_j$ . Analogously we create stable sets  $(D_1^i, D_2^i)$   $i \in \{1, \dots, n\}$  if  $D_2^i \neq \emptyset$ . This means  $D_1^i, D_2^i, D_1^j, \dots, D_1^j, D_2^j$ . But every time  $D_2^i = D_1^{i+2}$  holds, since otherwise no edge would be possible in  $G_s$ . We adjust all paths according to that, see figure 3.

Fig. 3: Illustration of  $G$  and  $G_s$  according to the proof of lemma III.10.

Every intersection of stable sets  $D^i$  and  $D^j$  is either empty or we adjust all nodes according to definition III.9. Since equation IP1 holds, this is true for all paths. All other nodes can be arbitrarily assigned to one stable set that covers this node. If we eliminate one stable set, this set covering was not minimal.

" $\Leftarrow$ " Since every graph partition is a graph covering we have to show that every pseudostable set according to lemma III.9 fulfils the definition III.5. It is obvious that two following stable sets in a pseudostable set are a pseudostable tuple. Each pseudostable set is a connected component of  $G_s$ . The value of this connected component is the same as in equation EQ. We can do this successively for every pseudostable set in the graph partition. Thus every partition holds the conditions for III.5.  $\square$

We will now introduce pseudocliques and show that they will solve the same problem on the complementary graph.

### C. Pseudocliques

It is also possible to define the problem on the complement graph  $\bar{G}$ . This graph is defined by  $\bar{G} = (V, E')$  where  $e \in E' \Leftrightarrow e \notin E$ . Since  $B \subset G$  now all blue edges are not in  $\bar{G}$  any more and  $B \not\subset \bar{G}$ .

**Definition III.11.**  $Q_i$  is a Pseudoclique if and only if  $Q_i = C_i$  is a clique or there exist stable sets  $C_j^i$  so that  $Q_i$  is partitioned in

$$C_1^i, p_1^i, C_2^i, p_2^i, C_3^i, \dots, p_{m_i-1}^i, C_{m_i}^i$$

with the same conditions as mentioned above. For multiple Pseudoclique this condition holds with several paths  $p_{j,k}^i$  between the stable sets.

A minimal Partition of  $G = (V, E)$  and a subgraph  $B \subset G$  in multiple pseudostable sets (minMPS) has a value of  $\zeta(G)$ . A minimal Partition of  $\bar{G}$  with  $B \not\subset G$  in multiple Pseudocliques (minMPC) has the value  $\bar{\zeta}(G)$ . We can conclude that both approaches are polynomial equivalent:

**Lemma III.12.** *Every minimal partition of a Graph  $G = (V, E)$  with a subgraph  $B \subset G$  in multiple pseudostable sets with value  $\zeta(G)$  implies a partition of  $\bar{G}$  with  $B \not\subset G$  in multiple Pseudoclique with the value  $\bar{\zeta}(\bar{G})$  and vice versa. This implies*

$$\zeta(G) = \bar{\zeta}(\bar{G})$$

Both approaches can be converted in polynomial time and have the same solutions and complexity. This is why we first focus on pseudostable sets and try to get some improvements by considering the problem on the complementary graph.

#### IV. A NEW CLUSTERING APPROACH WITH PSEUDOSTABLE SETS

We will now create a Graph  $G = (V, E)$ . Every document in our document set is one node  $n \in V$ . We would like to follow [8] and restrict our similarity measure on  $[0, 1]$ , “where one corresponds to a ‘full’ edge, intermediate values to ‘partial’ edges, and zero to there being no edge between two vertices.” Now we can define a limit and define edges between nodes if they are not similar enough.

Given a set of documents  $D = \{d_1, \dots, d_N\}$ , a similarity measure

$$\text{sim} : D \times D \rightarrow \mathbb{R}^+$$

and an  $\epsilon \in \mathbb{R}^+$ . The function is limited to  $[0, 1]$ . If not, we normalize it as  $\text{sim}' : D \times D \rightarrow [0, 1]$  as

$$\text{sim}'(x, y) = \frac{\text{sim}(x, y)}{\max \text{sim}(x, y)}$$

Our graph  $G$  is now defined as

$$G = (V, E) \quad V = D$$

$$E = \{(d_i, d_j) \mid \text{sim}(d_i, d_j) \leq \epsilon\}$$

Edges between documents exist only if they are less similar than  $\epsilon$ . A graph coloring approach would now create a graph partition into stable sets. This would result in a hard clustering. To achieve a soft clustering we can define another bound  $\iota$  with  $0 < \iota < \epsilon$  and another set of edges  $B = (V, E')$  with

$$E' = \{(d_i, d_j) \mid \iota \leq \text{sim}(d_i, d_j) \leq \epsilon\}$$

We can see that  $B \subset G$ . We have two kinds of edges, those edges  $e \in G$  but not in  $B$ . We call them black. These refer to documents which are not similar. But those edges  $e \in B$

called blue refer to documents that are also not similar, but less not similar than those edges not in  $B$ . If we set  $\iota = \epsilon$  then  $B = \emptyset$  and we have a hard clustering. If  $B \neq \emptyset$  we have a soft clustering if we use the following definition:

**Definition IV.1.** (PS-Document Clustering) *Given a graph  $G$  with  $B \subset G$  according to the definition above. A solution of minMPS'-a gives a Document Clustering in multiple pseudostable sets with  $\zeta(G)$  Cluster and Documents that are in between those clusters  $D$ .*

Before continuing, we will create the weighted Graph of the clustering. This definition is highly related to definition III.3. Every node refers to a document cluster and every edge refers to the number of paths between both clusters.

**Definition IV.2.** *The weighted Graph of the Clustering is a Graph  $G_c = (V_c, E_c)$  with*

$$V_c = \{D_j^i \in P_i\}, d(D_j^i) = |D_j^i|$$

$$E_c = \{(D_j^i, D_k^i), d(D_j^i, D_k^i) > 0\}$$

The weight  $d(D_j^i, D_k^i)$  can be defined in multiple ways. The easiest way is to sum all paths between both stable sets:

$$d_s(D_j^i, D_k^i) = |P| \text{ with}$$

$$P = \{p \mid p \cap D_j^i \neq \emptyset \text{ and } p \cap D_k^i \neq \emptyset\}$$

but more intuitive is the following weight:

$$d(D_j^i, D_k^i) = \sum_p \frac{|N(v) \cap D_j^i| + |N(v) \cap D_k^i|}{|D_j^i| + |D_k^i|} / |p|$$

$$\forall p = (u, v, w) \text{ with } p \cap D_j^i \neq \emptyset \text{ and } p \cap D_k^i \neq \emptyset$$

This weight counts all inner nodes  $v$  within a path  $p = (u, v, w)$  the number of neighbours in one of the stable sets. We can use this as a measure for the similarity of this node with the given stable set. If there is no edge from  $u$  to one node in the set, it might also be assigned to that stable set. Each such edge decreases this possibility. We normalize with the number of paths and thus have a value in between  $[0, 1]$ .

**Example IV.3.** *Given three documents with some similarity, see figure 4. We set  $\iota = 2, 5$  and  $\epsilon = 5$ . Now we have a graph with blue nodes and two blue edges. One edge is black. If we partition into pseudostable sets, we find two clusters with one document and one document in between both. The weighted graph of this clustering is also shown in figure 4. Every cluster is associated with a node in  $G_c$ .*

If we precisely use the Definition of pseudostable sets given by graph partition approach, this Graph needs to be acyclic. But we will follow the definition given in the first chapter and just notice that the definition by set covering approach is more clear. This Graph is important for visualization and assessment.

Fig. 4: Figure explaining the example IV.3. It illustrates the documents  $D$  with their similarity, the resulting Graph  $G$ , its partition into pseudostable sets  $D_1, D_2$  and the weighted graph  $G_c$  of that clustering.

## V. NEW APPROACHES

The main problem is that minMPS'-a is NP-complete. First of all, we will describe an Integer Linear Programming approach for calculating optimal solutions. Afterwards, we will discuss our Greedy-Approach for solving minMPS'-a. We want to show a small example on how all approaches solve the problem. Afterwards we will discuss some real-world data and the output.

### A. Integer Linear Program

Given a graph  $G = (V, E)$  with a subset  $B \subset G$  of blue nodes and edges.  $T$  is the list of all paths with length three within  $B$ .

$y_k$  denotes the variable, which indicates that a color  $k$  is used. Is  $y_k = 0$  color  $k$  will not be used.  $x_{i,k}$  indicates, if a node  $i \in G$  is colored with color  $k$ . Color  $k = 0$  will be used for those nodes which are in a path  $p$ .

$$[\text{minMPS'-a-IP}] \quad \min \sum_{k=1}^n y_k$$

$$\sum_{k=1}^n x_{i,k} = 1 \quad \forall i = 0, \dots, n \quad (1)$$

$$x_{i,k} - y_k \leq 0 \quad \forall i = 0, \dots, n, \forall k = 1, \dots, n \quad (2)$$

$$x_{i,k} + x_{j,k} \leq 1 \quad (i, j) \in E(G), \forall k = 1, \dots, n \quad (3)$$

$$x_{i,0} \leq 0 \quad \forall i \notin B(G) \quad (4)$$

$$x_{i,k} \geq 0 \quad (5)$$

$$y_k \leq 1 \quad (6)$$

$$x_{i,k} + x_{j,k} + x_{v,0} - 2 \leq 0 \quad (i, v, j) \in T, \forall k = 1, \dots, n \quad (7)$$

$$x_{i,0} + x_{j,0} + x_{v,0} \leq 1 \quad (i, v, j) \in T, \forall k = 1, \dots, n \quad (8)$$

$$x_{i,k}, y_k \in \mathbb{Z}$$

Condition 1 ensures that every node has a color or color  $k = 0$ . For each node  $i$  and every color  $k$   $x_{i,k} - y_k \leq 0$  is necessary. Is node  $i$  not in color  $k$ , inequality 2 holds. But if

it is in color  $k$ ,  $y_k = 1$  and thus the inequality holds. Two connected nodes  $i, j$  must not share the same color  $k > 0$ . Thus  $x_{i,k} + x_{j,k} \leq 1$ , see condition 3. Condition 4 ensures that no node which is not within  $B$  can be assigned to color  $k = 0$ . The last conditions ensure that if a node  $v$  is within color  $k = 0$  all within  $B$  connected nodes to  $v$  have a different color.

In practise we can only apply minMPS'-a-IP to small instances because of the exponential runtime.

### B. Greedy-Approach

Given a graph  $G = (V, E)$  with a subset  $B \subset G$  of blue nodes and edges. We run on a (not necessary minimal) graph coloring  $f : V \rightarrow F$  with  $F \subset \mathbb{N}$  and implement a greedy algorithm that puts every possible path in between two stable sets. Since we do not have perfect graphs for documents clustering we need to use heuristics to get an approximate graph coloring. Alternatively we can use the complement graph  $\bar{G}$  and use a partition into cliques which results in a coloring of  $G$ .

We will iteratively try to eliminate stable sets  $D$  given by the graph coloring heuristic and thus use the properties and characterizations of pseudostable sets:

- For each color  $i$  we consider node  $u$  in it:
  - Is this node not an endpoint of a path  $p$  (which is stored in *ende*) check if there exist two nodes  $v, w \in G$  which are connected by blue nodes with  $u$  and are in different color classes.
  - Is this true, remove  $u$  from  $i$  and create a new path  $p = [v, u, w]$ .

See algorithm 1 for pseudo code. We can not give an approximation guarantee and we will show that this heuristic does usually not provide an optimal solution.

We have used the following heuristics to start the graph coloring:

- Coloring using the *greedy independent sets* (GIS) approach with a runtime in  $O(mn)$ , see [13].
- Coloring using the SLF-Approach with a linear runtime  $O((m+n) \log n)$  (see [13] and [14]).
- Clique Partition on  $\bar{G}$  using the TSENG clique-partitioning algorithm described in [15] with a worst case runtime  $O(n^3)$ .

We assume to get a better solution by the third approach for instances where we have a huge amount of edges and it might

**Algorithm 1** GREEDY-DC

---

**Require:** Graph  $G$  with a coloring  $f$  and a list  $T = (t_1, \dots, t_{t_G})$  of all paths.  
**Ensure:** Partition  $P$  of  $G$  in MPS'-a

- 1: Sort all color classes  $f_1, \dots, f_{|F|}$  increasingly by size
- 2: **for** each color class  $f_i$  in  $F$  **do**
- 3:    $T_i \leftarrow$  all  $t \in T$  with a middle node in  $f_i$
- 4:   **for** each  $t_i = (a, b, c)$  in  $T_i$  **do**
- 5:     **if**  $f(a) \neq f(c)$  and  $\text{ende}(b) = \text{false}$  **then**
- 6:        $\text{ende}(a) \leftarrow \text{true}$
- 7:        $\text{ende}(c) \leftarrow \text{true}$
- 8:        $f(b) = 0$
- 9:     **end if**
- 10:   **end for**
- 11: **end for**
- 12: **return**  $P$ , where  $f$  denotes the stable sets and  $f_0$  all paths.

---

be less complex to solve the clique partition problem on the complement graph.

We will generate some random instances using the model of Gilbert, see [16]. This creates a simple undirected graph  $G = (V, E)$  with  $(n(n-1))/2$  possible edges as a model  $\mathcal{G}(n, p)$ . Edges will be added with probability  $0 < p < 1$ .

Erdős and Rényi designed a similar approach  $\mathcal{G}(n, m)$ , were all Graphs with exactly  $n$  nodes and  $0 < m < (n(n-1))/2$  edges are equal probable, see [17].

Both algorithms have a quadratic runtime. For small  $p$  Batagel and Brandes described a linear time approach with a runtime in  $O(n + m)$ , where  $m$  is the number of created edges, see [18].

We will chose  $p = 0.75$  and a second probability  $p' = 0.2$  which decides if edges are colored blue. This refers to the instances we have seen on real world data.

We will show the results for different random instances with 15 nodes in figure 5 and with 100 nodes in figure 6. We have also added the results of the integer linear program for small instances.

As we can see in both figures, the clique approach gives the worst partition into stable sets for large instances but the greedy approach eliminates most stable sets. SLF gives in general better results than GIS and also has a better runtime.

## VI. DOCUMENT CLUSTERING ON MEDLINE

We apply this new approach to perform document clustering over some subsets of MEDLINE data. MEDLINE (Medical Literature Analysis and Retrieval System Online) is a bibliographic database maintained by the National Center for Biotechnology Information and covers a large number of scientific publications from medicine, psychology, and the health system. For the clustering use case, we study MEDLINE abstracts and associated metadata that are processed by ProMiner, a named entity recognition system ([19]), and indexed by the semantic information retrieval platform SCAIView ([20]). SCAIView also offers an API that allows

programmatic access to the data. Currently, we only use meta information like title, journal, publishing year and the MeSH terms for our experiments.

We extract subset  $D$  of MEDLINE documents from SCAIView. Every document on MEDLINE should have a list  $M$  of keywords, so called MeSH terms. We may use them to calculate the Tanimoto similarity, also known as Jaccard similarity

$$\text{sim}(a, b) = \frac{|M_a \cap M_b|}{|M_a \cup M_b|} \forall a, b \in D$$

with  $\text{sim} : M \times M \rightarrow [0, 1]$ . This first approach is not suitable for all applications as we will show in the next section. This is why we postulate a distance model based on the vector of weighted words using NLP techniques.

We then build a graph  $G$  according to the bounds  $\epsilon$  and  $\iota$ . Following this, we create the directed graph of that partition by applying the Greedy approach. We also store further metadata like years and journals in nodes and edges.

We will now describe the result of one input set given by [21] and discussed by [22]. In both publications the first dataset consisted of 1660 documents obtained from two different queries 'escherichia AND pili' and 'cerevisiae AND cdc\*'. Both returned the same number of 830 documents. We had a similar result with 1628 documents trying to reproduce this query with data till 2001. This dataset covers two different topics, whereas the second dataset is related to the developmental axes of Drosophila. We will now discuss several outputs of our new approach.

Consequently, we have  $n = 1628$  nodes (documents). The number of edges  $e$  and blue edges  $b$  depend on the different values of  $\iota$  and  $\epsilon$  and the priorly used approach for similarity. We will discuss the following three measures: First an approach using a distance model  $d_V$  based on the vector of weighted words using NLP techniques for the abstracts. In addition a distance according to the journal, which is  $d_J(x, y) = \{0, 1\}$ . Thus we have

$$d_1(x, y) = \frac{d_V(x, y) + d_J(x, y)}{2}$$

The second approach is the usage of  $d_2 = d_V$ . The third approach uses only the Tanimoto similarity on MeSH terms described above, thus  $d_3 = \text{sim}$ .

We wanted to compare our results with those given by [21] and [22]. We will show that the comparability of clusterings with previous studies is highly dependent on the choice of this distance measurement. Every clustering produces unique details with the same heuristic running in the background. Thus it is not totally clear to connect clusters to topics. But first of all we want to proof our new approach and reproduce the results of both [21] and [22] which we will discuss for every distance measure.

**Distance measure  $d_1$ :** The results of our clustering approach with distance measure  $d_1$  are shown in figure 7 and table I. We got 13 clusters (Cluster 0 to 12) with documents between 5 (Cluster 11) and 359 (Cluster 8) documents.

Fig. 5: Results for random instances with  $n = 15$  nodes.

Fig. 6: Results for random instances with a node count  $n = 100$

Fig. 7: The partition of the first dataset with distance  $d_1$ . The numbers identify the clusters. The size of a node is related to the number of documents included. The edges and their widths and color describe their weight. A darker blue edge has a greater weight.

Our clustering heuristic is able to produce clusterings of variable detail by choosing different values for  $\iota$  and  $\epsilon$ . We have chosen values that visualize the benefit of the new graph theoretical approach. Referring to figure 7 it is easy to see that the first cluster is given by cluster 8. It has only weak dependencies and relations to other clusters as can be seen by the edges in the graph. Clusters 0, 9, 10, 11 are highly dependent and thus form the second cluster agglomeration. The MeSH terms that describe these clusters can be found in table I. We can see a similar result to [22]: the terms of both clusters describe the general concepts that are relevant to both search queries. So our approach produces similar results with this distance measure.

Those clusters which are in between the two main clusters share topics with both. For example cluster 7 is related to

Fig. 8: The partition of the first dataset with the distance  $d_2$ . This picture shows the weighted graph of the clustering. The color of the nodes indicate a high rate of documents from the respective queries (red: ‘escherichia AND pili’; green ‘cerevisiae AND cdc\*’).

Fig. 9: The partition of the first dataset with the distance  $d_3$ . This picture shows the weighted graph of the clustering. The color of the nodes indicate a high rate of documents from the respective queries (red: ‘escherichia AND pili’; green ‘cerevisiae AND cdc\*’).

Terms	
Global Cluster 1	Global Cluster 2
Cluster [ 8 ]	Cluster [ 0, 9, 10, 11 ]
Escherichia coli	Saccharomyces cerevisiae
Fimbriae, Bacterial	Saccharomyces cerevisiae Prot.
Fimbriae Proteins	Fungal Proteins
Bacterial Adhesion	Mutation
Plasmids	Cyclins
Fimbriae, Bacterial	CDC28 Protein Kinase, S cerevisiae
	Amino Acid Sequence
	Cell Cycle Proteins

TABLE I: The MeSH terms describing a selected set of global topic clusters which consist of highly related clusters for distance  $d_1$ .

‘Molecular Sequence Data’ and ‘Escherichia coli’. The benefit of our new graph theoretical approach is that we can visualize how much these clusters have in common and how dependent they are. We can also identify clusters that consist of different small clusters, but are highly connected.

**Distance measure  $d_2$ :** The results of our clustering ap-

proach with distance  $d_2$  are shown in figure 8. The weighted graph of that clustering is now different. We got 14 clusters (Cluster 0 to 13) with documents between 2 and 5 as well as 157 and 158 documents. We now have no isolated clusters.

In this clustering it is not easy to evaluate the different topics given through the search query by evaluating the edges within the weighted graph of the clustering. Thus we have colored the graph according to the rate of documents from each query. We would expect “clean” clusters, which means the clusters should have a high fraction of documents from only one query. We see a lot of relatively clean clusters, for example 1 or 5, 2, 7 and 3. But those are not highly connected. The documents in between are mostly related to clusters which are not clearly assigned to one of both search queries. Thus we could not clearly reproduce the results from [22] with this distance measure.

**Distance measure  $d_3$ :** The results of our clustering approach with distance  $d_3$  are shown in figure 9. We now have one strongly connected set of clusters. It is no longer possible to separate any of the topic clusters induced by the search query. Thus again we have colored the graph according to the fraction of documents from each query. We would expect “pure” clusters, which means the clusters should have a high fraction of documents from only one query. We get more pure clusters than with  $d_1$  and  $d_2$  but they are small. Most of the purest clusters are isolated and do not share documents with other clusters. Thus the result observed with  $d_2$  gets clearer. Only those clusters which cannot be clearly assigned to one of the search queries have edges within the weighted graph of the clustering.

Since all MeSH terms are weighted equally, those terms which are not significant but shared by many of documents, are scored higher, for example ‘Animals’ or ‘Microscopy’. And as a result, most documents have these terms in common. This explains the high connectivity of the resulting graph. Thus we could again not clearly reproduce the results from [22] with this distance measure.

## VII. CONCLUSION AND FUTURE WORK

We have shown a novel approach for document clustering considering hard clustering as well as soft clustering. We defined pseudostable sets and used the minMPS’-a approach to perform document clustering on a real-world example. We have introduced a integer linear programming and a greedy approach that gave valuable output on random instances as well as real-world data. This paper underlines that pseudostable sets have a broad application and can also be used to generalize other problems like document clustering. Since the problem is NP-complete, we could only produce and evaluate approximate solutions. Further research has to be done on evaluating the error given by the heuristics. Is it possible to find restrictions on  $G$  and  $B$  so that a solution in polynomial time is possible?

Because large graphs also increase the processing complexity, we identify the handling of such big data as an additional challenge. In the same course, it might be a good idea to

focus also on novel strategies to implement an online algorithm version of the greedy approach, which could significantly improve the scalability.

We compared three simple similarity measures using textual data given by the abstract as well as keywords. We have shown that the clustering process itself is only valuable when choosing the right similarity measure. Although we have proven that the hard clustering and soft clustering approach using pseudostable or stable sets is valid, we might need to evaluate more similarity measures. Thus further research has to be done on similarity measures. We are planning to improve document management with this novel clustering approach and do more empirical evaluation by using test sets.

**Abstract**—Event relation knowledge is important for deep language understanding and inference. Previous work has established automatic acquisition methods of event relations that focus on common sense knowledge acquisition from large-scale unlabeled corpus. However, in the case of domain-specific knowledge acquisition, such a method can not acquire much knowledge due to the limited amount of available knowledge sources. We propose an coverage-oriented acquisition method of event relations. The proposed method utilizes various patterns of dependency structures co-occurring with event relations than the existing method relying only on direct dependency relations between events. Experimental results show that the proposed method can acquire a larger amount of positive relation instances while keeping higher precision compared with the existing method and the proposed method also performs well for small sizes of corpora.

## I. INTRODUCTION

**S**EMANTIC relations between events are important knowledge for various NLP applications that require deep language understanding and inference, such as question answering and future scenario planning. For example, happens-before relation between events (e.g., *get the flu* causes *have a fever*) is required to predict future events from observed events, and entailment relation (e.g., *send a mail to someone* entails *contact someone*) is crucial to recognize similarity of events written with a different surface or in a different abstraction level of expressions.

Many methods have been developed to acquire event relations automatically from unlabeled corpus [1], [2], [3], [4], [5], [6], [7]. Knowledge acquisition methods can be evaluated in terms of accuracy and coverage, and both measures affect performance of downstream applications. In the case of acquiring domain-specific knowledge, we believe that it is important to acquire knowledge with high coverage rather than high accuracy, since accuracy-oriented methods would not acquire much knowledge from the limited amount of available domain corpus. Although coverage-oriented methods extract more incorrect knowledge, eliminating incorrect knowledge

from candidates is much easier than creating knowledge not acquired.

We categorize unsupervised or semi-supervised acquisition methods of event relations into the following two types on the basis of how they extract event pairs that correspond to candidate event relations. Methods of the first type [1], [6], [7] extract event pairs from a sentence. They acquire event relations written in a sentence by using syntactic information of the sentence (e.g. dependency relations) or lexical clues indicating clause relations (e.g. expressions such as “because” and “after”). Methods of the second type [2], [3], [4], [5] extract event pairs from sentences in one or more documents. They acquire event relations whose events distantly occur in documents, by using distributional similarities of events or lexical clues indicating sentence relations (e.g. expressions such as “therefore” and “consequently”) <sup>1</sup>. Methods of both types usually filter or rank extracted candidates using association measures among predicates and arguments composing a event pair. Note that methods of both types can acquire different relation instances and can be used complementarily <sup>2</sup>. In this work, we focus on event relation acquisition from a sentence.

The existing methods that target a sentence [1], [6], [7] aim to acquire common sense knowledge from large-scale knowledge sources with high accuracy. The methods relying on lexical clues [1], [7] can not acquire relation instances which explicitly occur without lexical expressions indicating event relations. In contrast, Shibata and Kurohashi [6] proposed a method relying almost only on syntax information to extract candidates of happens-before-like relations. Their method extracts event pairs that have dependency relation and ranks those pairs by using pointwise mutual information (PMI) between two events, which measures the degree of co-occurrence. However, their method can not acquire event relations which do not have direct dependency relation.

<sup>1</sup>Some lexical clues, such as discourse connectives, are in common used to detect event relations occurring in a sentence and ones occurring in two sentences.

<sup>2</sup>There is also research that acquires both relation instances occurring in a sentence and ones occurring in two sentences, such as the work by Do et al. [3].

<sup>†</sup> Present affiliation is National Institute of Information and Communications Technology, Kyoto, Japan.

In this work, we propose a method that acquires event relations with high coverage. We introduce various dependency patterns into the calculation approach of association between events by Shibata and Kurohashi. The main differences to that work are as follows:

- Our method detects various dependency patterns between related events and uses the acquired patterns to extract candidate event relations.
- Our method measures the strength of association between two events on the basis of our co-occurrence statistics, namely, the weighted association score. The score is weighted by the confidence of dependency patterns in order to rank instances effectively and obtain high precision.

We performed experiments on Japanese corpora and compared the proposed method with the baseline method that corresponds to the method by Shibata and Kurohashi. The results show that our method efficiently acquires a larger amount of positive relation instances. In addition, our method suppresses decrease of precision against decrease of corpus size and acquires reliable relation instances efficiently from limited sizes of corpora.

## II. RELATED WORK

Over the past two decades, many efforts have been focused on automatic acquisition of event relations such as entailment and causality. In particular, unsupervised or semi-supervised methods that target unlabeled corpora have been actively researched.

Torisawa [7], Abe et al. [1], and Shibata and Kurohashi [6] proposed acquisition methods that extract two events co-occurring in a sentence. Torisawa [7] extracts two predicates co-occurring in coordinated sentences to acquire happens-before-like relations. Using a bootstrapping strategy, Abe et al. [1] extract lexico-syntactic patterns co-occurring with given seed relation instances to acquire event relations of the given type, Shibata and Kurohashi [6] use co-occurrence statistics of predicate-argument (PA) pairs, which measures association among all predicates and arguments composing a PA pair, to acquire happens-before-like relations. These methods rely on lexical clues and/or limited syntactic information, and therefore they can acquire limited instances of event relations.

In contrast, acquisition methods that extract two events from multiple sentences have also been proposed. In order to discover paraphrase-like relations, Lin and Pantel [5] proposed DIRT algorithm, which measures distributional similarity of predicate phrases that are represented by path in dependency tree. Chklovski and Pantel [2] use manually created patterns to classify predicate pairs, which are extracted by DIRT algorithm, into fine-grained relation types such as happens-before and entailment. Hashimoto et al. [4] use distributional similarities between predicates on the basis of common shared arguments to acquire entailment relations. Do et al. [3] use discourse markers and three kinds of associations between predicate-predicate, predicate-argument, and argument-argument to detect causality relations. Do et al.

Fig. 1. A dependency tree of a Japanese sentence. Chunks in the sentence are separated by “/”. Dependency relations between chunks are denoted by directed edges that are drawn by solid or dotted line. Predicate chunks P1, P2, and P3 are denoted by underline. Predicates are denoted in bold. The smallest subgraph contains P1 and P2, which consists of three solid line edges, indicates the dependency pattern co-occurring with pair of P1 and P2.

extract event pairs occurring not only in two sentences but also in a sentence. Unlike the work by Do et al., our work targets broader type of relations including entailment and happens-before.

In recent years, supervised learning methods have also been applied to learn event relations. Weisman et al. [8] combine various semantic and syntactic features that indicate verb co-occurrence at the sentence, document, and corpus levels to learn entailment relations. Hashimoto et al. [9] use features based on noun relations, such as causality and made-of, between arguments and features based on the association measures of predicates and arguments to learn causality relations. Kloetzer et al. [10] use features based on the transitivity property of entailment to learn entailment relations. These approaches are effective in terms of enlarging existing knowledge base, but they sometimes require a large amount of training instances (e.g., more than tens of thousands of positive instances).

There is a line of research on statistical script models started by Chambers and Jurafsky [11] whereby stereotypical sequences of events (e.g., a visit to a restaurant) is learned. The first model by Chambers and Jurafsky learns statistical scripts involving single participants (e.g., *accuse X*, *X claim*, *X argue*, etc.) on the basis of association between events co-referring to the same protagonist. Chambers and Jurafsky [12] and Pichotta and Mooney [13] extended the first model to handle scripts with multiple protagonists. Recently, embedding-based approaches that can learn script models from large unlabeled corpora have been applied, such as the compositional neural network model by Granroth-Wilding and Clark [14] and the LSTM-based model by Pichotta and Mooney [15]. Unlike our work, these works on script models focus on prediction of missing events in a sequence of events rather than construction of static knowledge.

## III. EVENT RELATION ACQUISITION WITH HIGH COVERAGE

As shown in Fig. 1, a dependency tree of a Japanese sentence is expressed as a directed tree where a node represents a chunk and a directed edge represents a dependency relation between chunks<sup>3</sup>. Among all possible combinations

<sup>3</sup>In traditional Japanese dependency parsing, a sentence is divided into chunks, each of which contains one content word and zero or more function words, and then the dependent chunk of each chunk are specified.

Fig. 2. A dependency pattern between two predicates. Any pattern expressed as either (i) a serial or (ii) a parallel dependency structure. Serial patterns consist of two predicate chunks  $P$  and zero or more chunk  $N$ . Parallel patterns consist of two predicate chunks  $P$  and one or more chunk  $N$ . Patterns with the different number of nodes are distinguished from other.

of two predicates in the sentence, predicate pair  $\langle nyuuin-suru::kaifuku-suru \rangle$  ( $\langle$ be in hospital::become good $\rangle$ ), which comes from chunk pair of P1 and P2, can be interpreted as a happens-before relation instance.

To extract such relation instances, it is necessary to extract not only direct dependency relations but also various patterns of dependency structures. Here, we assume that every chunk except the root in a parsed sentence has one dependent chunk. In other words, chunks and dependency relations between them constitute a directed tree. Therefore, a dependency relation between any two predicates in a sentence can be expressed as the smallest subgraph that contains the nodes of the two predicate chunks. Since two predicates in a sentence correspond to two leaves in a directed tree, the smallest subgraph that contains the two predicates is equal to either a serial or a parallel dependency pattern as shown in Fig. 2. For example, the dependency pattern that co-occurs with pair of P1 and P2 in Fig. 1 is represented by parallel pattern  $\langle P \rightarrow N \leftarrow N \leftarrow P \rangle$ , where two  $P$  denote the slots of the predicate chunks in interest and the rest  $N$  denote the slots of the other chunks in between the predicate chunks. Note that serial pattern with no  $N$  nodes corresponds to direct dependency relation and we call other patterns as indirect dependency relations.

In order to improve extraction coverage of various relations instances, we propose an acquisition method that targets both direct and indirect dependency relations between events. An overview of the framework of our system is given in Fig. 3. The system follows three steps below. We assume that input text is dependency-parsed and annotated with dependency relations between chunks, and the parsed text is passed to both pattern acquisition and event pair extraction as input.

#### 1. Pattern extraction

The system takes parsed text and a small number of seed instances of event relations as input. Then it extracts dependency patterns between events. After that, it calculates the confidence scores of extracted patterns and selects them on the basis of the scores.

#### 2. Event pair extraction

The system takes parsed text and the extracted

Fig. 3. Framework of proposed system

patterns as input and then extracts event pairs co-occurring with the patterns.

#### 3. Event pair ranking

The system calculates the association scores of the extracted event pairs. Event pairs with higher scores are regarded as more reliable event relation instances.

We describe both of the pattern extraction step and the event pair extraction step in Section III-A and the event pair ranking step in Section III-B. We also explain the differences between our method and previous methods. In Section III-C, we describe the weighted association score, which are used in the event pair ranking step, aiming to rank event pairs so that more reliable instances have higher scores.

#### A. Dependency pattern extraction and event pair extraction

In the pattern extraction and event pair extraction steps, we apply the method by Abe et al. [1]. In this step, unlike the lexico-syntactic patterns in that work, which patterns consisting of word surfaces in directed dependency paths between two predicate chunks, we detect our dependency patterns described above.

a) *Pattern extraction step:* In the pattern extraction step, our method takes seed relation instances and extracts co-occurrence patterns from input text. Then it calculates confidence scores of patterns so as to enhance the confidence of patterns co-occurring with high-confidence relation instances. From given seed relation instances, confidence score  $r_\pi(p)$  for pattern  $p$  is calculated as follows:

$$r_\pi(p) = \frac{1}{Z_\pi} \sum_i \text{PMI}(i, p) \cdot r_i(i), \quad (1)$$

where confidence score  $r_i(i)$  for positive or negative seed instance  $i$  is respectively 1 or  $-1$ ,  $\text{PMI}(i, p) = \frac{P(i, p)}{P(i)P(p)}$  is pointwise mutual information between  $i$  and  $p$ , and  $Z_\pi$  denotes the absolute value of the maximum value of pattern confidence values to normalize the values to  $[-1, 1]$ <sup>4</sup>. Unlike the work by Abe et al. taking logarithm of the PMI, we define the PMI as above so that confidence of patterns take positive value only when associations with positive instances are stronger than ones with negative instances. The method selects patterns with positive confidence.

<sup>4</sup>We use the normalization similarly to Abe et al. [16] that describes a minor extension of their original work [1].

b) *Event pair extraction step*: In the event pair extraction step, our method extracts event pairs from input text by using the extracted patterns. At the time, it extracts not only predicates but also arguments depended by the predicates.

In addition, the method also calculates confidence scores  $r_i$  of event pairs defined as follows:

$$r_i(i) = \frac{1}{Z_i} \sum_p \text{PMI}(i, p) \cdot r_\pi(p), \quad (2)$$

where  $Z_i$  is the coefficient value for normalization defined similarly to  $Z_\pi$ . By using the confidence scores of event relation instances, the method can iterate both extraction steps of patterns and event pairs in a bootstrap manner. These iterations are optional procedures to increase new patterns and event pairs gradually. Then extracted event pairs at the event pair extraction step are passed to the event pair ranking step.

Note that we do not adopt the confidence score of event pairs based on co-occurrence patterns in Eq. (2) unlike Abe et al. Instead, we calculate scores of event pairs on the basis of the direct associations between the events in a similar way to Shibata and Kurohashi.

### B. Event pair ranking

In the event pair ranking step, we extend the method by Shibata and Kurohashi.

Our method takes event pairs co-occurring with one or more patterns from the event pair extraction step, and it calculates the PMI between two events as the association score, which we define later. It calculates not only the score of the original event pair but also the scores of any sub-pairs, that is, event pairs comprising two predicates and zero or more arguments of the original event pair. Then the sub-pairs with the highest scores are selected from among any sub-pairs including the original event pair. In the example below, the method also generates event pairs (b), (c), (d) and so on from event pair (a), and it calculates their association scores. Then it selects the pairs with highest scores, which in this case is expected to be pair (b).

- (a)  $\langle \text{kodomo-ga kaze-wo hiku::netsu-ga deru} \rangle$  ( $\langle \text{child catch a cold::have a fever} \rangle$ )
- (b)  $\langle \text{kaze-wo hiku::netsu-ga deru} \rangle$  ( $\langle \text{catch a cold::have a fever} \rangle$ )
- (c)  $\langle \text{kodomo-ga hiku::netsu-ga deru} \rangle$  ( $\langle \text{child catch::have a fever} \rangle$ )
- (d)  $\langle \text{hiku::deru} \rangle$  ( $\langle \text{catch::have} \rangle$ )

In order to handle event pairs co-occurring with multiple dependency patterns in a sentence, we define frequency  $c(e; s)$  of event  $e$  and frequency  $c(e, e'; s)$  of event pair  $(e, e')$  in sentence  $s$  so that they take 1 or 0 depending on whether or not it occurs in the sentence, as below:

$$c(e; s) = \begin{cases} 1 & (e \text{ occurs in } s) \\ 0 & (\text{otherwise}) \end{cases}$$

$$c(e, e'; s) = \begin{cases} 1 & ((e, e') \text{ co-occurs in } s \\ & \text{with at least one pattern}) \\ 0 & (\text{otherwise}) \end{cases}$$

Consequently, even if an event occurring once in a sentence co-occurs with multiple patterns, the event is not counted redundantly. The association score of event pair  $(e, e')$  is calculated from the total frequency  $C(e)$  of each event and the total frequency  $C(e, e')$  of the event pair in given corpus  $\mathcal{C}$ , as below:

$$\text{score}(e, e') = \text{PMI}(e, e') = \frac{\frac{C(e, e')}{N}}{\frac{C(e)}{N} \frac{C(e')}{N}} \quad (3)$$

$$C(e) = \sum_{s \in \mathcal{C}} c(e; s), \quad C(e, e') = \sum_{s \in \mathcal{C}} c(e, e'; s),$$

$$N = \sum_e C(e).$$

In addition, we use the discounting factor defined by Pantel and Ravichandran [17] in order to relieve the problem of the PMI being biased towards infrequent elements.

To calculate the PMI of a huge amount of sub-pairs efficiently, we apply Apriori, an association rule mining algorithm, similarly to the work by Shibata and Kurohashi. Association rule mining methods extract subsets of items with strong association from given sets of items as association rules. By pruning unnecessary candidates, Apriori algorithm efficiently calculates several association measures, including the PMI<sup>5</sup>, to select strongly-associated rules. We apply the algorithm to event relation acquisition, regarding each event pair  $(e, e')$  as a set of predicates and zero or more arguments.

Note that it sometimes happens that extracted instances lack a part of the necessary arguments due to arguments being omitted in text. In addition to the ranking of event pairs, Shibata and Kurohashi make up for lacking arguments of acquired relation instances by using case frames. In this work, we focus on extracting and scoring reliable event relations as the main part of event relation acquisition rather than post-processing to compensate lacking arguments. The extension to compensate arguments in our method remains as future work.

### C. Event pair ranking utilizing pattern confidence

In this section, we describe a more sophisticated association score, the weighted association score, between events. The scoring function gives higher scores to event pairs that often co-occur with more reliable patterns and do not often co-occur with more unreliable patterns.

Now, we define weighted frequency  $c_w(e, e'; s)$  of an event pair in sentence  $s$  as

$$c_w(e, e'; s) = \begin{cases} \max_{p \in P_{e, e'; s}} r_\pi(p) & (\exists p \in P_{e, e'; s} \text{ s.t. } r_\pi(p) > 0) \\ 0 & (\text{otherwise}) \end{cases}$$

where  $P_{e, e'; s}$  denotes the set of patterns co-occurring with event pair  $(e, e')$  in sentence  $s$ . Consequence of the normalized value of pattern confidence, weighted frequency  $c_w(e, e'; s)$  takes at most 1 and does not exceed frequencies of contained events  $e$  and  $e'$ . Then we define the weighted association score

<sup>5</sup>The association measure corresponding to the PMI is called “lift” in association rule mining.

between event  $e$  and  $e'$  on the basis of the total weighted frequency  $C_w$  of an event pair in given corpus  $\mathcal{C}$  as follows:

$$\text{score}_w(e, e') = \frac{\frac{C_w(e, e')}{N}}{\frac{C(e)}{N} \frac{C(e')}{N}} \quad (4)$$

$$C_w(e, e') = \sum_{s \in \mathcal{C}} c_w(e, e'; s) . \quad (5)$$

As a result of event pair frequencies being weighted by the confidence of the pattern whose confidence is the highest among co-occurring patterns, the weighted association score provides relatively larger values for event pairs co-occurring with higher-confidence patterns. Therefore it is assumed that the score can rank effectively reliable event pairs.

#### IV. EXPERIMENTS

We conducted two experiments to evaluate the proposed method in terms of precision and the amount of acquirable knowledge. First, we compared performance of the baseline method and some versions of the proposed method by using a corpus consisting of 1M documents. The baseline method is the method relying only on direct dependency pattern in the event extraction step of our method, and it corresponds to the method by Shibata and Kurohashi<sup>6</sup>. Second, we also evaluate performance of our method using several smaller sizes of corpora.

##### A. Experimental Settings

*a) Dataset:* We use Mainichi newspaper articles (MNA) from 1991 to 2007, which contain about 1.8M documents<sup>7</sup>, as input corpus for event relation extraction. In order to compare the performance of methods for a fixed size of input corpus, we use a subset of the corpus in each experiment.

Sentences in the corpus were parsed by CaboCha [18] (version 0.69), a Japanese dependency parser, and then each sentence was divided into chunks and annotated with dependency relations between chunks<sup>8</sup>. From every parsed sentence, we extract verbs as predicates and noun phrases with a case marker *ga* (NOM), *wo* (ACC), or *ni* (DAT) as arguments. However, we eliminated about 20 verbs that are too abstract to be interpreted as meaningful events, such as “*omou* (think)”, “*shiru* (know)” and “*motozuku* (be based on)”, by choosing among the most frequent verbs in the corpus manually.

<sup>6</sup>Compared with the baseline method in our experiment, the method by Shibata and Kurohashi additionally utilize case frames for the argument alignment and a word class dictionary for the argument generalization in their work. However, both methods are essentially equivalent in terms of extraction coverage.

<sup>7</sup>We use Mainichi Shimbun CD-ROM (1991-2007) provided by Mainichi Newspapers Co., Ltd. The substantive amount of MNA is actually less because it contains empty documents whose contents have been removed on account of copyright. We eliminated those documents in our experiments.

<sup>8</sup>Although we target dependency relation between chunks in a sentence, our method can be applied to extract dependency relation between words, which is widely used across many languages. However, it should be also examined whether effective patterns to capture event relations are extracted because (typed) word-based dependency patterns between predicates would tend to be longer and more complicated.

*b) Parameter settings:* For all the compared methods including the baseline and proposed method, we use the below thresholds to filter meaningless instances.

- Threshold of word frequency: Words, either predicate or argument, that occur less than 50 times in a given corpus are cut off. This is because infrequent words are sometimes almost meaningless due to tokenization errors, etc.
- Threshold of event pair frequency: Candidate event relations that occur less than five times in a given corpus are cut off. This is because infrequent elements tend to have a large PMI value but they are not usually reliable.

The proposed method has some additional settings related to pattern extraction.

- Seed relation instances: We manually created five positive instances and five negative instances as seed instances. We chose them from automatically extracted instances from a tiny subset of MNA by the baseline method, which does not require any seed instances.
- Maximum length of patterns: We define the length of a dependency pattern as the length of the corresponding undirected path. On the basis of preliminary experiments with changing the maximum length of extracted patterns, we confirmed that patterns with the larger length tend to have lower confidence. We decided to use at most five-length patterns because negative confidence patterns are extracted when we set five as the maximum length.
- Number of iterations: The pattern extraction and event pair extraction steps can be executed iteratively in a bootstrapping manner. We execute it only once because all possible patterns for each max length constraints were extracted in the first iteration of preliminary experiments.

*c) Evaluation Method:* Evaluation of the compared methods is done manually by two annotators. Every event pair  $(e_1, e_2)$  generated by each method is categorized into three relations by the annotators: happens-before ( $e_2$  often occurs after  $e_1$  occurs), entailment ( $e_2$  often occurs at the same time as  $e_1$  occurs), and precondition ( $e_2$  have often occurred before  $e_1$  occurs).

Some event pairs can not be regarded as positive instances by themselves due to absence of a part of arguments. In case that such event pairs are assumed to have a relation if annotators have compensated suitable additional arguments to them, we allow them as positive instances. In the examples below, pair (a) can be interpreted as a happens-before relation instance by itself. Although pair (b) has a somewhat ambiguous meaning, it can also be regarded as a happens-before relation instance if arguments such as “Website-*ni* (to a Website)” have been compensated for the former predicate. Therefore both examples are expected to be judged as correct.

- (a)  $\langle \text{kuuki-ni fureru}::\text{sanka-suru} \rangle$  ( $\langle \text{be exposed to air}::\text{get oxidized} \rangle$ )
- (b)  $\langle \text{access-suru}::\text{page-wo hiraku} \rangle$  ( $\langle \text{access}::\text{open a page} \rangle$ )

TABLE I

PRECISIONS OF EVENT RELATION ACQUISITION FROM THE CORPUS OF 1M DOCUMENTS. PRECISION FOR EACH SECTION AND FOR OVERALL SECTIONS ARE LISTED. DP AND MP INDICATE THE METHOD THAT USE ONLY THE DIRECT PATTERN AND MULTIPLE PATTERNS RESPECTIVELY. MPW IS THE METHOD THAT USE WEIGHTED ASSOCIATION SCORE IN ADDITION TO MULTIPLE PATTERNS.

Method	Precision for each section						Overall
	1-10k	10k-30k	30k-70k	70k-150k	150k-310k	310k-495k	
DP	0.56	0.46	0.18	0.10	—	—	0.231
MP	0.62	0.54	0.52	0.32	0.16	0.10	0.217
MPW	0.72	0.54	0.36	0.24	0.08	0.10	0.167

TABLE II

THE ESTIMATED AMOUNT OF ACQUIRABLE POSITIVE INSTANCES AND THE TOTAL NUMBER OF OUTPUT INSTANCES FROM THE CORPUS OF 1M DOCUMENTS. THE AMOUNT OF POSITIVE INSTANCES INCLUDED IN TOP  $N$  INSTANCES ( $N = 10k, 30k, 70k, 150k, 310k, 495k$ ) IS ESTIMATED FROM THE PRECISION IN TABLE I.

Method	No. of positive instances in top $N$ instances						No. of outputs
	~10k	~30k	~70k	~150k	~310k	~495k	
DP	5.6k	14.8k	22.0k	26.4k	—	—	114k
MP	6.2k	17.0k	37.8k	63.4k	89.0k	107.4k	495k
MPW	7.2k	18.0k	32.4k	51.6k	64.4k	82.8k	495k

We used the Cohen's kappa coefficient to measure the inter-annotator agreement, resulting in 0.55 ("moderate" agreement). We adopt each event pair as a positive instance only if two annotators judged it as correct.

#### B. Experiment 1: Comparison of performance among methods using fixed size of input corpus

In this experiment, we compare the following methods using the subcorpus of MNA consisting of 1M documents. Two versions of our method using multiple dependency patterns, MP and MPW, differ on scoring functions for ranking candidate event relations.

- DP: The baseline method using only direct dependency pattern, which corresponds to the method by Shibata and Kurohashi.
- MP: The proposed method using the ordinal association score in Eq. (3).
- MPW: The proposed method using the weighted association score in Eq. (4).

To estimate precision of each system, we divided relation instances output by each system into sections on the basis of their rank, that is, sections of 1<sup>st</sup>-10k<sup>th</sup>, 10k<sup>th</sup>-30k<sup>th</sup>, 30k<sup>th</sup>-70k<sup>th</sup>, 70k<sup>th</sup>-150k<sup>th</sup>, 150k<sup>th</sup>-310k<sup>th</sup>, and 310k<sup>th</sup>-last instances. Then, from each section, 50 relation instances were randomly sampled and judged by annotators. We show the precision for each method for each section in Table I.

The number of output instances from DP is 114k and those of MP and MPW are both 495k (These numbers are also shown in Table II). This result shows that higher ranked instances have higher precision in common among all methods. If we look at the precision of each system, both MP and MPW consistently outperform DP in all sections. In contrast, the overall precisions, which are estimated from all sections, of the

proposed methods are lower than that of DP. For the practical purpose of obtaining positive relation instances from among automatically acquired instances by systems, we assume that high rank instances keeping high precision are selected, and then those instances are cleaned by human check to be used for applications. From this point of view, more desirable method should keep higher precision in a wider range of ranked instances, and in that sense the proposed methods are more effective. Besides, in terms of score functions in the proposed methods, MPW performs best in the section of highest-rank instances although MP has the same or higher precision in the rest of the sections. From these results, we confirmed that weighted association score is effective to detect specifically reliable instances but does not maintain robust performance against all acquirable instances.

We also show in Table II the amounts of acquirable positive relation instances from each method, as estimated by the precision in each section and the total numbers of output instances. The results show that MP and MPW can acquire more than three times the amount of positive instances than DP due to use of patterns associated with seed relation instances. Note that, although the two proposed methods only differ on scoring functions, the numbers of acquirable positive instances by the methods are different. This difference, which corresponds to an error rate of about 5% against the total number of outputs, is caused by biases of the random samples.

#### C. Experiment 2: Validation of performance using different size of input corpus

In order to validate our method perform effectively if only a small size of corpus is available, we perform an evaluation using subcorpora consisting of 500k, 250k, and 100k documents of MNA. We evaluate precision of the top 20% instances for each method, assuming it provides just about the upper bound of precision of each method. The precision of each method and each subcorpus is calculated from 50 random samples similarly to the first experiment.

Table III shows the total number of output instances and the precision of the top 20% instances acquired by each method. Due to the difference between the numbers of output instances by the baseline method and those of the proposed methods, we can not directly compare the precisions between them. However, it is considered to be easier to acquire a larger amount of positive relation instances by the proposed methods because of the increased numbers of output instances compared to those of the baseline method.

Similarly to the first experiment, MPW outperformed MP for all input corpora. The results also show that the precisions of the proposed methods for the smaller size of corpora does not substantially decrease compared with ones for the larger size of corpora. Namely, our methods suppress decrease of precision against decrease of corpus size. Therefore we conclude that our methods can be applied to a limited size of domain corpus for efficient acquisition of reliable relation instances. We plan to acquire domain-specific knowledge by

TABLE III

THE TOTAL NUMBER OF OUTPUT INSTANCES AND PRECISION OF THE TOP 20% INSTANCES ACQUIRED BY EACH METHOD FROM EACH CORPUS OF 500K, 250K, AND 100K DOCUMENTS

	Method	500k-docs	250k-docs	100k-docs
No. of outputs	DP	49.6k	21.7k	5.9k
	MP/MPW	222.1k	101.4k	27.5k
Precision (top 20%)	DP	0.70	0.76	0.66
	MP	0.44	0.46	0.46
	MPW	0.56	0.60	0.48

applying the methods to various domain corpora in future work.

## V. CONCLUSION

We have described our method to acquire event relations with high coverage even from a limited size of knowledge sources. We extended the existing baseline method that relies only on direct dependency relation between events and proposed the method that leverages various dependency patterns co-occurring with event relations. We evaluated our method on a general newspaper corpus in Japanese and found that our method can acquire a larger amount of event relations while keeping higher precision compared with the baseline method. The results also show that our method suppresses decrease of precision against decrease of corpus size and it can acquire reliable relation instances efficiently from a limited size of corpus. In future work, we plan to apply the method to various domain corpora and demonstrate the effectiveness of the acquired knowledge for applications such as probabilistic inference.

**Abstract**—This paper reports comparative authorship attribution results obtained on the Internet comments of the morphologically complex Lithuanian language. We have explored the impact of machine learning and similarity-based approaches on the different author set sizes (containing 10, 100, and 1,000 candidate authors), feature types (lexical, morphological, and character), and feature selection techniques (feature ranking, random selection). The authorship attribution task was complicated due to the used Lithuanian language characteristics, non-normative texts, an extreme shortness of these texts, and a large number of candidate authors. The best results were achieved with the machine learning approaches. On the larger author sets the entire feature set composed of word-level character tetra-grams demonstrated the best performance.

## I. INTRODUCTION

MOST comments or forum posts on the Internet are written anonymously. Due to anonymity people can freely share their thoughts, but cannot feel protected from the negative behavior or cybercrimes. Protective mechanisms (monitoring IP addresses or requesting to register and submit personal data) are not always reliable enough: perpetrators change their IP addresses, use different pseudonyms, or route WebPages through proxy servers. However, even in such complicated situations, the identity can still be disclosed from the existing “stilometric fingerprint” unique to each individual [1].

Apart from the handwriting analysis [2], the textual authorship analysis covers very different applications: author profiling, authorship verification, plagiarism detection, etc. However, in this research we are focusing on the Authorship Attribution (AA) problem which has to detect who of the candidate authors is a real author of some anonymous text document. AA is one of the earliest problems in Computational Linguistics: the oldest attempts were restricted to attributing of the disputed long and homogeneous literary texts to one of few known authors. In the recent decades AA drifted towards practical applications: it copes with the huge number of candidate authors, extremely short texts, limited training data and for all these reasons AA is often called “needle-in-a-haystack” problem [3].

In this research we are solving the AA task using a corpus composed of the Lithuanian Internet comments. Although the corpus does not contain texts produced by convicted cyber criminals, it can perfectly serve for various experiments aimed

at detecting authors’ style characteristics. The aim of the paper is to determine the best approaches (in terms of the attribution paradigm, the feature type, and the feature selection technique) for the different author set sizes, containing 10, 100, or 1,000 candidate authors. The problem is complicated due to several reasons: 1) very short texts, covering a wide range of topics; 2) the morphologically and vocabulary rich Lithuanian language; 3) non-normative texts; 4) there are no recommendations what could work the best for our solving task. Consequently this research aims at finding the best solutions for the Lithuanian language. Moreover, we anticipate that these solutions could be also useful for the other Baltic or Slavic languages, sharing similar characteristics.

## II. RELATED WORK

The statistical methods used to tackle AA tasks can be grouped into two main paradigms: machine learning and similarity-based<sup>1</sup>. The comprehensive review of these methods and various feature types is presented in [4].

The majority of AA research works are carried out on a small number of candidate authors (up to few dozens) and even findings obtained from comparative experiments are very controversial due to the different experimental conditions (languages, datasets, author sets, etc.). Whereas, the comparative experiments tackling “needle-in-the-haystack” problems often claim the superiority of similarity-based approaches (e.g., [5], [6]). However, such experiments are rather rare: i.e., most often methods are chosen and applied without any considerations. Further we will focus on the influential research works dealing with at least one thousand candidate authors.

The experiments described in [7] are carried out on the Twitter corpus: the introduced “flexible patterns” (taking into account the surrounding information around function words) significantly outperform other feature types based solely on word or character n-grams with SVM. The work in [8] is addressing the open-class issue and deals with the blog dataset of 10,000 authors. It tests a combined similarity-based and machine learning technique on 3 text representation types: tf-idf on content words, tf-idf on various stylistic features, and

<sup>1</sup>Despite by the nature similarity-based approaches are the part of machine learning, they are distinguished and discussed separately in many AA works.

idf on content words. The similarity-based part of this hybrid approach ranks authors according to the cosine values and afterwards the top-rank pair (composed of the anonymous text and the most likely author) is tested on the meta-learning SVM classifier. The high precision in [9], [10], [11] is achieved using the cosine similarity-based technique aggregating several attribution decisions, taken on the different randomly selected subsets of character tetra-grams. These researchers, experimenting with 10,000 blog writers, are also addressing the open-class issue. The research in [12] solves the AA task on the Japanese microblogs of 10,000 authors with the cosine similarity-based approach and character-level n-grams (with n equal to 1, 2, and 3). Adopted three new techniques –in particular, the combined selection for the training dataset, the biased weighting scheme for n-grams, and the part-of-speech tag combined n-grams– assure both the relatively high precision and the short execution time. Another task of 19,000 blog writers is successfully tackled with the Latent Dirichlet Allocation (LDA) technique by measuring the distances between the LDA-based representations (as mixtures of topics) in the anonymous text and in training text samples. The authors of this research [13] claim that offered similarity-based technique applied on the author profiles with enough training data even yields state-of-the-art performance. The authors in [6] are dealing with 100,000 blog writers. They explored 3 different classifiers (SVMs, Naïve Bayes, and Regularized Least Squares Classification) and, in addition, estimated the confidence of their outputs – in particular, measured the difference between the best two matching classes, ran several classifiers, and presented the final AA decision only if they agreed.

Unfortunately the surveyed research works offer no research-based recommendations for the morphologically rich, highly inflective, derivationally complex non-normative Lithuanian language. Despite for the Lithuanian language there are done: 1) lots of descriptive research works (e.g., [14], [15]); 2) some experiments with machine learning (carried out on parliamentary transcripts or forum posts of only 100 candidate authors) [16] or similarity-based approaches (using very limited training data) [17]; these findings do not guarantee the best results for our solving AA task. Our aim is at performing the comparative investigation and at finding the best method, feature type, and feature selection technique for our AA task (with 10, 100, and 1,000 candidate authors) on the corpus of the Lithuanian Internet comments.

### III. THE CORPUS

The created corpus<sup>2</sup> is composed of the Lithuanian Internet comments.

The texts of authors were selected in the way not to get the topic-per-author distribution. Some author was included into the corpus only if all his/her comments were written under the same unique pseudonym and IP address (both considered as a single unit), but not included if 1) his/her pseudonym

was used under several IP addresses; 2) more pseudonyms were used under the same IP address. The aim was to reduce the risk of disputed authorship and to get as clean corpus as possible. Although some exceptions (when the same author is writing under several separate IP addresses using different pseudonyms) may still occur, we anticipate they are rare enough to have the significant impact.

During pre-processing all recognized non-Lithuanian characters and reply messages were filtered out, meta information about the author and his/her posts was also eliminated, comments shorter than 30 symbols were excluded.

The most important characteristics about the composed corpus, depending on the different author set sizes (experimentally investigated in this paper) are given in Table I. The authors with the largest number of texts were selected to form the author sets of 10 and 100 candidate authors. The average texts/per author distribution is  $\sim 155$ , but the corpus is unbalanced: i.e., text samples per author varies from only 39 to 2,837. 13 authors have more than 1,000 texts, 575 authors have less than 100, and only 12 authors have the least number of texts. The random ( $\sum_j P^2(c_j)$ ) and majority ( $\max(P(c_j))$ ) baselines (where  $P(c_j)$  is the probability of some author  $c_j$  obtained by dividing a number of texts written by particular  $c_j$  from all number of texts in the corpus) must be exceeded that the AA method could be considered appropriate.

There is no consensus about the minimal text length appropriate for the AA tasks: some researchers claim 2,500 words is optimal [18], others achieve reasonable results with  $\sim 60$  [19]. In our task we have to deal with extremely short texts where an average length ranges from  $\sim 20$  to  $\sim 26$  tokens. Besides we are dealing with the sparse non-normative texts full of out-of-vocabulary words, abbreviations, missing diacritics (where Lithuanian letters having the diacritic marks are replaced with the corresponding Latin equivalents), diminutives, etc.

TABLE I  
CHARACTERISTICS OF THE LITHUANIAN INTERNET COMMENT CORPUS.

Number of authors	10	100	1,000
Number of texts	14,443	63,131	155,078
Number of tokens (letters & digits)	289,462	1,511,823	4,068,231
Average text length (in tokens)	20.042	23.947	26.233
<b>Classification accuracy baselines</b>			
<i>Random baseline</i>	0.001	0.002	0.003
<i>Majority baseline</i>	0.018	0.018	0.018

### IV. CLASSIFICATION APPROACHES

In this research we have explored the following approaches:

- *Support Vector Machine* (SVM) (introduced in [20]), which efficiently handles the high dimensional feature spaces, the sparseness of the feature vectors, and does not perform an aggressive feature selection. In our experiments we selected Sequential Minimal Optimization (SMO) algorithm with the polynomial kernel implementation in WEKA, version 3.8 [21] and all remaining parameters were set to their default values.

<sup>2</sup>The corpus can be downloaded from [http://dangus.vdu.lt/~jkd/wp-content/uploads/2015/04/INT\\_KOMENTARAI\\_INDV2.7z](http://dangus.vdu.lt/~jkd/wp-content/uploads/2015/04/INT_KOMENTARAI_INDV2.7z).

- *Naïve Bayes Multinomial* (NBM) (introduced in [22]) which is often selected due to simplicity, low data storage resources, the fast processing, robustness to cope with the large number of features having equal significance. We used implementation in WEKA with the default parameter values.
- *Similarity-based approach* (SB) with cosine measure [23]. In this paper we explore a simple similarity-based approach with the top  $N$  ranked features (SB-TopN) and the approach based on the randomized feature sets (introduced in [9]) (SB-RFS). The SB-RFS technique is adjusted to cope with very concise texts; performs especially well on a small number of features, because the final attribution decision incorporates the generalized results of several decisions obtained during a few iterations. In our experiments we used SB-TopN and SB-RFS implementations presented in [17].

## V. FEATURE EXTRACTION

In our research we have investigated the impact of the most popular and the most accurate feature types (for the statistics see Table II):

- *lex* – a bag-of-words. In our corpus we do not have topic-per-author distribution, therefore this feature type can be used without any risk to get topic classification instead of AA.
- *lem* – a morphological feature type based on the word lemmas. This type is usually recommended for the highly inflective languages. The texts were lemmatized using “Lemuoklis” [24].
- *chr4* – a character feature type based on the word-level tetra-grams. This type was superior to the other types in the topic classification task for the Lithuanian language [25].

Lemmas and character features decrease the sparseness of the feature vectors (see Table II): the lower the sparseness is, the more robust classifier is created. The sparseness can also be reduced with the selection of the most relevant features, therefore in our experiments we investigated the following feature selection techniques:

- *Whole set of features* – i.e., we used the entire set of all  $N$  available features (presented in Table II). This technique was tested with SVM, NBM, and SB-TopN methods.
- *Feature ranking and selection of top  $N$* . All features were ranked according to their chi-square values and afterwards the top  $N$  were chosen to form the new set. In our experiments we have investigated  $N = 30,000$ , because this value was proved to be minimum but optimal in the similar AA experiments [17]. We have explored this technique with SVM, NBM, and SB-TopN.
- *Random selection of features with a fixed size  $N$* . The  $N$  features (with  $N = 30,000$ ) were randomly selected from the whole feature set. The random selection was done in  $K = 20$  iterations with SB-RFS method. The final attribution decision was based on the majority vote of attribution decisions obtained in all  $K$  iterations.

TABLE II  
FEATURE TYPES IN THE CORPUS OF THE LITHUANIAN INTERNET COMMENTS.

Feature type	Number of features		
	10 authors	100 authors	1,000 authors
<i>lex</i>	56,064	172,257	315,590
<i>lem</i>	39,498	109,935	201,469
<i>chr4</i>	40,855	78,773	119,008

## VI. EXPERIMENTAL SET-UP AND RESULTS

The experiments were carried out on the stratified corpus (described in Section III). Instances were selected for the training (of 80%) and testing (of 20%) sets. The same training/testing sets were used in all our experiments exploring different methods (see Section IV), feature types, and feature selection techniques (see Section V).

The experiments were evaluated using *accuracy* and *f-score* (averaged over different classes) performance measures. We also performed the McNemar test (with the significance level of 95%) to check if the differences between observed results are statistically significant.

The results obtained on the datasets with 10, 100, 1000 candidate authors are presented in Fig. 1, Fig. 2, Fig. 3, respectively. *Accuracy* and *f-score* values are presented in white and gray columns, respectively. The first two columns of the *accuracy* and the *f-score* present the results achieved on the entire feature set, the second two – on 30,000 features (with SB-RFS all results are obtained with 30,000 features). The dashed line indicates the higher one of the random and majority baselines.

## VII. DISCUSSION

Not all results are reasonable: i.e., the *accuracy* on the token lemmas (*lem*) with SB-RFS is below the majority baseline (equal to 0.018).

The similarity-based approaches are outperformed with machine learning in all our datasets of 10, 100, 1,000 candidate authors. The differences between *lex* + SB-RFS and 30,000 *lem* + NBM on 10 candidate authors and the differences between entire *chr4* + SB-TopN and 30,000 *lem* + NBM on 100 candidate authors are statistically significant with the probability density function  $p \ll 0.05$ . Whereas, the difference between entire *chr4* + SB-TopN and 30,000 *lem* + NBM on 1,000 candidate authors is not statistically significant with marginal  $p = 0.05$ . Since the NBM method and the similarity-based approaches maintain similar performance levels on the largest dataset, SVM is obviously superior to any similarity-based technique in any dataset ( $p \ll 0.05$ ). However, similarity-based approaches can still be suitable with the larger author sets. The superiority of SVM compared to the similarity-based methods with the increase of the candidate authors is declining and probably some breaking point can be reached. These investigations are already in our future plans.

If SVM is obviously superior to NBM, the similarity-based approaches produce very controversial results: *lex* + SB-RFS, entire *lex* + SB-TopN, entire *chr4* + SB-TopN are the best

Fig. 1. The influence of the selected approach on the results with 10 candidate authors.

Fig. 2. The influence of the selected approach on the results with 100 candidate authors.

Fig. 3. The influence of the selected approach on the results with 1,000 candidate authors.

approaches on the datasets containing 10, 100, and 1,000 candidate authors, respectively. Due to these findings is hard to say which similarity-based method is actually the best.

The important findings lie in the analysis of the various feature representation types. *lem* and *chr4* types give the best results with NBM; with SVM is difficult to determine the best type (because differences in the accuracies between different feature types are not statistically significant); *lex* is the best type with the similarity-based methods on the dataset of 10 candidate authors. *chr4* type gives the best results with NBM and SVM; with the similarity-based methods is difficult to determine the best type on the dataset of 100 candidate authors. *lex* and *chr4* types are the best with NBM; *chr4* type is the best with SVM; and marginally the best with the similarity-based approaches on the dataset with 1,000 candidate authors. Thus, summarizing all these findings it can be concluded that the best feature type (especially on the larger author sets) is character tetra-grams (*chr4*). Morphological tools are helpless on the non-normative texts, but character features are robust to deal with the morphologically complex languages by capturing the patterns of complex inflection morphology intrinsically.

The restriction of the feature set size to 30,000 features speeds up the calculation time, but, statistically significant degrades the accuracy, except with the SB-RFS method.

### VIII. CONCLUSIONS AND FUTURE WORK

The main contribution of this research is a comparative study of AA approaches (machine learning, similarity-based), feature types (lexical, morphological, character), feature selection techniques (whole set, feature ranking, random selection) and the author set sizes (of 10, 100, and 1,000 candidate authors) on non-normative Internet comments using the morphologically complex Lithuanian language.

The best results were achieved with the machine learning approaches; on the larger author sets the word-level character tetra-grams with the whole set of features demonstrated the best performance.

The obtained authorship attribution results are low enough to encourage us to continue seeking for the better solutions. In the future research we also plan to experiment with the larger authors sets and with the other types of non-normative texts.

### ACKNOWLEDGMENT

**Abstract**—Correct identity recognition based on a voice sample must deal with many problems such as too big or small distance from the microphone, noise or abnormal voice. Hoarseness, coughing or even stuttering can also be encountered as disturbance of the voice. Research on new aspects of intelligent processing for voice brings possibilities to use intelligent methods to increase efficiency in processing and quality of record. In this paper, a spectrogram analysis for the detection of specific data and remove these distortions in the sample is presented. The proposed solution has been tested and discussed for real use in identity verification systems.

## I. INTRODUCTION

VOICE and sound are present in digital form which is used in multimedia systems and various aspects of computer processing. Sound signal analysis finds many uses in practical applications such as identity verification or even analysis of specific commands used for controlling different hardware. This is the main motor for signal research to allow quick and accurate signal analysis and good data extraction. For this purpose, different tools are used like statistical artificial intelligence techniques. Sound analysis is very often associated with the processing of sound files or even images. In [1], the idea of using heuristic algorithms in conjunction with the neural classifier has been introduced as a tool for identity verification process. Again in [2], the authors presented the use of modified mellin transform for detection of selected voice disorders.

Processing sound samples is not only a distortion analysis or identity verification, but also analysis of information, for example in the form of singing. It is important to distinguish the singing from other forms of speaking [3]. Moreover, there is an algorithm to check if a recorded sound can be classified as a spoken form [4]. All these techniques and applications find their place in different systems where voice is an important element. In [5], smartphone user identity was presented where gait characterization was used and the same idea can be used with voice analysis. Again in [6], voice-based authentication for the purpose of application in mobile phones was discussed. Large systems need huge databases where samples and data will be kept. During using the data contained in the database, it is often necessary to select a variety of them by using search and sort algorithms [7], [8]. Of course, algorithm is needed in the construction of large systems but also programming

language are very important. In [9], [10], the development of human-friendly notation was shown.

In this paper, the algorithm for simple detection of sound samples distortion is presented. The main use of this algorithm is based on the analysis of samples in identity verification systems.

## II. VOICE DEFECT DETECTION

The ideal voice-based user verification system should almost always handle verification. The work of the system shall be possibly independent, that means we can expect the system to work despite distortion, noise, and sample size. Unfortunately, the number of different problems from detection methods, analysis to classification that this type of tool must handle is large therefore it must be continuously developed and improved for practical use. Let us think about practical implementation in a company to grant access to workers. In case of a large company, an employee i.e. coming to work must declare the name to the voice receiver. In order not to cause queues and unnecessary problems, the software should verify the person in spite of any possible voice transformations such as hoarseness or cough.

### A. Algorithm for detecting selected distortion of the voice sample

The proposed solution is based on creating a collection of voice samples with the same information from one person. For these, implemented system is trained to evaluate input signals. In the process we can distinguish two stages - pattern preparation and pattern analysis. In the methodology SURF method described in [11] is used to extract key-points from recorded spectrograms. The process is presented in Algorithm 1.

### B. Pattern preparation

At the beginning of processing, a spectrogram is created for each sample. The spectrogram is a graph of the amplitude spectrum, which is formed by the use of a short-time Fourier transform (STFT). The process of creating spectrograms is based on the principle of calculating the short-time fast

**Algorithm 1** Pattern creation process

---

```

1: Start,
2: Define the radius  $r$  and limit value  $\phi$ ,
3: Load all audio samples,
4: for each audio sample do
5:   Create spectrogram,
6:   Find key-points using SURF algorithm,
7:   Create white bitmap called pattern,
8:   for each key-point do
9:     Set key-point,
10:    Draw and fill the circle with radius  $r$  with key-point
        as center,
11:   end for
12:   Save pattern,
13: end for
14: Create an array filled with 0,
15: for each pattern do
16:   for each pixel on the pattern do
17:     if pixel is black then
18:       Increase the corresponding value in the array by 1,
19:     end if
20:   end for

Fourier transform. According to [12] these are most usefully represented by the following equation

$$\begin{aligned}
 STFT\{x[n]\}(m, \omega) &\equiv X(m, \omega) \\
 &= \sum_{n=-\infty}^{\infty} x[n]w(n-m)\exp(-j\omega n),
 \end{aligned} \tag{1}$$

where  $x[n]$  is the discrete signal and function  $w$  is the Hann window defined as

$$w(n) = 0.5 \left( 1 - \cos \left( \frac{2\pi n}{N-1} \right) \right). \tag{2}$$

In this way, the defined transformation allows the spectrogram to be calculated by

$$spectrogram\{x(t)\}(\theta, \omega) \equiv |X(\theta, \omega)|^2. \tag{3}$$

In the next step, we find key points in these images using SURF (Speeded Up Robust Features) algorithm [11]. It uses a

Hessian to find points of interest and indicates local changes around the area. It is defined as

$$H(x, \omega) = \begin{bmatrix} L_{xx}(x, \omega) & L_{xy}(x, \omega) \\ L_{xy}(x, \omega) & L_{yy}(x, \omega) \end{bmatrix}, \tag{4}$$

where  $L_{xx}(x, \omega)$  is the convolution of the image with the second derivative of the Gaussian and can be calculated as

$$L_{xx}(x, \omega) = I(x) \frac{\partial^2}{\partial x^2} g(\omega), \tag{5}$$

$$L_{yy}(x, \omega) = I(x) \frac{\partial^2}{\partial y^2} g(\omega), \tag{6}$$

$$L_{xy}(x, \omega) = I(x) \frac{\partial^2}{\partial xy} g(\omega), \tag{7}$$

where  $g(\omega)$  is the Gaussian kernel.  $I(x)$  is an integral image where  $x$  is the point that stores the sum value of all pixels in the neighborhood calculated by

$$I(x) = \sum_{i=0}^{i \leq x} \sum_{j=0}^{j \leq y} I(x, y). \tag{8}$$

The whole detection algorithm is based on non-maximal-suppression of determinant of Hessian matrix defined in (4). Then, the extremes are found, which can be considered as key-points. The next step of SURF is the description which is based on Haar wavelet. Mentioned determinant can be calculated as

$$\det(H_{approximate}) = D_{xx}D_{yy} - (wD_{xy})^2, \tag{9}$$

where  $w$  is the weight, and  $D_{xx}$  refers to  $L_{xx}(x, \omega)$ .

Having key-points of all the samples, a pattern can be created for each of them. For each spectrogram, we create a new image, where we transfer the key-points. Further, for each point, a neighborhood is created in the form of circle - key-point is a center and  $r$  is a radius.

### C. Pattern analysis

The next step in proposed methodology is creation of a general pattern and then comparison of this pattern to extract only interesting information. Such extraction will allow us to remove unnecessary areas for instance distortions such as coughing.

In the first step, we create an array corresponding to the image size  $n \times m$ . Each cell is equal to 0. For each pattern, the pixel value is checked - if it is black, the corresponding cell in the array is incremented by 1. After checking all the images, we define the minimum value  $\phi$  which will represent the limit value in the general pattern creation process.

New bitmap of size  $n \times m$  is created. If the value of the cell in the array is greater or equal  $\phi$ , a black pixel is set. Otherwise, the pixel is white. The effect of this algorithm is shown in the Fig. 1, and the whole idea is described in Algorithm 1.

Analysis is understood as fitting a new sample to the general pattern. Once the pattern is matched, the rest of the samples can be removed because it contains noises or other misleading information for the verification process. If the sample is larger

Fig. 1: In the figures we can: (a) original spectrogram, (b) spectrogram with key-points found by SURF algorithm, (c) pattern created on the basis of key points, (d) pattern created on the basis of all the spectrograms.

than the pattern, it is shifted from left to right to find at least 80% of the key-points within the general pattern. If it is smaller, the sample is resized to the pattern size and the position of key-points are verified. The example of the action is shown in Fig. 3.

Fig. 2: Data extraction results due to selected voice imperfections.

### III. EXPERIMENTS

A small database of 100 different samples of *Han Solo* sentences was created. 40 samples were recorded without any voice defect to create the original pattern matching the person.

The remaining samples, for test purposes, were divided into four groups of 15 samples, namely: cough, scream, stutter and hoarseness.

Tests were performed because of the different parameter values  $r \in \langle 1, 40 \rangle$  and  $\phi \in \langle 5, k \rangle$  where  $k$  is the number of samples without any defect. In the case of a radius, too little value caused no pattern matching. On the other hand, too big value caused the pattern to cover the sample. It turns out that the value of the radius should be matched by the size of the sample – for samples of 940x300. The best results were obtained with a radius of 20 pixels. Adjusting  $\phi$  value is much simpler. The greater the value, the less points will be transferred to the general pattern. The tests showed that the number of points should not be too high, because the voice may have different distortions, such as the distance from the microphone. The best results were obtained for  $\phi = 10$ .

For such selected parameters, the proposed technique was tested for each voice sample with a defect. The results are shown in Fig. 2. Extraction of the name in most samples labeled as stuttering failed what can be caused by wrong choice of parameters. In other cases, extraction was successful for almost every sample. For such data, the efficiency of the method is 80%, which is not the best result. However, a greater number of samples as well as a better selection of values could improve the performance index.

### IV. CONCLUSIONS

In the paper, the application of graphic processing for removing unnecessary data from the verification sample of a voice spectrogram has been demonstrated. The proposed solution is intended for identity verification systems based on a short audio sample containing only the name of the person. Technique was tested on a small database of sound samples, resulting in 80% efficiency in extraction of these specific information. Of course, such a solution would reduce the amount of calculations for classifiers because the sample will not only be smaller but contain only needed information. Unfortunately, there are also some imperfections that affect the percentage efficiency of the method, that is, manually adjusting the value of the parameters that significantly affect the process of matching a sample to the pattern.

In future research, adjustment of parameter values will be analyzed for the best adjustment for many people in the database and others datasets. The method will be subjected to more analysis in order to increase efficiency. Furthermore, the removed imperfections in the samples may be subjected to a certain classification for analysis.

### V. ACKNOWLEDGMENT

**Abstract**—This work presents a method of classification of text documents using deep neural network with LSTM (long short-term memory) units. We have tested different approaches to build feature vectors, which represent documents to be classified: we used feature vectors constructed as sequences of words included in the documents, or, alternatively, we first converted words into vector representations using word2vec tool and used sequences of these vector representations as features of documents. We evaluated feasibility of this approach for the task of subject classification of documents using a collection of Wikipedia articles representing 7 subject categories. Our experiments show that the approach based on an LSTM network with documents represented as sequences of words coded into word2vec vectors outperformed a standard, bag-of-words approach with documents represented as frequency-of-words feature vectors.

## I. INTRODUCTION

THE problem of automated classification of text documents is one of important tasks solved by text mining methods. A number of diverse applications of text classification were reported in literature, ranging from subject categorization [3], analysis of sentiment of reviews or opinions, to authorship recognition of documents [4], [8], [9], etc.

Standard methods of text classification consist in representing documents with usually high-dimensional feature vectors and then training classifiers such as SVM, Naive Bayes, k-NN, etc. [7], [5], [6]. Although several ways of representing documents with feature vectors were proposed (see e.g. [1]), a commonly used approach consists in constructing feature vectors which represent (possibly weighted) frequencies of selected words or collections of words (bigrams, n-grams, phrases) that appear in subsequent documents. These approaches can be broadly named as bag-of-words methods.

In this work, we want to investigate feasibility of a conceptually different approach to (i) representing documents with feature vectors, and (ii) training classifiers. The key difference is that rather than using feature vectors which are based on frequencies of words, we use feature vectors that rely on sequences of words in documents. As a consequence of this, we also need to change the type of classifier used: we use in this study a neural network with the long short-term memory (LSTM) [15] element, which allows to learn sequences from the training data. We use two different ways to of representing sequences of words for training the LSTM network: with

simple encoding of words, and with word2vec method which represents words in vector space [10].

We provide empirical verification of this approach based on a collection of Wikipedia articles which represent 7 subject categories (arts, history, law, medicine, religion, sports and technology), with 1000 articles per category. As this corpus was also used in our previous study [2], where subject classification was based on bag-of-words approach, we have a chance to compare performance of these two methods.

Technically, the presented approach to classification was implemented using the Keras with Tensorflow library for deep neural networks with the models trained on a GPU. We also provide some technical details regarding implementation of the classifiers, as this may be of use to the interested readers. Keras is a wrapper to Tensorflow that gives ability to construct neural networks layers in just few lines of code, which defines the layers that the model consist of. Figures included in this paper present what network architectures were developed (Fig. 1-4).

The idea behind this paper, was to show how to build effective text classifier using state-of-the-art Deep Learning methods and tools and show what issues can appear during this procedure.

## II. STANDARD (BOW) APPROACH TO CLASSIFICATION

In traditional Bag-of-Words approach the key-words are filtered from training data. Usually, some Natural Language Processing methods can be involved such as: Segmentation, Tokenization, PoS Tagging, Entity Detection, Relation Detection [12]. Creating such objects from text can give a lot of information about its content. The appearance and frequencies of specific tokens, entities are used as a basis for Bag-of-Words model. However, the number of this kind of object can be very large. Therefore, methods to reduce dimensionality of data are needed, for instance TF-IDF, PCA, LDA, SVD, t-SNE etc. [11], [20] to take only the most important words for classification.

### A. Related work

In this work, we used NLTK (Natural Language Processing Toolkit) algorithms for tokenization. However, we adopted a different approach to feature selection: rather than encoding

the frequencies of key-words, the words from sentences were directly transformed into sequences of encoding vectors and were used for training deep learning methods such as Long Short-Term Memory Network (LSTM). This approach has a common factor with probabilistic models such as n-grams, conditional random fields and other Markov-models, which also use sequences and are based on appearance probability of specific words.

LSTM neural networks are considered as state-of-the-art approaches offering very high accuracy results in several Natural Language Processing tasks such as: Bi-directional LSTM-CRF [18] for Part of Speech Tagging and Tree-LSTMs for sentiment analysis [19]. Also, simpler versions of LSTMs, referred to as Gated Recurrent Units (GRUs) [16] are used as key parts of larger systems like state-of-the-art Dynamic Memory Networks, developing more complicated tasks such as questions-answering systems [17].

#### *B. Sample data for empirical verification of the methods*

The dataset used for this work has been introduced in [2]. It is based on English Wikipedia articles. Each article has at least 400 characters. The corpus consists of 7 categories such as arts, history, law, medicine, religion, sports and technology with 1000 articles in each category. The data was split randomly into 800 training and 200 testing articles. Also, later in the tests k-fold validation was performed. The test was performed for 2, 3 and 7 categories independently.

Prior to feature selection and model development, we pre-processed the text data using standard NLP methods (with NLTK library) – the first step was to tokenize the text documents. This approach was similar to previous work [2] and is a part of traditional NLP processing chain. We used English Punkt as sentence tokenizer for segmentation task. Next, the sentences were split to words by RegexpTokenizer over white spaces and punctuation was removed from the text. After that, all letters were changed to lowercase. Finally, all stopwords were removed from data.

The corpus used in this study was very diversified. Each article had on average 520 words with standard deviation of 902. The largest article had 14591 words, however, for training purpose each of the articles was cropped to 500 or 1000 words in length.

#### *C. Results of BOW method for this dataset in previous work*

This work is an extension of the previous research [2], where subject classification was done using standard Machine Learning such as Decision Trees, Naive Bayes classifier etc., with the focus on distributed implementation, in order to manage large volumes of data. The best results in the previous work was obtained using Bag-of-Words model with TF-IDF and Naive Bayes, where recognition of three categories: History, Arts and Law was done with ca 75.28% accuracy on the testing corpus.

### III. PROPOSED APPROACH TO REPRESENTATION OF TEXT DOCS FOR CLASSIFICATION

The goal of this work was to apply the new Deep Learning approach to problem of subject classification and compare this with the results of the study solved previously. During this research, two approaches to feature selection were tested. In order to use Deep Recurrent Neural Network (i.e. deep networks with the LSTM component), all the data had to be used as vectors of sequences. The first approach to obtaining such vectors was based on a very simple vocabulary encoding. It worked well for binary classification, however its accuracy deteriorated when the number of classes (subject categories) increased. The second approach was based on more sophisticated word2vec method, which was more stable and elastic solution.

#### *A. Method 1 – Simple encoding of word sequences*

The first idea presented in this paper came from Kaggle challenge called "Sentiment Analysis on Movie Reviews" [21], in which was provided IMBD Movies reviews dataset was provided for sentiment classification, which is a quite close related problem to subject classification. This dataset is also available in Keras. Based on this approach, also the Wikipedia tokenized corpus used in this work was encoded.

The simplest idea to encode words is to enumerate them. In this approach, the words are encoded using the following mapping: word\_from\_dictionary: number. The dictionary is ordered from most frequent words in learning set to the least frequent ones, with the conventions: 1 - denotes the start of the sentence, 2 - means word out-of-vocabulary, 0 - is padding if the vector is shorter. This padding is done in front of the vector and the start of the vector is truncated if the sequences are longer than 1000 words. The vocabulary size was 10 000 tokens. Larger number of tokens would provide computational difficulties and this was the reason why this method has limited application. Example vector, which represents sentence can have a form [0, 0, 0, 1, 3565, 2, 3214, ...]. This method worked with 91.52% accuracy on two classes, but on three classes it decreased to 76.53% and 58.93% on seven classes (table I).

#### *B. Method 2 – word2vec - based encoding*

Word2vec is a method of representation of words in multi-dimensional vector space, recently proposed by Mikolov et al. [10]. Vector representations of words created (trained) on sufficiently large text corpus exhibit interesting linguistic regularities, e.g. distance between vector representations of words is an indicator of semantic similarity between the words. Due to these properties, vector representations of text have been used as features in many tasks related to natural language processing, such as word clustering, machine translation etc. In this work we want to investigate if word2vec representations of sequences of words can yield successful features for subject classification of documents.

In case of this work, the word2vec was calculated on a small number of words from training set with the dimensionality of the vector space equal 100. These first results show that

the training corpus was too small to properly calculate this vector values, because fraction of out-of-vocabulary words was almost 69% in binary classification and decreased to 67% in seven category multinomial classification. This lead to 78% and 14% accuracy in classification tasks, respectively.

The problem that emerged here was to gather more data. However, it was not feasible to get the required volume of training data (articles) from Wikipedia. Also, artificial text augmentation wouldn't be easy. The solution in order to overcome these limitations which we chose was to use a technique commonly applied in image classification called transfer learning. In Natural Language Processing this is usually done by using pretrained word vectors. One of the easily accessible vectors where available at the Google News word2vec official site [13]. It is worth to mention, that the Wikipedia is a domain specific set of texts, rather different than Google News. The fraction of out-of-vocabulary words was almost equal both for two and seven categories and was 53% comparing to previously mentioned 69% and 67% training set Word2vec. As a result, the efficiency was 92.25% for binary and 86.21% for seven category multinomial classification (table I). It has shown that even the Google News vectors had less corresponding words in the training data, it is enough general, that the LSTM Network can be effectively trained and it works even better than word vectors created from the training data. However, to fit a model with this type of vectors on a single GPU the length of sequences had to be shortened from 1000 to 500. Using the same size of length for simple vectorizer resulted that, it wasn't possible to fit this model. The reason was that Google News Word2vec had 300 vector length per word.

#### IV. ARCHITECTURE OF THE PROPOSED RECURRENT DEEP NETWORK

The idea in this paper was to use a standard LSTM network. This network has an advantage over standard Recurrent Neural Network that it doesn't have problems with vanishing gradients [14]. Simpler version of LSTM is GRU (Gated Recurrent Unit), that is almost as effective as LSTM, but it can be trained faster. However, the corpus used in this work had only 40 MB, therefore this wasn't necessary. The number of cells in LSTM was 500.

For each type of approach and number of categories slightly different network was used. In the simple vectorization approach an Embedding Layer was used. This layer encoded each token into 32 dense vectors. This is needed for proper LSTM training. In Word2vec approach this can be omitted. Other differences are in the last, dense, fully-connected layer. The number of units in this layer depends on the number of categories that each network is supporting (Fig. 1-4).

#### V. EMPIRICAL VERIFICATION

The results were obtained using Keras framework with Tensorflow backend (table I). All the experiments were done on NVIDIA 1080 Ti GPU with 11GB of RAM. The maximum number of epochs used in training was 50. The duration of

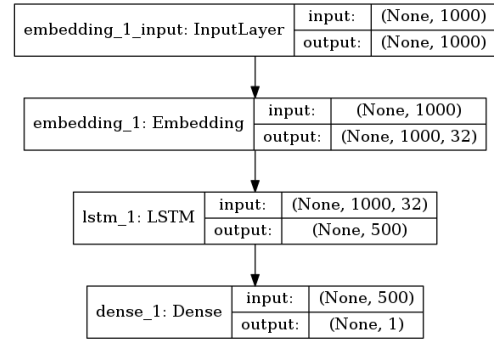

Fig. 1. Neural network used with simple vectorizer for binary classification. The simple encoded vectors with 1000 length are transformed into dense 1000x32 embeddings. LSTM has 500 units and dense layer has 1 unit.

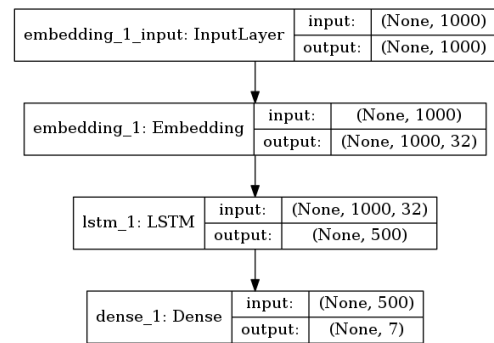

Fig. 2. Neural network used with simple vectorizer for multinomial classification. The simple encoded vectors with 1000 length are transformed into dense 1000x32 embeddings. LSTM has 500 units and dense layer used for classification has 7 units.

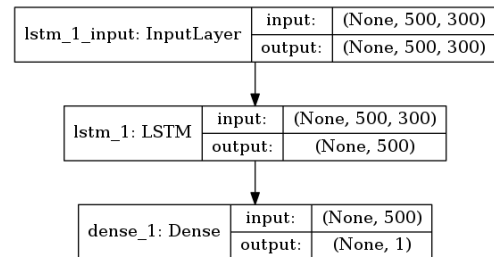

Fig. 3. Neural network used with Word2vec vectorizer for binary classification. The 500 length sequences with 300-length word vectors are put into 500 units LSTM. The dense layer used for classification has 1 unit.

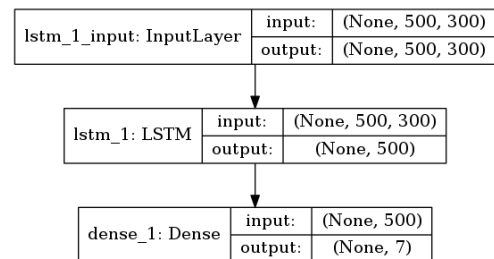

Fig. 4. Neural network used with Word2vec vectorizer for multinomial classification. The 500 length sequences with 300-length word vectors are put into 500 units LSTM. The dense layer used for classification has 7 units.

TABLE I  
DEEP NEURAL NETWORKS ACCURACY

Nr of classes	Simple Vectorizer	Word2vec	Class	Arts	History	Law	Medicine	Religion	Sports	Technology	Avg.
2	91.52 %	92.25 %	LSTM Prec.	89.5	79.5	92.5	87.5	82.0	90.5	82.0	86.21
3	76.53 %	89.52 %	CNN Prec.	82.5	62.0	88.0	85.5	83.0	89.5	83.5	82.07
7	58.93 %	86.21 %									

each epoch was from 5 seconds with Google News word2vec to 30 seconds for simple vectorizer multinomial classification. Batch size was 200. For binary classification binary crossentropy was used, and for multinomial - sparse categorical crossentropy as a loss function. The optimizer was Adam with default parameters, for instance learning rate was 0.001. The activation function was traditional sigmoid.

Also, the result for seven category classification with Google News word2vec for LSTM was compared with Convolutional Neural Network with architecture similar to [22], but without dropout regularization and it achieved ca 82% accuracy (table I). In this table we can also see that LSTM has better precision than CNN in most cases. Therefore CNN was less effective, but it could be trained an order of magnitude faster.

## VI. CONCLUSIONS

In this work we demonstrated a method of subject classification of text documents with the documents represented by sequences of words, which were used for training an LSTM neural network. We tried several ways of coding words appearing in the sequences, and found that the most promising results of classification were obtained with words represented in the word2vec vector space. We used word2vec models trained on a large Google news corpus and found that application of models trained on small corpora does not yield successful features for classification. We evaluated the method based on a sample corpus of Wikipedia articles, and obtained accuracy of ca 86% (accuracy of model trained to recognize one out of 7 subject categories). This best performance was realized with LSTM models trained with word2vec-coded sequences of words; these models outperformed a standard bag-of-words approach reported in our previous work. Although training deep neural networks is commonly regarded as resource-demanding, we found that training deep LSTM neural models as presented in this case study is now feasible using robust libraries such as Keras with Tensorflow and using mid-range GPU devices (system with 11GB of RAM was used). We also provide some technical hints regarding how such tasks can be solved with deep-learning approach.

The research can be continued in future work in order to increase the accuracy. The idea here would be to create better word vectors on larger corpora than Google News or using other word vector representation such as GloVe (Global Vectors) [23]. Also, some updates of network architectures with regularization method can be considered. However, the results show, that generalization of vector representation is a fundamental part in creating effective Deep Neural Network models for NLP and this vectors can be effectively used for texts that was not their main target.

**Abstract**—Today, large scale companies are receiving tens of thousands of feedback from their customers every day, which makes it impossible for them to evaluate the feedbacks manually. As sentiments expressed by the customers are vitally important for companies, an accurate and swift analysis is needed. In this paper, a hierarchical approach is proposed for sentiment analysis and further categorization of Turkish written customer feedback to a private airline company. First, the word embeddings of customer feedbacks are computed by using Word2Vec then averaged in proportion with the inverse of their frequency in the document. For binary sentiment analysis, i.e. determination of 'positive' and 'negative' sentiments, an extreme gradient boosting (xgboost) classifier is trained on averaged review vectors and an overall accuracy of 92.5% is obtained which is 16.8% higher than that of the baseline model. For further categorization of negative sentiments in one of twelve pre determined classes, an xgboost classifier is trained upon document embeddings of negatively classified comments, which were calculated using Doc2Vec. An overall accuracy of 71.16% is obtained for the task of categorization of 12 different classes using the Doc2Vec approach, thereby yielding a classification accuracy 19.1% higher than that of the baseline model.

**Index Terms**—customer relationship management, word2vec, doc2vec, classification, sentiment analysis, xgboost

## I. INTRODUCTION

CUSTOMER Relationship Management (CRM) has gained importance with the advent of the big data phenomenon. Millions of customers are sharing their opinions about the products they use every day. According to [1], 77% of customers care about other people's comments, while 75% of customers trust comments on social media rather than personal recommendations. CRM enables companies to focus on their customers' needs: e.g., what do they want and what needs to be fixed [2]. When a problem occurs, swift action needs to be taken by companies according to customer feedback to prevent any sort of damage. But, without an automated system, swift evaluation of tens of thousands customer feedback is impossible.

Advances in natural language processing (NLP) algorithms have enabled the development of automated CRM systems.

Companies are using these algorithms to determine their marketing strategies by observing their customers opinion about their products [3], [4]. However, sentiment analysis has not been widely investigated for agglutinative languages, such as Turkish. In [5] sentiment polarities of Turkish written movie critics data set were analyzed using an N-gram language model. Kaya et. al. [6] applied a maximum entropy and N-gram language model to classify sentiments of political news from several Turkish news sites. In some studies, a lexicon based approach is applied to conduct sentiment analysis on a movie critics data set [7] [8]. Lately, algorithmic innovations on NLP has enabled the emergence of various word embedding algorithms, among which the most popular is Word2Vec [9]. To the best of our knowledge, as of yet the performance of Word2vec for sentiment analysis in Turkish written text has not yet been investigated.

This paper proposes the use of unsupervised word/document embedding methods for sentiment analysis of Turkish written customer reviews and their further categorization to one of twelve classes. Word2vec is used to capture semantics of words from unlabeled large corpora of customer reviews. After which, a classifier is trained upon word embeddings of labeled training samples for the binary sentiment analysis task, where each word is proportioned by their tf-idf values, then averaged in order to have an averaged review vector for each customer review. Then, a document embedding algorithm, Doc2Vec [10] is trained on negatively classified customer reviews to extract document embeddings for customer reviews. Lastly, a classifier is trained upon document embeddings for the discrimination of the 12 pre-determined categories. Results of both sentiment analysis and categorization are compared with a baseline model: an xgboost classifier trained upon a bag of words vectors. The justification of not choosing a deep neural network approach is that we do not have enough labeled samples to feed the deep neural network. Neural networks are required huge amounts of data in order to yield a good generalization [11]. Also, the usage of transfer learning [12] is not possible since there are no models that have been trained

with a Turkish written data set.

The paper is structured as follows: In Section II, details about the evaluated data set is presented. In section III details for the proposed method is given. Finally, in Section IV, results of both sentiment analysis and categorization are shared and discussed.

## II. DATA SET

The data set evaluated in this work was collected by a private airline company. The company directly asked its customers about their opinions of their journey in overall, from airport to final destination. The data set contains a total of 14000 customer reviews ( $\approx 532000$  words after pre-processing) written in Turkish, where 1070 of them are labeled. The labeled part of the data set consist of labels for both sentiments and specific categories of reviews. The number of reviews and their average length for each sentiment are shown in Table I. There are 12 specific categories namely, flight crew, customer loyalty program, pantry, overall satisfaction, seat, baggage, boarding, in-flight entertainment (IFE), catering, time performance, lounge, check-in. Positive reviews are assigned to only one category: overall satisfaction. While positive reviews are made up of short sentences in general, negative reviews are complex and long. In addition, the distribution of negative reviews by category is disproportionate, as can be seen from Table II. Examples of customer reviews are given in Table III, translated to English for the benefit of readers.

## III. METHODOLOGY

The methodology used in this paper is summarized in Figure 1. First, the customer reviews are pre-processed in order to reduce the data complexity for word embedding methods. Then, word embeddings are calculated by using Word2Vec [9] [13] on unlabeled corpus. Furthermore, the word vectors are proportioned by their tf-idf values and then averaged in order to have a single review vector for each review. Then, an extreme gradient boosting (Xgboost) [14] classifier is trained on [15] review vectors of labeled customer reviews for the task of binary sentiment analysis, i.e. classification of positive and negative sentiments. The trained model is then used to classify all the CRM data in order to subtract positive sentiments from the data set. After the sentiment analysis, further categorization of negative sentiments are analyzed. Compared to the binary sentiment task, categorization of reviews is more challenging as the class complexity is higher as well as the labeled samples are being imbalanced. For the categorization of the negative comments, a paragraph embedding method Doc2Vec is employed [10], but only on the reviews which are indexed as negative by the first classifier. Since the labeled data set is imbalanced, the Synthetic Minority Oversampling Technique (SMOTE) [16] is applied to the negative reviews to solve the imbalanced learning problem. Then another Xgboost classifier is trained on document vectors for the categorization task. 10 fold cross validation is applied in training of models. Aforementioned steps are explained in detail in the following subsections.

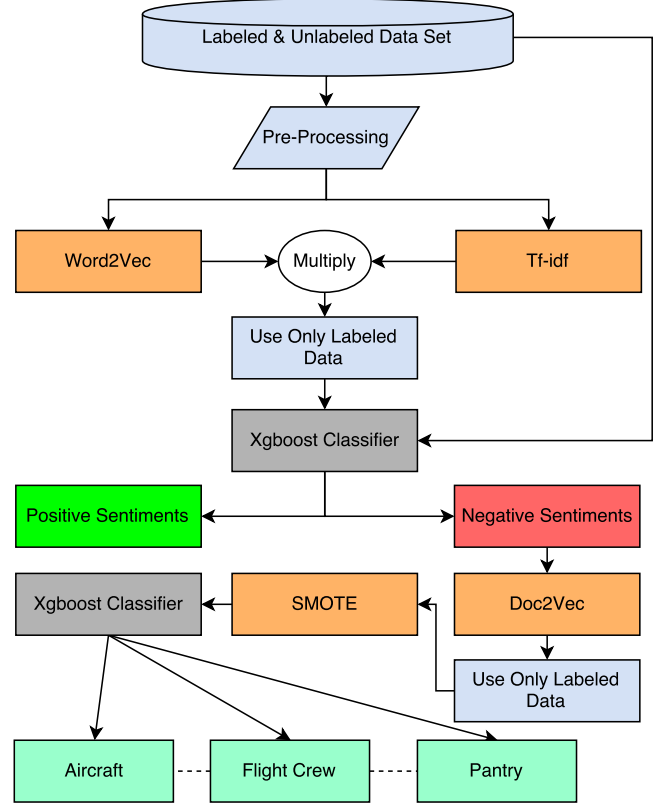

Fig. 1. Flow diagram of the proposed algorithm

### A. Pre Processing

To obtain proper word embeddings, a pre-processing stage is essential. Thus, the data set cleansed from numbers, punctuations and stop words. Lemmatization and tokenization is also applied.

**Tokenization)** Tokenization is an operation which splits a given sentence into individual words. However, Turkish contains several non-ascii letters, namely, 'ı', 'ç', 'ğ', 'ş', 'ö', 'ü', which makes this problematic for standard tokenizers. In this study, Zemberek, an open source tokenization and deasciification library specifically developed for Turkish language is used [17].

**Elimination of Stopwords, Punctuations and Numbers)** Stop words are referring to the frequently used words. In this work, 165 words such as 'fakat, de, da, ama, en, ki, ve' are considered stop words of which holds conjunctions and pronouns. These are removed from the data set but adjectives, such as good, nice etc. are kept as they are related to the subject of interest. Punctuations are fairly irrelevant in the data set. For example, exclamation mark is both used in negative and positive sentiments nearly the same amount. Therefore, all punctuations are discarded. Numbers also contain very little or no information considering the objective of this work.

**Lemmatization)** Lemmatization is an important operation in order to reduce the word complexity. As mentioned, Turkish is a agglutinative language, which makes stemming/lemmatizing

TABLE I  
DISTRIBUTION OF LABELED DATA ACCORDING TO THE POSITIVE AND NEGATIVE SENTIMENTS AND THEIR AVERAGE LENGTH

Sentiments	Number of Reviews	Average Length After Pre Processing (in terms of words)
Positive	406	21.7
Negative	664	48.9

TABLE II  
NUMBER OF LABELED REVIEWS FOR EACH NEGATIVE SENTIMENT CATEGORY

Class	Flight Crew	Customer Loyalty Program	Pantry	Overall Satisfaction	Seat	Baggage	Boarding	Ife	Catering	Time Performance	Lounge	Check-in
Sample Size	120	112	80	80	47	42	39	32	35	29	26	23

TABLE III  
SOME EXAMPLE REVIEWS (TRANSLATED TO ENGLISH)

Feedback	Category	Sentiment
Everything was great, thank you. Keep on going!	Overall Satisfaction	Positive
The call centre I contacted about my luggage delay were extremely unhelpful. They misinformed me about where to file my complaint, took 17 days to reply to my email and most importantly, they did not solve my problem.	Baggage	Negative

difficult. In this work, an open source lemmatization library *turkish-lemmatizer*, which is specifically designed for Turkish language, is employed [18]. The library uses longest matched stemming algorithm for lemmatization .

### B. Feature Extraction

In this paper, unsupervised word/document embedding methods are employed, such as Word2Vec and Doc2Vec, for feature extraction. The word vectors created by Word2Vec are averaged by their TF-IDF values to have a 'review vector' for each customer review. Also, for baseline model the bag of words technique is used for feature extraction.

**Word2Vec)** Word2Vec is a word embedding method that has been shown [9] to be useful as it preserves the semantics of words in unsupervised manner. Word2Vec is a shallow neural network in general, which has one input, one hidden and one output layers. There are two Word2Vec models available; Continuous Bag of Words (CBOW) and Skip-Gram. In CBOW, model predicting a word from its surrounding words, thus the order of words are ignored. In Skip-Gram, which is the opposite of CBOW, the model is predicting the context from the given word. In this paper, the Skip-Gram approach is used as it takes into account the order of the words. For detailed mathematical explanation of Skip-Gram approach, authors recommend reading [19] and references therein. A simplified explanation can be given as follows: Let  $w$  denote the corpus of words and let  $c$  be the context of words for a given data set  $D$ . The skip-gram model is trying to maximize the conditional probability  $p(c|w)$  by optimizing its parameters  $\theta$ . Thus the objective function can be given given as:

$$\arg \max_{\theta} \prod_{(w,c) \in D} p(c|w; \theta) \quad (1)$$

Each word in corpus needs to be encoded into one hot vectors in order to be used in the model. Let  $v_c$  and  $v_w$  be the encoded versions of  $c$  and  $w$  respectively and let  $C$  represent the whole context. To maximize Equation 1, the softmax function is employed:

$$p(c|w; \theta) = \frac{e^{v_c \cdot v_w}}{\sum_{(c' \in C)} e^{v_c \cdot v_{w'}}} \quad (2)$$

Nominator of Equation 2 is the dot product between an encoded word vector  $v_w$  and its context  $v_c$ . Intuitively, the related words, i.e. the words in the same context, should yield a higher dot product value compared to the unrelated words. On denominator,  $c'$  refers to all contexts for a given corpus. It is computationally very expensive to calculate all word pairs, therefore an approximation is needed. In order to prevent this bottleneck, the authors of Word2Vec developed a method called *negative-sampling*. Negative sampling states that, if some unrelated  $w, c$  pairs are added to the network by creating  $D'$  from random  $w, c$  pairs, the network learns a unique representation for each word.

Gensim has a popular Word2Vec implementation of which we have used in this work [20]. Word2Vec implementation of Gensim requires some hyperparameters to be tuned. In this work, hyperparameters are determined empirically where vector dimensionality for each word is selected as 200, context size of 10 and downsampling factor of  $10^{-3}$  is used. In order to observe the quality of the word embeddings, we have investigated some of the key words. For example, the word 'koltuk' ('seat' in English) is most similar (yields a high dot product value) to the words; dar(narrow), geniş(wide), boy(size/length). The word eğlence (entertainment) is most similar to the words altyazı (subtitle), Türkçe (Turkish) and sistem (system).

**Bag of Words)** Bag of words algorithm is based on creating a document vector by word counts [21]. The algorithm creates a histogram-like document vector based on word count i.e. by counting each word that appears more than the given threshold for a given document. In this work, threshold value is selected as 4000, which indicates that we use the most frequent 4000 words. The value of threshold is determined empirically.

**Tf-idf)** TF-IDF is the abbreviation of the term frequency inverse document frequency. Term frequency measures the frequency of terms occurring in the document. Inverse document frequency measures the importance of words. The IDF coefficients are often very useful for weighting frequent words. Because, some words might occur more than others which might impact the vectorization quality of customer reviews. Thus, instead of directly averaging word embeddings of each word in a customer review, it is beneficial to calculate review vectors by proportioning each word embedding with their idf value.

**Doc2Vec)** Doc2Vec is an unsupervised learning algorithm, which aims to find the embeddings of documents. The Doc2Vec algorithm, is implemented by adding a paragraph vector to the aforementioned Word2Vec algorithm. Similar to Word2Vec, there are two Doc2Vec models, namely, Distributed Memory (similar to CBOW) model and Distributed Bag of Words (similar to Skip-Gram) model. While the latter ignores word ordering, the former keeps it by concatenating the paragraph vector and word vectors in order to predict the next word in the given context. Doc2Vec algorithm has two advantages; first, it preserves word order and second, it is an unsupervised learning algorithm. Keeping the word order is seen to be essential in categorization task as it is much more complicated compared to the binary sentiment analysis task. Also, being an unsupervised learning algorithm makes Doc2Vec suitable for this task as we have a large corpus of unlabeled comments, where Doc2Vec can learn semantics of customer comments without in need of the labels. Gensim also has an implementation of Doc2Vec of which we have used in this work where document dimensionality is selected as 200, context size of 10 is used and downsampling factor of  $10^{-3}$  is used.

### C. Post Processing

As mentioned previously, the review categories are somewhat imbalanced. In order to prevent imbalanced learning SMOTE is employed. SMOTE creates synthetic samples in the local neighbors of features by subtracting the feature vector from its nearest neighbor then multiplies the result by a random number between 0 and 1 and adds it to the feature vector. In order to prevent overfitting, SMOTE is applied only to the training data.

### D. Classification Model

The extreme gradient boosting (Xgboost) algorithm is selected for the classification task. Xgboost is a supervised tree boosting algorithm which combines many weak learners to produce a strong learner. For the given training samples  $x_i$

and their labels  $y_i$ , Xgboost algorithm uses  $K$  weak learners to predict the output  $\bar{y}_i$ :

$$\bar{y}_i = \sum_{k=1}^K f_k(x_i) \quad (3)$$

Here  $f_k$  denotes a tree structure which contains a continuous score  $w_i$  on its  $i_{th}$  leaf. The score of each tree is calculated by minimizing the following objective function

$$L^{(t)} = \sum_{i=1}^n l(y_i, \bar{y}_i^{(t-1)} + f_t(x_i)) + \Omega(f_t) \quad (4)$$

where  $l$  denotes a convex loss function which can be differentiated in order to measure the difference between  $y_i$  and  $\bar{y}_i^{(t)}$ . Here  $\bar{y}_i^{(t)}$  denotes the prediction of the  $i_{th}$  sample at  $t_{th}$  iteration.  $\Omega$  is the regularization term where  $\Omega(f_t) = \frac{1}{2} \lambda ||w||^2$ . The regularization term prevents leaf scores to have large values.  $f_t(x_i)$ 's of which decreases the Equation 4 are greedily added to the tree to obtain the final classification tree. Detailed explanation of Xgboost algorithm is given in [14].

## IV. RESULTS

Even though the labeled data set is not very large, the usage of unsupervised techniques such as Word2Vec and Doc2Vec made it possible for us to utilize the large unlabeled corpus that we have. The confusion matrices of both the categorization task and the sentiment analysis are given on Table-IV and Table-V where classification accuracies are reported as 71.16% and 92.5% respectively. For both tasks, our approach surpasses the baseline model by a great margin, where we have obtained 75.7% accuracy for sentiment analysis and 52.1% accuracy for categorization by utilizing a bag of words approach. It is important to note that, the baseline method is implemented in a non-hierarchical way as we considered sentiment analysis and categorization separately.

By analyzing the results of the sentiment analysis, we report that the confusion between sentiments is caused by the reviews that are comprised of 'neutral' emotion of which we have not investigated in this work. Furthermore, most of the confusions between classes in the categorization task are dependent upon two main reasons: First and foremost, we assumed that a customer feedback is only related to a certain category, however some reviews contain multiple categories. For example, feedback related to the lounge are confused with the customer loyalty program, which is intuitive as in most of the feedback many customers have mentioned that they need to be given better rights at lounge when utilizing the customer loyalty program. Same phenomena applies for some other classes as well. Secondly, the classes with high error are seen to have the classes that have small number of training samples where SMOTE is failed to generate proper samples. Authors conclude that, instead of multi-class classification the categorization task can be thought as a multi-label classification, where a single feedback can be comprised of multiple labels.

TABLE IV

**Abstract**—The sheer usage of social media presents an opportunity for an automated analysis of a social media user based on his/her information, activities, or status updates. This opportunity is due to the abundant amount of information shared by the user. This fact is especially true for countries with high number of active social media users such as Indonesia. Extraction of information from social media can yield insightful results if done correctly. Recent studies have managed to leverage associations between language and personality and build a personality prediction system based on those associations. The current study attempts to build a personality prediction system based on a Twitter user's information for Bahasa Indonesia, the native language of Indonesia. The personality prediction system is built on Support Vector Machine and XGBoost trained with 329 instances (users). Evaluation results using 10-fold cross validation shows that the system managed to reach highest average accuracy of 76.2310% with Support Vector Machine and 97.9962% with XGBoost.

## I. INTRODUCTION

STATISTICS show that 1 in every 3 minutes of Internet Usage is spent on social media [1]. The sheer usage of social media means that a lot of information are shared by users during their social media usage. Information can be shared explicitly or implicitly. One of the information that can be analyzed from social media usage is user's personality.

Recent studies on automated personality assessment (hereinafter personality prediction) have been conducted in the past on several social medias. The current study focuses on Twitter. Twitter has gained high popularity over the years. Statistics show that the number of active users on Twitter are constantly rising each quarter and reaching up to 313 million active Twitter users as of June 2016 [2], [3].

Unlike other studies which focuses on English as the prediction system's main language, this study focuses on Bahasa Indonesia, the mother tongue of Indonesia. There are several statistics which show that Indonesia has high Twitter usage. The first among them is a study by [4], in which they mentioned that 2.4% of worldwide tweets are posted by users of Jakarta, the capital city of Indonesia. Mr. Roy

Simangunsong, Indonesia's Twitter Country Head, reported that 77% of Indonesians are active on Twitter every day [5]. An observation by eMarketer on November 2015 also shows the rise of Twitter users in Indonesia from year 2014-2015 and is predicted to keep rising until 2019 [6].

Fig. 1 Number of Twitter users in Indonesia per year 2014 – 2019 in millions

The personality prediction system for this study is built to classify a user's personality based on The Five Factor Model, a personality model by McCrae and Costa, which divides an individual's personality into 5 traits, namely Agreeableness, Conscientiousness, Emotional Stability, Extraversion, and Openness. The contributions of this paper are the personality prediction system built for the Bahasa Indonesia language, set of scenarios which contribute to the system's accuracy, and the comparison of 2 machine learning algorithms implemented into the prediction model.

## II. RELATED WORKS

Previous studies have attempted to implement personality prediction on Twitter. [7] and [8] built a personality prediction system for The Five Factor Model. A personality prediction system was also built for the Dark Triad personality model in [9]. [7], [8], and [9] built the personality prediction system for English using tools such as LIWC (Linguistic Inquiry and Word Count) and MRC Psycholinguistic Database. Another study by [10] also used LIWC to build a personality prediction system on Facebook. These tools are predefined categories of words which can be

Fig. 2 Overview of methodology

used to assess the tendency of a user to talk about a certain category. Such tools have also been utilized to create a prediction system in non-English languages such as Spanish, Dutch, Italian [11], and Chinese [12].

A literature review on personality prediction by [13] states that among the literatures that they examined, more than half utilized such tools to build their personality prediction system. Despite its usefulness, LIWC and MRC have language limitations—it doesn't support all languages. The tools are not supported in Bahasa Indonesia, so another approach must be applied to this study.

Other recent studies have come up with another approach by assessing the tendency of a user's choice of words. This is done by counting the usage frequency of a certain n-gram by a user. This method has been implemented in the past with data from various social platforms such as blogs [14] [15] and Facebook [16][17]. Said method has also been applied for non-English languages such as Chinese [18] and Bahasa Indonesia [19].

In [19], they managed to build a personality prediction system for The Five Factor Model using myPersonality, which is a corpus consisting of status updates from users which have been labelled with The Five Factor Model personality traits. The dataset is translated into Bahasa Indonesia to build a prediction system in said language. Therefore, this study attempts to apply the personality prediction task on an original, non-translated Bahasa Indonesia corpus.

### III. THE FIVE FACTOR MODEL

Personality is regarded as the main factor of what causes an individual to act a certain way in online interactions [20]. The Five Factor Model is one of the most widely used concepts in studies observing the association between personality and social media use [21][22][20][23][24]. Results from these studies show that the Five Factor Model can indeed act as a predictor in social media use.

The Five Factor Model is a hierarchical structure of personality traits which consist of 5 main dimensions: Extraversion, Agreeableness, Conscientiousness, Neuroticism, and Openness to Experience [25]. In fact, the Five Factor Model is commonly used among psychologists to comprehensively describe personality. The naming of personality traits is done through a series of literature reviews and studies. One of the examples is Neuroticism, which corresponds to low scores of Emotional Stability [25].

The neuroticism trait cannot be viewed as someone with psychopathological characteristics, but someone who is unsatisfied with his/her life [26] or an individual who tends to experience psychological distress [20]. Individuals with low Extraversion (Introversion) are viewed as reserved, not unfriendly, and independent individuals. They also prefer to be alone without having social anxiety [26]. Extraverted people are interpreted as individuals who tend to be sociable and experience positive emotions [20]. Individuals with high Openness scores are individuals who are open to new ideas while cautiously implementing them. On the other hand, individuals with low Openness scores have smaller scope of interest [26]. People with Agreeableness trait are trusting of others, sympathetic, and cooperative [20]. Individuals with high scores on the Conscientiousness trait are active in planning and organizing their activities, while an individual with a low Conscientiousness score is usually more laid-back in their work [26].

The previous study between Facebook and the Five Factor Model shows that individuals with Extraversion trait have higher number of friends [20][24]. Introverted individuals tend to present more personal information on their social media [20]. Individuals with high Neuroticism show the tendency to post photos of themselves more compared to those with low scores [20]. This study however contradicts results from a previous study by [24]. Individuals with high Openness score are known to be more expressive on their Facebook profiles [20]. People with high Conscientiousness trait have more friends and have tendency to post pictures compared to individuals with low Conscientiousness [20]. This result too, contradicts the results from [24]'s study. Finally, more observation is required regarding the correlation between Agreeableness trait individuals towards their social media usage [20].

### IV. METHODOLOGY

This study consists of 3 main tasks: data collection, preprocessing, and building the prediction model. Figure 2 shows an overview of the method applied in this study.

#### A. Data Collection

Preparation of dataset is done to obtain the training dataset and testing dataset. The dataset acquired contains Twitter user information and a maximum of 100 of the user's latest tweets. Users are chosen based on the following criteria:

TABLE I.  
TRAINING DATASET DISTRIBUTION

	Agreeableness	Conscientiousness	Emotional Stability	Extraversion	Openness
High	134	92	150	202	163
Low	195	237	179	127	166

TABLE II.  
TESTING DATASET DISTRIBUTION

	Agreeableness	Conscientiousness	Emotional Stability	Extraversion	Openness
High	19	16	21	24	16
Low	11	14	9	6	14

1. User posts on Twitter at least once a month.
2. User uses Bahasa Indonesia as their main language.

The user information extracted covers 12 features:

1. Number of tweets
2. Number of followers
3. Number of following
4. Number of favorites
5. Number of retweets from extracted tweets
6. Number of retweeted tweets from extracted tweets
7. Number of quote tweets from extracted tweets
8. Number of mentions from extracted tweets
9. Number of replies from extracted tweets
10. Number of hashtags from extracted tweets
11. Number of URLs from extracted tweets
12. Average time difference between each tweet

A total of 359 data were collected, where 1 data represents Twitter data from 1 user. 329 data were utilized as training data, and the remaining 30 data as testing data. The dataset was then annotated with “high” or “low” label for each personality trait by 3 psychology experts. A “high” label indicates that the user has a high level of a certain personality trait, while “low” label represents that the user has a low level of a certain personality trait. Thus, each user consists of 5 labels, each label representing the level (high or low) of each personality.

Table 1 shows the distribution of the training dataset, while table 2 shows the distribution of the testing dataset.

### B. Preprocessing

To preprocess the extracted information from Twitter, a series of automated and manual removal of elements were applied. Automatic element removal involves omitting retweets, replacing mentions with “[UNAME]” token, replacing hashtag with “[HASHTAG]” token, removing hyperlinks/URLs, and removing emoji. After applying automatic element removal, several manual element removals were applied to reduce the noise in the training data (e.g. non-Bahasa Indonesia content, non-Twitter content).

Next, tokenization is applied to the resulting dataset from the previous step, which produces a series of unigram and bigram. The occurrence of each unigram and bigram is counted. Each n-gram goes through a series of n-gram normalization functions to reduce the occurrence of unrecognized words (e.g. misspelled or slang words). The n-gram normalization functions applied were adapted from [27] and [28].

Omission of stop words was also applied in scenarios which require said action. The scenarios are further explained in section 4.3. The list of stop words was adapted from [29].

Finally, the system also utilized LDA (Latent Dirichlet Allocation) generated topics. Topics were generated using a Bahasa Indonesia Wikipedia dump file. The dump file contains the content of every article available on the Bahasa Indonesia version of Wikipedia. This file is loaded into the LDA algorithm with Gensim [30] to produce 100 topics, where each topic consists of 20 words.

The final output of the dataset consists of the 13 features presented in section 4.1 representing the user information, and the frequency of each n-gram.

### C. Build Prediction Model

The personality prediction system consists of 5 classifiers. Each classifier is tasked with the prediction of 1 personality trait. The system is trained with 329 instances of the output from the preprocessing step. Classifiers built on the Support Vector Machine and XGBoost are trained with the same dataset. The Support Vector Machine classifier was run on Weka, while XGBoost was run on R.

After the training process, the system is evaluated using 10-fold cross validation and loading the 30-instance testing dataset into the system. The evaluation measure used for evaluation is accuracy.

The personality prediction system is tested on different scenarios with the following actions:

1. Minimum occurrence of n-gram (minimum occurrence=1 or minimum occurrence=2)

TABLE II.  
SCENARIOS FOR EVALUATION

Scenario	Minimum occurrence of n-gram		n-gram weighting scheme		LDA topic features		Stop words omission	
	1	2	Boolean	TF	Use LDA	Don't use LDA	Omit	Don't omit
1	✓		✓		✓		✓	
2	✓		✓		✓			✓
3	✓		✓			✓	✓	
4	✓		✓			✓		✓
5	✓			✓	✓		✓	
6	✓			✓	✓			✓
7	✓			✓		✓	✓	
8	✓			✓		✓		✓
9		✓	✓		✓		✓	
10		✓	✓		✓			✓
11		✓	✓			✓	✓	
12		✓	✓			✓		✓
13		✓		✓	✓		✓	
14		✓		✓	✓			✓
15		✓		✓		✓	✓	
16		✓		✓		✓		✓

Refers to the number of times an n-gram appears in the list of extracted tweets.

If minimum occurrence is set to 1 for a scenario, then the system will take all the user's existing n-grams into consideration for the prediction.

If the scenario's minimum occurrence is set to 2, then the system will only take n-grams that appear at least twice into consideration for the prediction.

2. n-gram weighting scheme (Boolean or TF weighting)

Refers to how an n-gram's weight is calculated.

If the weighting scheme for a scenario is Boolean, then the n-gram's weight is set to 1 if it appears in the list of tweets, and 0 if otherwise.

However, if the weighting scheme for a scenario is TF, then the n-gram's weight is set to the number of times it appears in the list of tweets.

3. LDA topic features (use LDA topic features or don't use LDA topic features)

Refers to whether LDA-generated topic features are used in a scenario.

4. Stop words omission (omit stop words or don't omit stop words).

Refers to whether stop words are omitted from the list of n-grams in a scenario.

Combining these actions results in a total of 16 scenarios, which are shown in table 3. Each row represents a single scenario. The checked cells on said table are the actions used in the row of the corresponding scenario.

## V.RESULT AND DISCUSSION

The system is evaluated with a held-out test set of 30 data and 10-fold cross validation. A test set evaluation is included to make sure the system still performs the same way as when evaluated with 10-fold cross validation.

The evaluation results are shown on Figures 3 to 6. Due to the large number of scenarios tested, only the top 5 average accuracies for each evaluation are presented in the figures below.

The results from Figure 3 show that the highest average accuracies are dominated by scenarios 6, 5, 13, and 14. The 4 scenarios have 2 things in common: the usage of TF weighting scheme and LDA topic features. The highest average accuracy is 79.9392%, which is achieved on the Extraversion personality trait with scenario 5.

The results from Figure 4 are dominated by scenarios 14 and 13. The common feature shared by both scenarios are that they utilize TF weighting scheme and LDA topic features. Evaluation on test set with Support Vector Machine managed to achieve 90%, the highest accuracy for the Agreeableness trait with scenario 6, and Extraversion trait with scenarios 13 and 14.

Figure 5 presents the results from 10-fold cross validation with XGBoost, which are dominated by scenarios 6, 5, 14, and 13. The mentioned scenarios also have the same thing in common as the previous evaluations: usage of TF weighting scheme and LDA topic features. In this evaluation, Emotional Stability with scenarios 5 and 6 managed to achieve highest accuracy, which is 98.7900%.

Figure 6 presents the accuracy of the XGBoost classifier when evaluated with a 30-instance test dataset. The evaluation results are dominated by scenarios 13 and 14, where both scenarios utilize TF weighting scheme and LDA topic features. 100% accuracy is achieved on the Emotional Stability and Extraversion personality trait with scenario 13, and on Openness with scenario 14.

Fig. 3 Accuracy of Support Vector Machine using 10-fold cross validation

Fig. 4 Accuracy of Support Vector Machine using test dataset

The TF weighting scheme managed to achieve higher accuracy as it provides the system with information of how many times the word occurs from a user with a particular type of personality. The Boolean weighting scheme doesn't contain this information since the values only show whether a particular word is used by the user.

The LDA topic features also contributed to the system's accuracy because it does not restrict the system to assess by the user's choice of words, but also by the user's choice of topics.

Results from XGBoost show a significant increase in accuracy compared to Support Vector Machine, even when evaluated on 10-fold cross validation or a prepared test set. This is also consistent with other literatures which claim that XGBoost managed to achieve the best prediction when compared to other algorithms [31][32][33]. The creator of XGBoost also reports that XGBoost was used by the top 10 winning teams in KDD Cup 2015 [34].

Fig. 6 Accuracy of XGBoost classifier using test dataset

## VI. CONCLUSIONS AND IMPROVEMENTS

In this study, we have presented a personality prediction system for Bahasa Indonesia based on a Twitter user's information. Results of this study show that personality prediction in Bahasa Indonesia is indeed possible without using a tool with predefined words (LIWC, MRC), but by assessing a user's choice of words. The current study compares 2 different classifiers: Support Vector Machine and XGBoost. Both classifiers are tested under different scenarios which involve minimum occurrence of n-gram, n-gram weighting scheme, usage of LDA topic features, and omission of stop words. Evaluation using 10-fold cross validation showed that the personality prediction system built on Support Vector Machine managed to achieve a highest average accuracy of 76.2310%, while XGBoost achieved 97.9962%.

Evaluation results using 10-fold cross validation and 30-instance test dataset also showed that usage of LDA topic features and TF frequency weighting scheme contributed greatly to the personality prediction system's accuracy.

The results also showed that even when tested under the same scenario and same dataset, the personality prediction system built on XGBoost managed to perform significantly better than on Support Vector Machine.

Future developments of this study may utilize a larger training and testing dataset, which will allow the system to immerse itself in a wider variety of tweets. Improving n-gram normalization functions may also increase the system's accuracy since it allows the system to recognize and assess more words.

#### ACKNOWLEDGMENT

The authors would like to thank Mr. Tri Swasono Hadi for his participation in labelling the personality traits for each data. Mr. Tri is a practitioner in clinical psychology.

This research and publication is fully supported by grant named "Penelitian Produk Terapan" from Ministry of Research, Technology and Higher Education of the Republic of Indonesia with contract number 039A/VR.RTT/VI/2017

**Abstract**—Internet can be misused by cyber criminals as a platform to conduct illegitimate activities (such as harassment, cyber bullying, and incitement of hate or violence) anonymously. As a result, authorship analysis of anonymous texts in Internet (such as emails, forum comments) has attracted significant attention in the digital forensic and text mining communities. The main problem is a large number of possible authors, which hinders the effective identification of a true author. We interpret open class author attribution as a process of expert recommendation where the decision support system returns a list of suspected authors for further analysis by forensics experts rather than a single prediction result, thus reducing the scale of the problem. We describe the task formally and present algorithms for constructing the suspected author list. For evaluation we propose using a simple Winner-Takes-All (WTA) metric as well as a set of gain-discount model based metrics from the information retrieval domain (mean reciprocal rank, discounted cumulative gain and rank-biased precision). We also propose the List Precision (LP) metric as an extension of WTA for evaluating the usability of the suspected author list. For experiments, we use our own dataset of Internet comments in Lithuanian language and consider the use of language-specific (Lithuanian) lexical features together with general lexical features derived from English language. For classification we use one-class Support Vector Machine (SVM) classifier. The results of experiments show that the usability of open class author attribution can be improved considerably by using a set of language-specific lexical features together with general lexical features, while the proposed method can be used to reduce the number of suspected authors thus alleviating the work of forensic linguists.

## I. INTRODUCTION

THE Internet has become a critical enabling factor of economic and social transformations, affecting how governments, businesses and citizens interact and offering new, often unforeseen, ways of addressing challenges of sustainable development. Building trust in online services is essential to the continued growth and development of the Internet, while cybersecurity is vital for supporting sustainability and stability of the Internet. People need to have confidence that their data are secure, and networks and services they use are secure and reliable, while the societies and the state need to be sure that

the tools of the Internet are not misused for criminal activities. The growth in extent and complexity of cybercrime combined with the lack of time and resources in addressing cybercrime, and the need to confront cybercrime in near real time raises a need to process available digital evidences on the Internet using computational intelligence techniques such as Natural Language Processing (NLP) [1].

Currently, web-based communication platforms and social sites (such as Facebook, Twitter, blogs, discussion forums, online knowledge portals, and chatting tools) allow users to publicly express their views and share information online. Information spread using such platforms and websites becomes readily available to a large number of people. A large audience of readers is a great medium for radical extremists to declare their views and try to influence public opinion, organize information attacks against individual groups of society or the whole countries. Public cyberspace and social networks can become channels of information to apply black public relations technologies for propaganda of violence and hate. The individuals who tend to spread ethnic, racial hatred, extremism and inciting war, or threatening public or national security often exploit the openness of social media by trying to hide behind nicknames or using other opportunities to stay anonymous. Establishing the authorship of an anonymous text based on the characteristics of the text only is a tedious and laborious task, which can be performed only by skilled forensics linguistics experts.

Manual work of experts who carry out monitoring is accurate, but ineffective: carried out in real time and round the clock, it would require having huge human resources in case of emergencies (information war, hybrid war, riots, armed conflict). Because of these limitations, currently forensic linguists are only asked to analyse texts of only a small number of authors (usually, a maximum of four or five). Any tools and methods that could help to reduce the amount of work and allow to expand the number of analyzed suspects in order to establish the true author (such as, e.g., by reducing the number

of suspected authors) are needed by the forensics community. The results of such automated (or software-generated) analysis can play a role in criminal investigations and trials [2].

The forensic analysis of electronic web-based texts for solving their authorship problem is called *authorship analysis* [3]. It involves analyzing the writing styles or stylometric features from the document content. As writing style varies from one author to another, the aim of *authorship attribution* is the correct classification of texts into classes based on the style of their authors. Besides *author identification* where the style of individual authors is examined, *author profiling* can also distinguish between categories of authors such as gender, age, or native language. *Authorship verification* checks whether a target document was written or not by a specific individual. In *authorship attribution*, the actual author is known to be included in the set of candidates (closed case) [4]. In *open class authorship attribution*, the analyzed text might not have been written by the candidate authors (open case). Given the examples of the writing of a single author the task is to determine if given texts were or were not written by this author [5], therefore, it provides a more realistic interpretation of the task since it approximates better what forensic linguistics experts do. Authorship attribution can be performed using stylometric techniques through the analysis of linguistic styles and writing characteristics of the authors [6]. Applications include email analysis [7] and spam filtering [8], computer forensics [9], plagiarism detection [10], cyberpredator identification in online chats [11], tagging of online texts [12] and news media analysis [13]. In all of these domains, the goal is to confirm or reject the authorship hypothesis for documents with respect to a set of candidate authors, given sample documents written by the considered authors. A close problem is plagiarism detection, where usually two texts are compared to find similarities between them [10]. The practice is also relevant for developing sustainable research and science. In many cases of plagiarism, the misconducting authors attempt to diffuse responsibility across many (perhaps innocent) co-authors [14]. So the question of establishing the true culprit is appropriate. As noted in [15], when dealing with more than twenty candidates, it is beneficial to identify a smaller subset of candidates using other scalable methods. The aim of this paper is 1) to propose a method of open class authorship attribution aimed at producing the list of suspected authors rather than a single prediction result, 2) to discuss the measures for evaluating the usability of the proposed method, and 3) to consider language-specific (we focus on the Lithuanian language) text features to improve the accuracy of authorship attribution.

The structure of the paper is as follows. We describe the problem formally in Section II. We discuss the language-specific text features in Section III. We describe the proposed method in Section IV. We discuss the evaluation metrics in Section V. Finally, the results are provided and discussed in Section VI, and conclusions are given in Section VII.

## II. PROBLEM OF AUTHORSHIP ATTRIBUTION

The main element of authorship analysis process is text classification, i.e., the process of assigning predefined category labels to new documents. The formal description of our task is given below.

Let  $t \in T$  be a text message, which belongs to a text space  $T$ . Let  $A$  be a finite set of authors:  $A = \{a_1, a_2, \dots, a_N\}$ .

Let  $T^L$  be a training set and  $T^K$  be a testing set of text messages, containing instances  $I$  of text feature vectors  $v \in V$  which belong to a feature space  $V$  (where each  $v$  corresponds to a text message  $t$ ) with their appropriate class labels:  $I^L = \langle v, a \rangle$ ,  $I^K = \langle v, a \rangle$ .

The text message  $t$  represented by the feature vector  $v$  is linked to exactly one author  $a \in A$ .

Let function  $\xi$  be a function that generates instances  $I$  from text messages  $t$  based on the feature space  $V$ :  $\xi : T \times V \rightarrow I$ .

Feature space  $V$  can be partitioned into a number of non-overlapping feature subspaces  $V_k$  as follows:  $V = \bigcup_{1 \leq k \leq M} V_k$ ,  $\bigcap_{1 \leq k \leq M} V_k = \emptyset$ , here  $M$  is the number of features.

Let  $V_1$  be a set of text features representing general text features used independently of text language, and  $V_k, k \geq 2$  are sets of language-specific text features.

Let function  $\gamma$  be an authorship attribution function mapping a text message  $t$  to an ordered set of authors  $A'$ ,  $\gamma : T \rightarrow A'$ , where  $A' = \langle A, r \rangle$  and  $r$  is a binary relation of authors  $a_i$  and  $a_j$  that is equal to 1, if  $a_i$  is more likely to be the author of the message than  $a_j$ , and 0, if otherwise.  $A$  is a sorted list with the most likely authors on top.

Authorship attribution of text consists of associating a real value  $p$ ,  $0 \leq p \leq 1$  to each pair  $(t_j, a_i) \in T \times A$ , where  $T$  is the set of text messages,  $A$  is the set of authors, and  $p$  reaches its maximum for a true author of the text.

Let  $\Gamma$  denote a supervised learning method, which given a set of instances  $I$  as the input, returns a learned mapping function  $\gamma$  as the output:  $\Gamma : I \rightarrow \gamma$ .

Let  $\pi$  be an evaluation metric (function) mapping from a testing set of texts  $T^K$  to a real value  $q$ ,  $0 \leq q \leq 1$  that evaluates the quality of author attribution:  $\pi : T^K \rightarrow R$ .

We attempt to find a best feature subspace  $V_k$  that given a text space  $T$  would maximize the authorship attribution function  $\gamma'$ . We define the best authorship attribution function with regard to  $V_k, k \geq 2$  as the function  $\gamma' = \max_{\gamma} \pi(\gamma(T^K))$ , where  $\gamma = \Gamma(\zeta(T^L, V_1 \cup V_k))$ .

Further we employ the one-class learning approach for authorship attribution of language-specific texts, which has been introduced first by Koppel and Shler in [16]. One-class classifier defines a boundary around the target class that leaves out the outliers. The reference author is assigned to the target class and all other authors are attributed to the outlier class [17]. For each author, we have sample documents written by her/him. Sample documents for the author under consideration are considered as positive examples, whereas

sample documents for other authors are considered as negative examples. Features are extracted from documents and a classification model is built for the author. For a large number of features, Principal Component Analysis (PCA) can be used to derive a reduced number of 'effective' features, which retain most of information [18].

### III. LANGUAGE SPECIFIC FEATURES

Establishing features that work as effective discriminators of texts is one of critical issues in research on authorship analysis. The problem so far is that most research in the area of authorship identification is focused on the English texts (with a few notable exceptions such as Greek [19], Portuguese [20], and Croatian [21], while applications for other languages usually focus on the application and adaptation of the text features and methods adopted from English (e.g., using n-grams [22]). In case of a language-specific discourse, two approaches are prevalent: one approach ignores the specifics of a national alphabet by transliterating language-specific alphabet letters to standard Latin or English alphabet letters. The other approach leaves language-specific letters in feature space for further analysis.

Typically, the same or a similar set of features are used and consequently the use of language-specific letters does not lead to significant improvement of author identification results. New language specific features (such as variable-length language-specific syllables instead of fixed-length n-grams [23]) are required to capture the specifics of the national language (i.e., a language that has unique syntactical features such as special letters, which are not present in other languages).

In text classification almost all words contain some information. Rudman [24] finds that more than 1,000 different style markers have been proposed. Different feature ranking methods can be applied to reduce the feature set, however, as Joachims [25] has demonstrated, even the features ranked lowest still contain considerable information and are relevant for classification. There is a significant amount of research still to be done in formulating and studying the language-specific features on all levels (syntactical, semantic, prosodic, etc.) such as the frequency of language-specific letters, frequency of n-grams with language-specific letters, forbidden n-grams, etc. [26]. Hereinafter we analyze the specific features of Lithuanian language texts.

The Lithuanian language is spoken by approximately 3.2 million people and is subject to numerous linguistic studies. It belongs to the Baltic group of the Indo-European family of languages. Lithuanian is considered an archaic language because it has preserved a lot of features otherwise found only in the ancient languages, such as Greek, Latin, and Sanskrit but which have disappeared in other modern languages. Such features are the preservation of Indo-European vowels and consonants, richness of inflection, preservation of old endings, and wide use of participial forms. The Lithuanian alphabet consists of the Latin alphabet letters (excluding Q, q, W, w, X, x) with eighteen extra letters with diacritics (nine capital and

nine small). The Lithuanian language has thirty two letters, of which twelve are vowels (a, ą, e, ę, è, i, j, y, o, u, ū, ū), six are semivowels (v, j, l, m, n, r) and 14 are consonants (b, c, č, d, f, g, h, k, p, s, š, t, z, ž). However, in electronic discourse, the letters with diacritics are very often replaced with matching Latin letters (e.g.: ą → a, č → c, ę → e, ž → z, etc.) or pairs of letters expressing the same sounds as in English (e.g.: č [tʃ] → ch, š [ʃ] → sh, etc.). There are nine diphthongs: ai, au, ei, eu, oi, ou, ui, ie, and uo. The principal feature of the Lithuanian language is the fact that the language has very many forms. Nearly all the inflectional parts of the language have 24–28 forms. E.g., the English word “two” has five forms in the nominative case alone, while there are thirty forms of the Lithuanian word “du” (= two) alone [27]. The Lithuanian language is particularly characterized by unusual richness in suffixes: there are 615 nominal suffixes, while in modern English there are only 113 nominal suffixes. On the other hand, the number of prefixes is not large: in Lithuanian there are only thirty six prefixes [28], while modern English has fifty seven prefixes. Lithuanian is highly inflective, ambiguous (47 per cent of words are ambiguous), has rich vocabulary (0.5 million headwords) and has complex word derivation system (e.g., seventy eight suffixes for diminutives) [29]. Verbs have 3 conjugations, and are inflected by four tenses, three persons, two numbers, and three moods. Non-conjugative forms of verbs retain the same root, but have different suffixes and endings in different inflection forms. There is a significant difference between frequency of unigrams in Lithuanian and in other (English, Polish, Serbian) languages (see Table I). Previous experiments in authorship identification using Lithuanian texts have demonstrated that content-features are more useful compared with function words or POS tags [29], while best results were obtained with word-level character tetra-grams and a set of lexical, morphological, and character features [30].

The promising directions of research are the use of unique character combinations in national languages, e.g., “eux” in French, “ery” in English, and “lj” in Serbo-Croatian [31], the use of language-specific function words such as “ale”, “i”, “nie”, “to”, “w”, “z”, “ze”, “za”, “na” in Polish [32] and “neden-why”, “ayrıca-furthermore”, “belki-maybe”, “daima-always” in Turkish [33], and the use of non-standard words such as abbreviations, acronyms [34].

Function words are words which serve to express grammatical relationships with other words within a sentence or to specify the attitude or mood of the speaker but do not have a specific lexical meaning. They can signify structural relationships between different words in a sentence. Function words might be prepositions, pronouns, auxiliary verbs, conjunctions, grammatical articles or particles. The frequency statistics for several languages is presented in Table II. Further we have analyzed and performed experiments with two subsets of textual features: one subset contains sets of language-independent stylometric features, which have been commonly used for authorship analysis of English texts as follows: number of words, number of lines, ratio of uppercase letters, frequency of numbers, frequency of white characters,

TABLE III  
LEXICAL AND MORPHOSYNTACTIC FEATURES OF LITHUANIAN LANGUAGE

No.	Feature types	Examples of features and description
1	Function words	Frequency of each Lithuanian function word. Examples: "ant" (= on), "apie" (= about), "ar" (= whether), "arba" (= or), "aš" (= I), "be" (= without)
2	All function words	Cumulative frequency of all Lithuanian function words
3	Stop words	Frequency of each Lithuanian stop word. Examples: "į" (= into), "šalia" (= near), "šįjį" (= this, <i>masc.</i> ), "šiają" (= this, <i>fem.</i> )
4	All stop words	Cumulative frequency of all Lithuanian stop words
5	Word endings	Frequency of each Lithuanian language specific word ending. Examples: "a", "ai", "ajam", "ame", "ams", "ant"
6	Uncommon bigrams	Frequency of each bigram uncommon to Lithuanian language. Examples: "qu", "sh", "zh", "ch", "ux", "xu"
7	All uncommon bigrams	Cumulative frequency of all uncommon bigrams
8	Prefix "ne"	Frequency of words with prefix "ne" (= not)
9	Letters	Frequency of each Lithuanian language specific letter. Examples: "ą", "č", "ė", "ė", "į", "š"
10	All letters	Cumulative frequency of all Lithuanian language specific letters
11	Abbreviations	Frequency of each Lithuanian language specific abbreviation. Examples: "gyd." (= medical doctor), "kun." (= priest), "tūkst." (= thousand), "vyr." (= senior)
12	All abbreviations	Cumulative frequency of all Lithuanian language specific abbreviation
13	Similes	Frequency of each Lithuanian simile. Examples: "pavyzdžiui" (= for example), "kaip" (= like), "tarkim" (= say)
14	All similes	Cumulative frequency of all Lithuanian similes.

frequency of letters, ratio of short (less than four letters) words, mean word length, number of sentences, mean sentence length, ratio of unique words, frequency of the most frequent word, ratio of delimiters, number of paragraphs, mean line length, frequency of endings, frequency of bigrams, ratio of unique bigrams, ratio of abbreviations, ratio of similes. Another one contains lexical features that are specific to Lithuanian language texts. The types of features used to calculate lexical features are summarized in Table III.

#### IV. METHOD

We perform authorship attribution using one-class classification. The one-class classification problem is the problem of distinguishing one class of objects from all others, given training data only for the target class. It has been introduced by [35] to handle training using only positive class information. As opposed to binary classification problems, here a boundary in the space of the objects of interest has to be inferred only from samples of positive class. One-class classification is often used for outlier or novelty detection because it attempts to differentiate between data that appears normal and data that appears abnormal with respect to training data.

We have selected Support Vector Machine (SVM) [36] based on comparative research indicating that SVM classifiers perform best on a variety of text classification experiments in the text analysis domain [25]. The One-Class SVM separates all the data points from the origin (in feature space  $V$ ) and maximizes the distance from this hyper-plane to the origin. This results in a binary function which captures regions in the input space where the probability density of the data lives. Thus the function returns +1 in a region capturing the training data points and -1 elsewhere.

The classifier constructs a decision function  $F$  using the following *Decision function construction algorithm*:

```

ALGORITHM: constructDecisionFunction
INPUT: feature space  $V$ , training text set  $T^K$ 
OUTPUT: decision function  $F$ 
BEGIN
  FOREACH feature  $v$  IN feature space  $V$  of  $T^K$ 
    IF value of feature  $v$ 
      is predicted to arise from the
      distribution which generated
      the training samples of  $T^K$ 
    THEN
      LET  $F(v) = 1$ 
    ELSE
      LET  $F(v) = -1$ 
    END IF
  END FOREACH
  RETURN  $F$ 
END

```

For classification, we use the Sequential Minimal Optimization (SMO) algorithm [37] based implementation of one-class SVM classifier from DLIB C++ Library [38]. The classifier uses Radial Basis Function (RBF) kernel with default parameter values. The decision function  $F$  is used to create a ranked

list of authors for each unknown text  $t$  as follows (see the following *Suspected author list construction algorithm*). Note that Heaviside function  $H$  is used to calculate the number of positive values of the decision function  $F$ .

```

ALGORITHM: createSuspectedAuthorList
INPUT: decision function  $F$ , testing text set  $T^L$ ,
      list of authors  $A$ , number of suspects  $L$ 
OUTPUT: ranked list of authors  $RL$ 
BEGIN
  FOREACH  $a$  IN  $A$ 
    FOREACH feature  $v$  IN feature space  $V$  of  $T^L$ 
      LET  $LIST(a) = \text{sum}(H(F(v)))$ 
      %  $H$  is the Heaviside function
    END FOREACH
  END FOREACH
  LET  $RL = \text{sort}(LIST)$ 
  % return a ranked list of authors  $RL$ 
  RETURN  $RL(1:L)$ 
END

```

#### V. EVALUATION

We treat the author attribution system as the recommender system that using training data outputs a ranking order for the authors based on their predicted authorship relevance values. This approach known as Learning-to-rank is widely used in commercial search engines and recommender systems [39]. The evaluation of the authorship attribution system is not a trivial task. Commonly, such systems are evaluated using hard classification accuracy metrics such as precision and recall, which are often combined into a single measure such as F-score. These are set-based measures: authors in the ranking list are treated as unique and the ordering of results is ignored. We however claim that hard classification measures do not fit for the authorship attribution problem as they imply a strong oversimplification of reality. Therefore, we use soft classification measures based on the membership of a true author in a ranked list rather than direct match. When testing, the rank of the true author (which should be equal to equation (1) is to be compared with the predicted rank of the true author.

The simplest precision measure is to assume that we are only interested in the first suspected author and calculate the average probability of predicting the true author as the first author directly (Winner-Takes-All, WTA) [40] as follows:

$$WTA = \frac{1}{|T^K|} \sum_{T^K} H(\text{rank}(a_{true}) = 1) \quad (1)$$

where  $\text{rank}(a_{true})$  is the rank of the true author  $a_{true}$ ,  $H$  is the Heaviside function, and  $T^K$  is the testing set of texts.

A more relaxed measure is to calculate if the list of the suspected authors contains the true author regardless of the position of the author within the suspected list. We call this metric List Precision (LP) and define in equation (2):

$$LP(L) = \frac{1}{|T^K|} \sum_{T^K} H(\text{rank}(a_{true}) \leq L) \quad (2)$$

where  $L$  is the length of the list of suspected authors. Note that  $LP(1) = WTA$ .

Other measures used are based on evaluating ranked results, where importance is placed on returning a true author higher in the ranked list of suspected authors. These measures can be expressed using the gain-discount based model as a sum over authors in a ranked list as follows:

$$\pi \leftarrow \sum_{k=1}^K \text{gain}(k) \cdot \text{discount}(k) \quad (3)$$

where the *gain* function represents the gain associated with the true author appearing at rank  $k$ , and the *discount* function represents a discount associated with rank  $k$ , which is independent of the author, and  $K$  is the length of the suspected author list.

Equation (3) can be interpreted in terms of a simple model that simulates the work of a forensics expert: the expert starts with the first author and works his way down the list, eventually stopping [41]. The discount value indicates the probability that the expert continues his/her work at rank  $k$ , and the gain value represents the benefit (usability) to the expert of analyzing the author at rank  $k$ . Thus, the sum in equation (3) can be understood as expected total benefit experienced by the expert, with various gain values and discount formula corresponding to different assumptions about complexity of the expert's work.

Several different gain and discount functions have been proposed in the literature, which results in mean reciprocal rank [42], normalized discounted cumulative gain [43] and rank-biased precision [44] metrics. We describe the measures in brief below.

Mean reciprocal rank (MRR) is a statistic measure for evaluating any process that produces a list of possible responses to a sample of queries, ordered by probability of correctness. Here it is interpreted as the average of the inverse of the rank of the true author for a sample of test text dataset as in equation (4):

$$MRR = \frac{1}{|T^K|} \sum_{T^K} \frac{1}{\text{rank}(a_{true})} \quad (4)$$

Discounted cumulative gain (DCG) computes a value for the number of correctly recognized authors that includes a logarithmic discount function to progressively reduce the importance of authors placed further down the ranked list. This simulates the assumption that the experts will prefer the results which place the true author higher in the ranked list. The measure also makes the assumption that highly relevant authors are more useful than partially relevant authors, which in turn are more useful than non-relevant authors. DCG is defined in equation (5):

$$DCG = \frac{1}{|T^K|} \sum_{T^K} \frac{1}{\log_2(\text{rank}(a_{true}) + 1)} \quad (5)$$

Rank-Biased Precision (RBP) (in equation (6)) assigns an effectiveness score to a ranking by computing a geometrically weighted sum of author relevance values, with the

monotonically decreasing weights in the geometric distribution determined via a persistence  $p$ ,  $0 \leq p < 1$ , where a smaller  $p$  value places greater emphasis on authors that appear early in the ranking, and a larger  $p$  spreads the weight further down the author ranking, but in both cases all authors in the ranking contribute to the final score.

$$RBP = \frac{1}{|T^K|} \sum_{T^K} p^{\text{rank}(a_{true})-1} \quad (6)$$

where  $p$  is an abstraction of the expert's searching persistence, expressed as a parameter between 0 and 1. Previous studies suggest that for web search a  $p$  value of 0.8 is an appropriate value, however, in practice, values as high as 0.95 are used [45].

## VI. RESULTS AND DISCUSSION

The dataset was composed of Internet comments harvested from the Lithuanian news portal DELFI (<http://www.delfi.lt>) and covers the period of 8 months, from January, 2015 to August, 2015.

These comments were posted by anonymous users expressing their opinions about articles. Internet comments cover wide range of topics, are single units, do not necessary refer to each other; moreover, authors, hiding behind the anonymity curtain when expressing their opinions, have no reasons to pretend "better", therefore usually make no efforts to modify their writing style. But as the result of it, Internet comments are full of non-normative vocabulary words, include diminutives, hypocoristic words, and words with missing diacritics.

The authorship of the Internet comments was established based on an assumption that the identity of some author can be revealed, if his/her texts are written under the unique IP address and the unique pseudonym (taking both together as a single unit). Although some exceptions (when the same author is writing under several different IP addresses using different pseudonyms) may still occur, we anticipate they are too rare to make the significant influence on the overall authorship identification results.

Text fragments containing non-Lithuanian alphabet letters (except punctuation marks and digits) were eliminated; replies to comments and meta-information were discarded out as well leaving just plain texts. Besides, the texts shorter than thirty symbols (excluding white-space characters) were not included. Finally, all texts by the same author were concatenated, yielding the texts consisting of between 3,543 and 119,169 symbols. The composed corpus contains the texts of 200 authors. While the corpus is not very large, it is larger than datasets commonly used in the authorship forensics domain, e.g., [46] use only 300-word texts of three authors. The characteristics of the dataset (length of the longest, mean, and shortest text message in characters and words) are summarized in Table IV.

In our experiment, we have randomly selected 80 per cent of each author texts for training, while the remaining 20 per cent of texts together with texts of other authors were used for testing. The results of one-class classification were used for constructing a list of suspected authors. First, we ranked

TABLE IV  
CHARACTERISTICS OF THE DATASET

Characteristic	Value
Number of authors	200
Number of texts	200
Length of shortest text, characters	3,543
Length of shortest text, words	504
Length of longest text, characters	119,169
Length of longest text, words	15,874
Average length of text, characters	15,866
Average length of text, words	2,267

authors based on author attribution using general features only. Next, we added the language-specific (Lithuanian, LT) features and to see if there was an improvement of the position of the true author in the rank of the suspected authors. For evaluation, the process was repeated for each of 200 authors.

Fig. 1 presents the results of experiments (in terms of List Precision) using only general text features as well as general and language-specific features. The results demonstrate a marked improvement in precision when Lithuanian language-specific lexical features have been added for classification. For comparison, a random baseline, which represents the probability that the true author will be assigned to the suspected author list, is also shown.

The evaluation of experimental results using the gain-discount model based rank evaluation metrics is given in Table V (mean values are given). To demonstrate the efficiency of the one-class classification approach for ranking we compare the values of metrics with the random guess baseline, which shows the lowest accuracy threshold which that be exceeded that the applied approach could be considered as effective and reasonable enough for author attribution tasks. An improvement of accuracy achieved using language-specific lexical features is given with 95 percent statistical confidence interval (mean  $\pm 1.96 \cdot$  standard deviation). The paired t-Student confirmed (at 0.05 level) that the differences between the obtained results were statistically different for all considered metrics ( $p < 10^{-8}$ ).

Finally, we present the evaluation of language-specific subsets of lexical features by calculating the average improvement in the rank position of the true author (see Fig. 2).

The results obtained (see Fig. 2) show that the best improvement is achieved using language-specific function words (column 1), word endings (column 5) and stop words (column 3).

These results are consistent with the findings of authors using function words as a reliable base for textual comparison, which are not strongly affected by a text's topic or genre, or an author's conscious control while writing [47].

Word endings have been noted to contribute to the success of character n-grams in stylometric analysis [48], however, in Lithuanian language the word endings are typically longer than bigrams or trigrams commonly used as general features (we used bi-grams only), thus a separate feature type of Lithuanian

word endings seems to be useful.

Stop words are a very strong indication of writing style that convey very little semantic meaning in a sentence but serve to add details to it. Stop words on the other hand are inevitable in the output of any author and hence a generalizable technique cannot but tap their properties. Moreover stop words are result of a subconscious process of constructing sentences and thus may serve as a writeprint of the authors [49].

The use of features based on language-specific letters of alphabet (column 9) yielded negative results due to the non-normative use of such letters in the electronic space, e.g., replacement with similar Latin alphabet letters without diacritics or with similarly sounding English bigrams.

## VII. CONCLUSIONS

In this paper we have presented a one-class classification based method for open-class authorship attribution. The method produces the list of suspected authors rather than a single predicted author, therefore, reducing the problem from being on a large scale to smaller scale. The method could be used by the forensic linguistics expert community to help identify the list of suspects to be analyzed further using manual methods. The proposed method allows to reduce the number of suspected authors by fourfold (from 200 to 50) with a probability of 0.90 and eightfold (from 200 to 25) with a probability of 0.80 that the true author is listed as the suspected author.

We have discussed the metrics for evaluation of the result and suggested using rank correlation based metrics. We have proposed the List Precision metric to evaluate the usability of the derived suspected author list based on the length of the list. We also have identified language-specific lexical features.

The experimental results using the online Lithuanian language texts (dataset of online forum comments) classified using one-class SVM classifier show that Lithuanian function words together with Lithuanian word endings and stop words are the ones which contribute most towards the improvement of the classification results (0.13-0.17, based on different evaluation metrics).

The results were evaluated statistically using paired t-Student test showing that the improvement in the value of usability metrics was statistically significant.

In future research we are planning to increase the number of authors in the datasets; to analyze different domains (e.g.

Fig. 1. Accuracy of general and language-specific features using List Precision measure

TABLE V  
EVALUATION RESULTS USING RANK CORRELATION BASED METRICS

Metric	Random baseline	Without language-specific (LT) features	With language-specific (LT) features	Improvement in accuracy (with 95% stat. confidence limits)

**Abstract** - This study aimed to aid the enormous effort required to analyze phraseological writing competence by developing an automatic evaluation tool for texts. We attempted to measure both second language (L2) writing proficiency and text quality. In our research, we adapted the CollGram technique that searches a reference corpus to determine the frequency of each pair of tokens (bi-grams) and calculates the t-score and related information. We used the Level 3 Corpus of Contemporary American English as a reference corpus. Our solution performed well in writing evaluation and is freely available as a web service or as source for other researchers.

### I. INTRODUCTION

A person's second language, or L2, is a language that is not the native language of the speaker but is used in the locale of that person. In contrast, a foreign language is a language that is learned in an area where that language is not generally spoken. Some languages, often called auxiliary languages, are used primarily as second languages, or lingua francas. More informally, a second language can be said to be any language learned in addition to one's native language, especially in the context of second language acquisition, (that is, learning a new foreign language) [1]. A person's first language is not necessarily their dominant language, the one they use most or with which they are most comfortable. For example, the Canadian census defines first language for its purposes as "the first language learned in childhood and still spoken," recognizing that for some, the earliest language may be lost, a process known as language attrition. This can happen when young children move, with or without their family (because of immigration or international adoption), to a new language environment [2].

In the process of language development, lexical indices are not as popular as the utilization of syntactic procedures. In the area of foreign linguistics, there has been a constant lexicalization of the teaching curriculum, which has a phraseological basis. Moreover, it is also recognized that the process of language production is affected by the pre-pattern segments described by [3]. Corpus language methods have highlighted the broad range of word combinations that were previously analyzed.

It is important to analyze the role of corpus linguistic studies in the grading of L2 writing. In such grading, it is essential to analyze the writing based on functional skills and the independent construction of written text to communicate in a purposeful context. A human writer cannot be used to demonstrate the requirements of the standards, as this does not meet the requirement for independence. In writing assessment, we should consider whether or not information and ideas were presented concisely, logically, and persuasively. It is also important to determine whether or not a writer clearly presented information on complex subjects, used a range of writing styles for different purposes, and employed a range of sentence structures, including complex sentences and paragraphs, to effectively organize their written communication. We should also evaluate the accuracy of punctuation in written text using commas, apostrophes, and quotation marks. Lastly, written work should fit the purpose and audience, with accurate spelling and grammar that support clear meaning [4].

Corpus analysis is both qualitative and quantitative in nature. One of the biggest advantages of using corpus language is that we can easily provide quantitative data to assess concerns for which intuition cannot be considered reliable. In other words, much more than just counting bi-grams is involved [5]. Prior research highlights the variety of questions that need to be addressed on the vital role played by L2 writing [6].

### II. EVALUATION METHODS USING N-GRAMS

An n-gram is a contiguous sequence of n items from a given sequence of text. Depending on the application, the items can be phonemes, syllables, letters, words, or base pairs. N-grams are typically collected from a text or speech corpus. When the items are words, n-grams may also be called shingles. An n-gram of size 1 is known as a unigram (1-gram), size 2 is a bigram (2-gram), size 3 is a trigram, and so on. An n-gram model is a type of probabilistic language model for predicting the next item in such a sequence in the form of an (n-1)-order Markov model [7]. The n-gram models are widely used in probability, communication theory, computational linguistics (e.g., statistical natural language processing), computational biology (e.g., biological sequence analysis), and data compression. Two benefits of n-gram models (and algorithms that use them) are simplicity and scalability [7].

The n-gram based evaluation method consists of removing the arrangement of n-words for bigrams, learner corpus data, and data that contain native combinations of tokens [5]. The results of different n-gram models are not directly comparable, as they utilize different criteria to identify relevant units. However, they can indicate some general trends in L2 writing that rely on the most restricted repertoire of lexical bundles as compared to that of native writers [8]. L1 writers utilize more phrases that are familiar with poor sequences and fewer native-like phrases. They also report having difficulty while introducing speech-like phrases into their official language. These studies highlight various features of L2 phrasing because of the lack of huge longitudinal corpora of L2 writing and the effort required to collect them.

Complex lexical phrases are very rarely used by the lowest skilled writers. Learning traditional strings of words at an elementary level has been found to be productive at advanced and secondary levels. However, this finding relied only on the frequency of multi-word units and paid no attention to the degree of association within units. Very common words stand a much greater chance of frequent arrangements than uncommon words of different varieties.

Mutual information (MI) and t-score are used in this research to calculate the comparative frequency of occurrence of word sequences in a reference corpus. They also indicate the probability of a word sequence appearing due to the frequency of the words of which it is composed. MI will highlight word sequences that are developed from a small rate of word reoccurrence, for example, the term “tectonic plates” is a very low-occurring word sequence. Similarly, t-score works with word sequences of highly recurrent sets of words. However, a study by Durrant and Schmitt [9] focuses on one type of sequence, an adjoined pair of words used as a modifier. The studies show that, unlike native writers, L2 writers of English use collocations with the highest MI ratings at a very low frequency. This means that the usage of MI with high frequency is not very popular among them, whereas collocations with t-scores are frequently used. The same pattern can be observed with transitional and sophisticated learners. Learners in their transitional phase are more inclined to very often use frequently-occurring collocations and make minimal use of lower frequency collocations. The present study has utilized the same methodology but is unique in two aspects. First, it uses a preset system to obtain word sequences from a tagged part of speech. Second, it simulates longitudinal corpora. We evaluated L2 writers who had multiple levels of proficiency. Therefore, it was very important to assess the phraseological index of the longitudinal data in question; our study strongly considered this aspect. This study has incorporated both longitudinal and pseudo-longitudinal approaches that assist in recognizing the

given input of all the research designs in the analysis of L2 writing [10].

### III. DATA AND METHODOLOGY

Our writing evaluation application consists of three main sub-tools. First, a user interface, implemented in ASP.NET and shared as a web service, handles user inputs, manages them, and requests solutions from the other software components on behalf of the user. The website is responsible for loading the user input files and generating the final download link of the results as a ZIP file for the user. The results are output in Excel-compatible CSV files. Each separate file contains different analysis results for each bi-gram, such as frequency in the L2 text, frequency in the reference corpus, mean frequency in the reference corpus, MI score, and t-score. For multi-file analysis, the tool calculates the number of unique 1-grams and 2-grams, the number of 2-gram types, the number of 2-grams collocated in the reference corpus, the percentage value of L2 coverage in the reference corpus, and a summary that includes how many 2-grams were not found, MI, and t-scores.

Second, we employ the CLAWS part-of-speech (POS) Tagger<sup>1</sup> for better text tokenization and identification of the proper parts for speech recognition and comparison with n-grams in the reference corpus in their correct form. We also use it for recognition of Germanic genitive markers. In our web service, we used the web crawler and demo version of CLAWS. For the full version, a CLAWS license must be purchased.

As a reference corpus, we used an n-gram model based on the largest publicly-available, genre-balanced English corpus - the 520 million word Corpus of Contemporary American English (COCA)<sup>2</sup>. With this n-gram<sup>3</sup> data (2, 3, 4, and 5-word sequences, with their frequency), we conduct queries. The main advantages of using this corpus are that it is already genre balanced and includes part-of-speech tags. In addition, it includes the lemmatized forms of words and pre-calculated word and phrase frequencies. For faster processing, we converted the n-gram COCA corpus into an SQL database and pre-calculated all required 1-gram and 2-gram dependencies.

Our solution relies heavily on an automatic procedure. First, each part of the learner's text is tokenized and tagged with POS. This step aids the recognition of proper names and punctuation marks. In this context, CLAWS [11] was used, due to its high degree of accuracy. When we are comparing corpora of diverse sizes, it is important to normalize the frequencies of occurrence to a common base, such as per million tokens. Next, bigrams are extracted from each L2 text. Association scores are then computed. In this step, each bigram is searched in the corpus and is assigned its corresponding MI and t-scores, which are calculated by the formulas reported in Evert [13].

<sup>1</sup> <http://ucrel.lancs.ac.uk/cgi-bin/claws72.pl>

<sup>2</sup> <http://corpus.byu.edu/coca/>

<sup>3</sup> <http://www.ngrams.info/intro.asp>

The last step is the computation of our tool profiles. Our profiles of L2 texts are designed to use three major indices: MI, mean t-score, and proportion of absent bigrams. They are estimated by a combination of tokens and types in the texts. The MI score lets us count the association between two words depending on the independent relative frequency of the given two words. It does not depend on the size of the corpus. Even if the given corpora are of different sizes, it can be calculated. It outputs detailed information about lexical behavior.

The calculations are made in accordance with the following equations:

- Expected Frequency

$$E(w1, w2) = \frac{f(w1)f(w2)}{N}$$

- MI

$$MI(w1, w2) = \log \frac{O(w1, w2)}{E(w1, w2)}$$

- T-score

$$t(w1, w2) = \frac{O(w1, w2) - E(w1, w2)}{\sqrt{O(w1, w2)}}$$

The solution topology, shown in Fig. 1, illustrates the time sequence and user actions during the lifetime of the solution:

- The vertical dashed line represents the lifetime of each component of the application, the time that component is active and running.
- The arrow represents an action triggered by one object to another (or to itself if the arrow is curved to start and end to the same object).
- The rectangle represents an object.
- An orange rectangle represents an object inside our solution.
- A blue rectangle represents an object outside our solution.

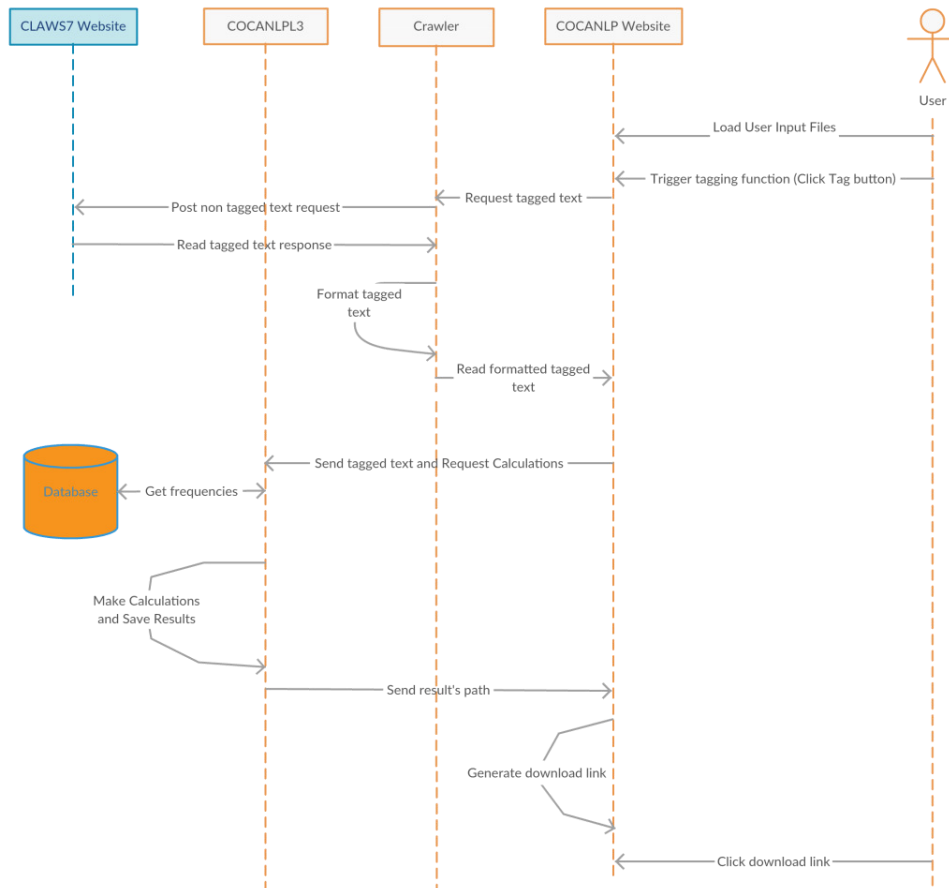

Fig. 1: Application topology

Time-sequence:

- Each point represents an arrow on the diagram.
- The application starts with a user action on the website (<http://localhost/default>) to select the input files (browsing the system's files and selecting the desired input text files).
- The user then triggers another action.
- The web application uploads the input files, reads them, and then sends a request to the crawler tool with the non-tagged text of each input file, requesting the corresponding tag text.
- The Crawler formats the non-tagged text appropriately.
- The Crawler waits for the response and reads it.
- The Crawler then extracts the output from the response of the HTML page.
- Then the Crawler sends the formatted tagged text to the website.
- The website redirects the formatted tagged text to our web application.
- Web application takes the tagged text, generates the bigrams, then communicates with the database to get the unigram and bigram frequencies using SQL stored procedures.
- Finally, our application makes all the calculations described above and saves a local (on the server) copy of the results as a zip file.
- Then sends the website a link to the saved copy of the results.
- Finally, the website generates a link of the zip file and displays it to the user.

#### IV. EXPERIMENTAL EVALUATION

To evaluate our tool, 50 participants were asked to write an article on the same topic ("Memories from the best trip of their life."). Those stories were supposed to be between 1,000 and 1,200 words and were evaluated by our tool and by 10 random native English speaking teachers (having certified high proficiency in English). Instead of giving grades, they were supposed to mark all the corrections that needed to be done and to calculate the translation error rate (TER) metric.

TER was designed to provide a very intuitive machine translation evaluation metric, which requires less data compared with the other techniques while avoiding the labor intensity of human evaluation. It calculates the number of edits required to make a translated text exactly match the closest reference translation in fluency and semantics [13]. The TER metric calculation is defined in [14].

$$TER = \frac{E}{w_R}$$

where  $E$  represents the minimum number of edits required for an exact match. The average length of the reference text is given by  $w_R$ . Edits may include the deletion of words, word insertion, word substitutions, and changes in the word or phrase order [13]. In our research, this metric was used to measure the difference between students work and corrections made by teachers. It provided us a much more accurate evaluation than just grading. The TER result were compared with MI and t-scores, as presented in Table 1. All TER, t-score, and MI metrics were normalized to fit between 1 and 100 scale, where 100 means that the writing was perfect.

TABLE I.

RESULTS OF MINING AFTER PROGRESS

Sample No.	TER	MI	t-score
1	72.98	67.65	79.45
2	86.56	69.23	83.44
3	76.62	68.34	83.19
4	71.98	67.12	78.52
5	87.29	70.34	84.47
6	82.36	68.79	81.97
7	79.20	67.86	80.28
8	75.47	64.13	78.45
9	83.20	71.43	81.44
10	89.23	73.57	84.22
11	75.69	68.89	80.43
12	79.28	67.91	80.42
13	82.12	71.91	82.04
14	76.53	65.78	79.67
15	86.79	72.86	83.65
16	85.23	72.73	83.25
17	70.98	66.36	77.39
18	76.58	65.12	78.24
19	71.29	63.28	77.42
20	84.28	72.37	82.07
21	82.19	72.01	82.13
22	89.14	75.12	85.91
23	87.48	74.27	84.24
24	78.95	67.89	89.12
25	77.23	61.23	65.29
26	81.49	71.24	81.86
27	85.57	73.03	83.49
28	75.78	64.28	77.11
29	72.20	64.34	76.38
30	73.16	65.87	77.91
31	83.35	72.95	82.49
32	87.69	74.34	84.37
33	86.29	73.48	83.29

34	74.82	66.29	76.89
35	76.46	67.15	78.11
36	86.18	74.58	86.12
37	75.12	67.29	63.29
38	87.24	74.59	84.52
39	85.34	73.29	84.11
40	89.28	75.82	85.49
41	86.34	73.39	84.52
42	85.26	72.79	84.12
43	73.29	66.89	75.31
44	71.39	65.79	75.21
45	76.28	68.12	72.12
46	79.68	69.13	79.14
47	73.37	67.21	78.72
48	87.78	74.61	87.12
49	78.75	67.79	79.28
50	88.24	74.87	85.69

The results showed in Table I reveal a positive correlation between TER and MI scores, which means our tool is well suited for automatic student evaluation.

## V. DISCUSSION AND CONCLUSIONS

In summary, our tool is capable of tracking the development of phraseological competency in L2 writing [12]. It can be easily adapted to support other languages. Only a language model change is required, along with use of a language-specific POS tagger and tokenizer. However, languages like Mandarin will require an additional segmenting step in the data pre-processing phase.

Our tool can identify collocations that are frequently used by learners, particularly native speakers of the language. Such information can help in writing L2 instruction.

Our technique evaluates the associated scores of every bigram, which are calculated on the basis of a reference corpus. A bigram is described by the study as any adjacent pair of words in the L2 text. This technique is also known as the unsupervised CollGram technique, on which there has been extensive research [10]. Previously mentioned research was also used to quantify the collocation power of each of three measures:

1. The mean MI score indicates the number of collocations that are produced from uncommon words.
2. The mean t-score measures the number of collocations produced from the collection of common words.
3. We also calculated the proportion of bigrams that are not present in the reference corpus and, therefore, will not be a part of any associated rating.

In the future to further improve the tool, we envision using multiple parameters to obtain the best analysis of the learner texts. For instance, we can remove spelling errors from identical pairs of words. Similarly, instances of adding or reducing one

or two letters can also be discovered. POS tagging can be very useful in achieving the goal.

From the dataset, we empirically observed that the MI value relates to the bigrams. Such bigrams can contain a flawed combination of words or even a slightly creative combination. However, we have also observed that if there are punctuation marks in the text, then it will eventually interfere with the bigrams. This is because punctuation marks will not let the system record the readings and scores, and hence proper calculation will not be taken into account.

We can categorize the highest and lowest rated bigrams in the learner corpus. They can be categorized in diminishing order of the unqualified value of the MI and t-scores. The lowest rated bigrams in the category are the ones that exist in the reference corpus and will occur at a very small frequency.

Bigrams in the learner corpus that are not present in the reference corpus should have a prominent place in the analysis of the categories. On the basis of the theoretical framework, we can say that bigrams are of two types. First, one is the creative combination, which will most probably be used by advanced learners. Second, erroneous combinations will be produced in a very small quantity by advanced learners.

Statistical correlation is observed between the quality of text that was already scored, the MI score, the fraction of bi-grams not present in the system, and a combination of the two indices in question. This result enhances the quality of the prediction. [10]

Lastly, in the future we plan to extend the tool so that it can also calculate MI and t-score using trigrams and quadragrams. This is expected to improve the accuracy and analytic scope for linguists. We also plan to conduct an evaluation of domain-adapted language models [15].

**Abstract** - Based on big data training we provide 5-gram language models of contemporary Polish which are based on the Common Crawl corpus (which is a compilation of more than 9,000,000,000 pages from across the web) and other resources. We prove that our model is better than the Google WEB1T n-gram counts and assures better quality in terms of perplexity and machine translation. The model includes lower-counting entries and also de-duplication in order to lessen boilerplate. We also provide POS tagged version of raw corpus and raw corpus itself. We also provide dictionary of contemporary Polish. By maintaining singletons, Kneser-Ney smoothing in SRILM toolkit was used in order to construct big data language models. In this research, it is detailed exactly how the corpus was obtained and pre-processed, with a prominence on issues which surface when working with information on this scale. We train the language model and finally present advances of BLEU score in MT and perplexity values, through the utilization of our model.

### I. INTRODUCTION

There are a large number of language processing tasks available that make web-scale corpora attractive and needed due in most, to the vast amount of information which exists in different languages. Language modelling is of great significance, where web-scale models for language have demonstrated their ability to enhance automated speech recognition performance and machine translation quality [1, 2, 3]. There are also other NLP tasks that depend greatly on language modelling e.g. language quantification. [4]

Contained within, are language models trained on the Common Crawl corpus and n-gram counts. Google has discharged n-gram counts which have been trained on 1,000,000,000,000 tokens of text [5]. N-grams which were present on fewer than forty occasions were pruned, and words which were present fewer than two hundred times were replaced with the unknown word. The counts are not suitable for judging a language model with the Kneser-Net smoothing algorithm due to this pruning as the algorithm needs unpruned counts, although pruning will happen on the last model anyway.

There is another challenge with the Google n-gram counts that are available publicly, [5] and this due to the fact that the training information was not de-duplicated, meaning that boilerplate, like copyright notices have got excessively high

counts [6]. Despite Google sharing a version [7], in limited context [6], that has been de-duplicated, this was never officially released to the public [8]. Before adding up the n-grams, the training data was de-duplicated. There is a web service which is provided by Microsoft [9], you can query it for language model probabilities. However, this is limited to English language only, whereas our model preparation methodology is compatible with more languages outside of English. Additionally, there was an experiment conducted on the re-ranking of machine translated Polish, due to the number of queries from the output, the service crashed on several occasions, even with client-side caching. Utilization of the service from Microsoft, throughout machine translation decoding, would mean there is a requirement for a lower latency and there would be a greater volume of queries.

Summing up in our research we show how to build a contemporary language model from big data amounts of texts for any language supported in Common Crawl project (based on Polish). We compare its quality to Google WEB1T model and to set of freely available Polish corpora found in the web. We evaluate quality of our approach by measuring perplexity and showing higher quality of machine translation systems that use our model. Lastly, we share publicly results of our work as plain text data, trained 1-,2-,4- and 5-gram language model, RNN based language model and dictionary sorted by most frequent unigrams together with dictionary cleaned from numbers, names and less likely words. The data publicly available (<https://goo.gl/hO1hTz>).

### II. PREPARATION OF THE DATA

A crawl of the web which is in the available in the public domain is the CommonCrawl project. It contains petabytes of data collected over the last 7 years. It contains raw web page data, extracted metadata and text extractions.

The data is accessible as text only files as well as raw HTML. The text only files contain all the RSS and HTML files that the tags were stripped from. The text is converted to UTF-8 and the HTML is in the original encoding. There is a distinct benefit to be gained when using the HTML files because the structure of the document can be used to choose paragraphs, and can tell actual content from boilerplate. Parsing vast amounts of HTML needs a lot of normalization step and it is non-trivial.

Throughout this work, the focus is on dealing with the text-only files that were downloaded and processed on a small cluster locally. The benefits of structured text are unable to cancel out the additional computing power that is needed for the processing.

There were many problems that needed to be solved as pre-processing step. First of all, the selection of data only in a specific language. CommonCrawl also has some mistakes with encoding when parsing to UTF-8 which resulted with spelling errors. What is more, some texts are repeated many times e.g. copyright, comment, data, etc. Many text structures were ungrammatical or contained strange insertions. There were also some language specific difficulties that must have been addressed as well for each language separately. In addition, data contained both samples of spoken texts like dialogs or written articles and literature. The text domain also was not defined.

#### A. Differences between Polish and English languages

In general, Polish and English differ in syntax and grammar. English is a positional language, which means that the syntactic order (the order of words in a sentence) plays a very important role, particularly due to the limited inflection of words (e.g., lack of declension endings). Sometimes, the position of a word in a sentence is the only indicator of the sentence's meaning. In a Polish sentence, a thought can be expressed using several different word orderings, which is not possible in English. For example, the sentence "I bought myself a new car." can be written in Polish as "Kupiłem sobie nowy samochód.", or "Nowy samochód sobie kupiłem.", or "Sobie kupiłem nowy samochód.", or "Samochód nowy sobie kupiłem." The only exception is when the subject and the object are in the same clause and the context is the only indication which is the object and which is subject. For example, "Mysz liże kość. (A mouse is licking a bone.)" and "Kość liże mysz. (A bone is licking a mouse)."

Differences in potential sentence word order make the translation process more complex, especially when using a phrase-model with no additional lexical information [10]. In addition, in Polish it is not necessary to use the operator, because the Polish form of a verb always contains information about the subject of a sentence. For example, the sentence "On jutro jedzie na wakacje." is equivalent to the Polish "Jutro jedzie na wakacje." and would be translated as "He is going on vacation tomorrow." [11]

In the Polish language, the plural formation is not made by adding the letter "s" as a suffix to a word, but rather each word has its own plural variant (e.g., "pies - psy", "artysta - artyści", etc.). Additionally, prefixes before nouns like "a", "an", "the", do not exist in Polish (e.g., "a cat - kot", "an apple - jabłko", etc.) [10].

The Polish language has only three tenses (present, past, and future). However, it must be noted that the only indication

whether an action has ended is an aspect. For example, "Robiłem pranie." Would be translated as "I have been doing laundry", but "Zrobiłem pranie." as "I have done laundry", or "płakać - wypłakać" as "cry - cry out" [10].

The gender of a noun in English does not have any effect on the form of a verb, but it does in Polish. For example, "Zrobił to. – He has done it.", "Zrobiła to. – She has done it.", "lekarz/lekarka - doctor", "uczeń/uczenica = student", etc. [10]

Because of this complexity, progress in the development of SMT systems for West-Slavic languages has been substantially slower than for other languages. On the other hand, excellent translation systems have been developed for many popular languages.

#### B. Spoken vs written language

The differences between speech and text within the context of the literature should also be clarified. Chong [11] pointed out that writing and speech differ considerably in both function and style. Writing tends towards greater precision and detail, whilst speech is often punctuated with repetition and includes prosody, which writing does not possess, to further convey intent and tone beyond the meaning of the words themselves.

According to William Bright [12], spoken language consists of two basic units: Phonemes, units of sound, (that are themselves meaningless) are combined into morphemes, which are meaningful (e.g., the phonemes /b/, /i/, and /t/ form the word "bit"). Contrary alphabetic scripts work in similar way. In a different type of script, the basic unit corresponds to a spoken syllable. In logographic script (e.g., Chinese), each character corresponds to an entire morpheme, which is usually a word [12].

It is possible to convey the same messages in either speech or writing, but spoken language typically conveys more explicit information than writing. The spoken and written forms of a given language tend to correspond to one or more levels and may influence each other (e.g., "through" is spoken as "thru").

In addition, writing can be perceived as colder, or more impersonal, than speech. Spoken languages have dialects varying across geographical areas and social groups. Communication may be formal or casual. In literate societies, writing may be associated with a formal style and speech with a more casual style. Using speech requires simplification, as the average adult can read around 300 words per minute, but the same person would be able to follow only 150-200 spoken words in the same amount of time [13]. That is why speech is usually clearer and more constrained.

The punctuation and layout of written text do not have any spoken equivalent. But it must be noted that some forms of written language (e.g., instant messages or emails) are closer to spoken language. On the other hand, spoken language tends to be rich in repetition, incomplete sentences, corrections, and interruptions [14].

When using written texts, it is not possible to receive immediate feedback from the readers. Therefore, it is not possible to rely on context to clarify things. There is more need to explain things clearly and unambiguously than in speech, which is usually a dynamic interaction between two or more people. Context, situation, and shared knowledge play a major role in their communication. It allows us to leave information either unsaid or indirectly implied [14].

#### C. Main types of errors found in textual data

Another problem was that the data contained many errors. This data set had spelling errors that artificially increased the dictionary size and made the statistics unreliable. Some of them were casual errors and most of them were because of wrong text encoding conversion. We extracted randomly 10,000 segments of text from different (also) random parts of the CommonCrawl corpus. Then, a dictionary consisting of 92,135 unique words forms was created from TED 2013 (iwslt.org) data. The intersection of those two dictionaries resulted in information that that about 12% of the whole test set were spelling errors.

What was found to be more problematic was that there were sentences with odd nesting, such as:

Part A, Part A, Part B, Part B., e.g.:

“Ale będę starał się udowodnić, że mimo złożoności, Ale będę starał się udowodnić, że mimo złożoności, istnieją pewne rzeczy pomagające w zrozumieniu. Istnieją pewne rzeczy pomagające w zrozumieniu.”

Some parts (words, full phrases, or even entire sentences) were duplicated. Furthermore, there are segments containing repetitions of whole sentences inside one segment. For instance:

Sentence A. Sentence A., e.g.:

“Zakumulują się u tych najbardziej pijanych i skąpych. Zakumulują się u tych najbardziej pijanych i skąpych.”

or: Part A, Part B, Part B, Part C, e.g.:

”Matka może się ponownie rozmnażać, ale jak wysoką cenę płaci, przez akumulację toksyn w swoim organizmie - przez akumulację toksyn w swoim organizmie - śmierć pierwszego młodego.”

The analysis identified that 4% of test data contained such mistakes.

In addition, there were numerous untranslated English names, words, and phrases mixed into the Polish texts. There are also some words that originate from other languages (e.g., German and French).

#### D. Language Detection

The initial stage in the data acquisition pipeline is to separate the information by language. We looked at the option of detecting the main language automatically for each page, however, we discovered the mixed language occurs frequently within one page, and is relatively common. We implemented python tool that worked in 3 phases. Firstly, we used Python LangDetect [15] library to discover entire pages that seemed to

be in Polish language. In the second phase, we used plWordnet [16] in order to compare vocabulary of extracted articles with Polish vocabulary. We removed articles that contained less than 30% of Polish words. What is more before using the plWordnet the aspell tool was used in order to correct spelling errors that could be corrected automatically. In the last step, we divided text into sentences using automatic tool implemented within [17] research. When data was divided into sentences each sentence was checked by calculating its probability in Google WEB1T language model. We removed 20% of less likely sentences. This assured removal of grammatically incorrect sentences or sentences in different languages while maintaining data that included additional Polish data not calculated in Google WEB1T.

By facilitating this technique, we were able to gather 278GB of clean textual data in UTF-8 encoding, that was sentence spited. The text contained 1,962,047,863 sentences in total.

#### E. Deduplication and normalization

Because the CommonCrawl consists of web pages there are many fragments which are not content, but are artefacts of auto-page generation, copyright notices are just one example, it is essential to remove such data because it would alter wrongly the statistical model. It must also be noted that some texts are repeated over the internet many time e.g. press information. To lessen the volume of boilerplate, before further processing, we took out any lines which were duplicated. For the purpose of deduplication, we implemented a python tool. The comparison was done at the level of sentences. The following Table I contains details about quantity of data before and after deduplication.

TABLE I.  
DEDUPLICATION RESULTS

	Size in GB	Number of sentences	Number of unique words
Before	296,1	1,962,047,863	87,543,726
After	94,8	920,517,413	87,543,726

The step of de-duplication takes out around 75% of the Polish data. This is on par with the reductions reported by Bergsma et al. [18].

As well as de-duplicating the information, data was restricted to printable UTF-8 characters, we replaced all email addresses with the identical address, and removed the left-over HTML tags. Prior to the creation of the language models, punctuation was normalized utilizing the script which was supplied by the Workshop on Statistical Machine Translation [19], by using the Moses tokenizer [20] it was tokenized, and then the Moses true caser was applied.

### III. EVALUATION

In order to measure the performance of new language model we used the perplexity measure. Perplexity, developed for information theory, is a performance measurement for a language model. Specifically, it is the reciprocal of the average probability that the LM assigns to each word in a data set. Thus, when perplexity is minimized, the probability of the LM's prediction of an unknown test set is maximized. [21, 22, 23, 24] To be more precise, we chose 3 different test sets a corpus of TED lectures from IWSLT<sup>1</sup> conference, European Medicines Agency Leaflets (EMEA)<sup>2</sup> corpus and OpenSubtitles<sup>3</sup> corpus. From all 3 corpora, we randomly selected 1,000 sentences for the evaluation with perplexity. The details of used corpora are shown in Table II:

TABLE II.  
TEST CORPORA SPECIFICATION

	Number of sentences	Number of PL words	Number of EN words
TED	210,549	218,426	104,177
EMEA	1,046,764	148,230	109,361
OPEN	33,570,553	1,519,948	758,238

Secondly, using the same data sets, we trained 3 statistical machine translation models using Moses SMT toolkit. The translation took place from English to Polish. Translation systems were enriched with prepared language models and evaluated with BLEU metric.

BLEU was developed on a premise like that used for speech recognition, described in Papineni et al. [25] as: "The closer a machine translation is to a professional human translation, the better it is." Hence, the BLEU metric is designed to measure how close SMT output is to that of human reference translations. It is important to note that translations, SMT or human, may differ significantly in word usage, word order, and phrase length [25]. To address these complexities, BLEU attempts to match phrases of variable length between SMT output and the reference translations. Weighted match averages are used to determine the translation score [26]. Several variations of the BLEU metric exist. The basic metric requires calculation of a brevity penalty PB as follows:

$$P_B = \begin{cases} 1, & c > r \\ e^{(1-r/c)}, & c \leq r \end{cases}$$

where  $r$  is the length of the reference corpus, and candidate (reference) translation length is given by  $c$  [27]. The basic BLEU metric is then determined as shown in [26]:

$$BLEU = P_B \exp\left(\sum_{n=0}^N w_n \log p_n\right)$$

where  $w_n$  are, positive weights summing to one, and the  $n$ -gram precision  $p_n$  is calculated using  $n$ -grams with a maximum length of  $N$ . There are several other important features of BLEU. Word and phrase positions in the text are not evaluated by this metric. To prevent SMT systems from artificially inflating their scores by overuse of words known with high confidence, each candidate word is constrained by the word count of the corresponding reference translation. The geometric mean of individual sentence scores, by considering the brevity penalty, is then calculated for the entire corpus [26].

The baseline results of SMT systems for each corpus are shown in Table III.

TABLE III.  
TEST CORPORA SPECIFICATION

Corpus Name	Baseline system score (BLEU)
TED	17,42
EMEA	36,74
OPEN	58,52

For language model training we used SRILM toolkit [28]. The fundamental challenge that language models handle is sparse data. It is possible that some possible translations were not present in the training data but occur in real life. There are some methods in SRILM, such as add-one smoothing, deleted estimation, and Good-Turing smoothing, that cope with this problem [23].

Interpolation and back-off are other methods of solving the sparse data problem in  $n$ -gram LMs. Interpolation is defined as a combination of various  $n$ -gram models with different orders. Back-off is responsible for choosing the highest-order  $n$ -gram model for predicted words from its history. It can also restore lower-order  $n$ -gram models that have shorter histories. There are many methods that determine the back-off costs and adapt  $n$ -gram models. The most popular method is known as Kneser-Ney smoothing. It analyses the diversity of predicted words and takes their histories into account [20]. We used this smoothing method and trained 5-gram language models.

For machine translation, we used the Experiment Management System [20] from the open source Moses SMT toolkit to conduct the experiments. Binarization of 5-gram language model was accomplished in our resulting systems using the KenLM Modeling Toolkit and language modelling itself, as mentioned, with SRILM [28] with an interpolated version of Kneser-Key discounting (interpolate – unk – kndiscount) that was used in our baseline systems. Word and phrase alignment was performed using SyMGIZA++ [29]

<sup>1</sup> iwslt.org

<sup>2</sup> opus.lingfil.uu.se

<sup>3</sup> opensubtitles.org

instead of standard The OOV's were handled by using Unsupervised Transliteration Model [30].

Summing up in this research we used big data CommonCrawl based corpus (COMMON), Google Corpus (WEB1T) and corpus gathered from available resources and crawled sources (OTHER). All but WEB1T that was already trained by Google in 5-gram order. The details about those corpora and number of ngrams are showed in following Table IV.

TABLE IV.

NUMBER OF N-GRAMS IN LANGUAGE MODELS

	COMMON	WEB1T	OTHER
1-grams	102,742,823	9,749,397	18,953,166
2-grams	1,227,434,111	72,096,704	248,705,481
3-grams	1,208,818,561	128,491,454	350,220,758
4-grams	1,513,980,357	128,789,635	468,203,863
5-grams	1,433,864,427	113,097,133	431,451,627

#### IV. EXPERIMENTS

The new data were:

- A Polish – English dictionary (bilingual parallel)
- Additional (newer) TED Talks data sets not included in the original train data (we crawled bilingual data and created a corpus from it) (bilingual parallel)
- E-books
- Subtitles for movies and TV series
- Parliament and senate proceedings
- Wikipedia Comparable Corpus (bilingual parallel)
- Euronews Comparable Corpus (bilingual parallel)
- Repository of PJIT's diplomas
- Many PL monolingual data web crawled from main web portals like blogs, chip.pl, Focus news archive, interia.pl, wp.pl, onet.pl, money.pl, Usenet, Termedia, Wordpress web pages, Wprost news archive, Wyborcza news archive, Newsweek news archive, etc.

“Other” in the table below stands for many very small models merged together. EMEA are texts from the European Medicines Agency, KDE4 is a localization file of that GUI, ECB stands for European Central Bank corpus, OpenSubtitles [31] are movies and TV series subtitles, EUNews is a web crawl of the euronews.com web page and EUBOOKSHOP comes from bookshop.europa.eu. Lastly bilingual TEDDL is additional TED data.

TABLE V.

CRAWLED CORPORA SPECIFICATION

Data set	Dictionary	Sentences
EMEA	148,230	1,046,764
KDE4	131,477	185,282
ECB	62,147	73,198
OpenSubtitles	2,446,006	33,570,553
EBOOKS	1,283,060	17,256,305
EUNews	33,591	43,534
NEWS COMM	85,380	1,209,608
EUBOOKSHOP	599,405	593,818
UN TEXTS	606,989	5,312,280
DICTIONARY	92,121	n/a

DIPLOMAS	490,616	666,576
TEDDL	129,436	54,142

Data perplexity was examined by experiments with the TED lectures, OPEN and EMEA corpora. Perplexities for the test sets are shown in Table VI. The perplexity (PPL) values are with Kneser-Ney smoothing of the data.

TABLE VI.

PERPLEXITY-BASED LANGUAGE MODEL EVALUATION

CORPUS	MODEL	PERPLEXITY (PPL)
TED	Common Crawl	1471
TED	WEB1T	1523
TED	OTHER	1628
OPEN	Common Crawl	480
OPEN	WEB1T	671
OPEN	OTHER	823
EMEA	Common Crawl	1163
EMEA	WEB1T	1253
EMEA	OTHER	1417

The following Table VII provides results of our language model evaluation using SMT systems. We trained 3 baseline systems (Baseline BLEU) and then augmented them with our CommonCrawl-based language model (Augmented BLEU). The same was done using WEB1T and OTHER language models. The translation was conducted into Polish direction. The Delta column contains difference between baseline and augmented systems. It must be noted that we did not conduct any in-domain adaptation of language models.

TABLE VII.  
SMT-BASED LANGUAGE MODEL EVALUATION

CORPUS	LANGUAGE MODEL	Baseline BLEU	Augmented BLEU	Delta
TED	Common Crawl	17.42	18.33	0.91
TED	WEB1T	17.42	17.97	0.55
TED	OTHER	17.42	17.76	0.34

EMEA	WEB1T	36.74	37.93	1.19
EMEA	OTHER	36.74	37.26	0.52

## V. RESULTS AND CONCLUSIONS

Summing up, we successfully released n-gram counts and language models built using big data textual corpora which overcomes limitations of other smaller, publicly available resources. In addition, we were able to show that after some basic pre-processing of the data we were able to obtain BLEU and perplexity results that outperform state-of-the-art language models like WEB1T and other smaller corpora even after merging them together. We proved that improvements in perplexity and also in machine translation lead to better language knowledge utilisation. The results of our work are free and publicly available. The resources we share are the raw data after pre-processing, raw data tagged with POS using Morfeusz tagger [32], trained 5-gram language model with pruned 20% of less likely n-grams, dictionary with count of most frequent words in Polish based on CommonCrawl corpus and lastly a similar dictionary without counts but manually cleaned from noisy data by native Polish translators.

## VI. ACKNOWLEDGEMENTS

Work financed as part of the investment in the CLARIN-PL research infrastructure funded by the Polish Ministry of Science and Higher Education and was backed by the PJATK legal resources.

# 10<sup>th</sup> International Workshop on Computational Optimization

**M**ANY real world problems arising in engineering, economics, medicine and other domains can be formulated as optimization tasks. These problems are frequently characterized by non-convex, non-differentiable, discontinuous, noisy or dynamic objective functions and constraints which ask for adequate computational methods.

The aim of this workshop is to stimulate the communication between researchers working on different fields of optimization and practitioners who need reliable and efficient computational optimization methods.

## TOPICS

The list of topics includes, but is not limited to:

- combinatorial and continuous global optimization
- unconstrained and constrained optimization
- multiobjective and robust optimization
- optimization in dynamic and/or noisy environments
- optimization on graphs
- large-scale optimization, in parallel and distributed computational environments
- meta-heuristics for optimization, nature-inspired approaches and any other derivative-free methods
- exact/heuristic hybrid methods, involving natural computing techniques and other global and local optimization methods

The applications of interest are included in the list below, but are not limited to:

- classical operational research problems (knapsack, traveling salesman, etc)
- computational biology and distance geometry
- data mining and knowledge discovery
- human motion simulations; crowd simulations
- industrial applications
- optimization in statistics, econometrics, finance, physics, chemistry, biology, medicine, and engineering.

## BEST PAPER AWARD

The best WCO'17 paper will be awarded during the social dinner of FedCSIS 2017.

The best paper will be selected by WCO'17 co-Chairs by taking into consideration the scores suggested by the reviewers, as well as the quality of the given oral presentation.

**Abstract**—Finding efficient solutions for search and optimisation problems has inspired many researchers to utilise nature informed algorithms, where the interactions in swarm could lead to promising solutions for challenging problems. One problem in machine learning is class imbalance, which occurs in real-world applications such as medical diagnosis. This problem can bias the classification or make it entirely out of context where the algorithms being applied to classify the data can potentially ignore the important minority class instances. In this paper, a parameters optimisation algorithm is proposed, which uses a swarm intelligence technique, Dispersive Flies Optimisation (DFO), to optimise the support vector machine kernel's parameters and perform cost sensitive learning to improve the classifier's performance on imbalanced data. The use of the swarming behaviour of the flies and their diversity in the search space in conducting cost sensitive learning are investigated on eight real-world datasets. The proposed algorithm has been compared with other techniques to optimise the classifier's parameters, that includes the well-known particle swarm optimisation, the frequently used grid search as well as random search, which is used as a control algorithm. The results demonstrate the statistically significant outperformance of the proposed optimisation technique over other techniques on the same datasets.

## I. INTRODUCTION

OVER the last decade, there has been a rapid increase in datasets worldwide due to the unparalleled growth in globalisation, as well as global markets. However, datasets are rendered useless unless there is a way to analyse them in a meaningful way. Data mining technologies have been adopted by various businesses like banking, retailing and telecommunication as the upcoming technology to help in converting large amounts of data which have been stored on a database into actionable knowledge and useful information. Nevertheless, dealing with large datasets present its own challenges, such as the issue of class imbalance that occur in real-world applications: fraud detection, medical diagnosis, direct marketing campaign and many other predictive models. This problem occurs when the number of instances in one class (i.e. majority class) extremely outnumber the number of instances in the other class (i.e. minority class). This is often due to the limitations of a data collection process such as high cost or privacy problems; for instance, biomedical data, which is derived from a rare disease and an abnormal condition, or some data that is often obtained via expensive experiments.

Numerous research have applied data mining techniques in solving imbalanced data issue at both data and algorithmic levels [1]. In this paper, a swarm intelligence model is proposed to optimise the support vector machine (SVM) parameters: two important parameters for the radial basis function (RBF) kernel are  $c$  and  $\gamma$ , as the choice of their values affects the classification accuracy. The model uses Dispersive Flies Optimisation (DFO) to tune the classifier's parameters and improve its performance on an imbalanced dataset without changing the dataset distribution.

## II. SWARM INTELLIGENCE AND DATA MINING

Swarm intelligence and evolutionary computation have been widely used to solve challenging problems in data mining such as feature selection and class imbalance [2]. When it comes to class imbalance and cost sensitive learning, choosing the kernel's parameters values is a challenging problem. Various swarm intelligence techniques have been used for parameters tuning or optimisation [3], [4]. Despite the rapid development in using swarm intelligence techniques to solve the class imbalance problem at the algorithmic level by optimising the kernel's parameters, these techniques face the challenge of the slow convergence rate, the trap to local optima and the number of tunable parameters. Al-Rifaie (2014) proposed a new meta heuristic, Dispersive Flies Optimisation, derived from the swarming behaviour of flies, which they use to locate the food source and the way it is communicated to other flies so that they can access the food source with minimal attempt to locate it [5]. In this paper, DFO will be used to perform SVM cost sensitive learning on various benchmarks data and compare the proposed method with both evolutionary and non evolutionary search based techniques from the literature on the same datasets. In the next section, DFO is described and its main components are explained.

### A. Dispersive Flies Optimisation

DFO, first introduced in [5], is an algorithm inspired by the swarming behaviour of flies hovering over food sources. The swarming behaviour of flies is determined by several factors including the presence of threat which disturbs their convergence on the marker (or the optimum value). Therefore,

having considered the formation of the swarms over the marker, the breaking or weakening of the swarms is also noted in the proposed algorithm. Algorithm 1 summarises the DFO algorithm.

The algorithm is characterised by two main components: a dynamic rule for updating flies position (assisted by a social neighbouring network that informs this update), and communication of the results of the best found fly to other flies. As stated earlier, the swarm is disturbed for various reasons; one of the impacts of such disturbances is the displacement of flies which may lead to discovering better positions. To consider this eventuality, a stochastic element is introduced to the update process. Based on this, individual components of flies' position vectors are reset if a random number,  $r$ , generated from a uniform distribution on the unit interval  $U(0,1)$  is less than the *disturbance threshold* or  $dt$ . This guarantees a disturbance to the otherwise permanent stagnation over a likely local minima<sup>1</sup>.

In summary, DFO is a simple numerical optimiser over continuous search spaces. DFO is a population based stochastic algorithm, originally proposed to search for an optimum value in the feasible solution space. The simplicity of the algorithm has been compared against several other swarm and evolutionary computation techniques in [6] where the elegance of the algorithm in having only one tunable parameter (the disturbance threshold), is explored. It has also been shown that DFO outperforms the standard versions of the well-known Particle Swarm Optimisation, Genetic Algorithm (GA) as well as Differential Evolution (DE) algorithms on an extended set of benchmarks over three performance measures of error, efficiency and reliability [5]. It is demonstrated that DFO is more efficient in 84.62% and more reliable in 90% of the 28 standard optimisation benchmarks used; furthermore, when there exists a statistically significant difference, DFO converges to better solutions in 71.05% of problem sets. Further analysis is also conducted to explore the diversity of the algorithm throughout the optimisation process, a measure that potentially provide more understanding on algorithm's ability to escape local minima. In addition to theoretical research on this algorithm, DFO has recently been applied to medical imaging [7]; furthermore, ongoing and current research are being conducted in the fields of image analysis, simulation and gaming [8], computational aesthetic measurements [9], (digital) arts [10], [11], protein folding, etc.

### III. EXPERIMENTS

In this paper, DFO is used to search for the optimal kernel parameters:  $c$  and  $\gamma$ . In this model, F-measure is deployed as an evaluation metric and the performance of DFO is compared against other parameters optimisation techniques to find the optimal kernel values over a set of benchmark datasets.

In order to evaluate the performance of the proposed technique, eight real-world datasets are used and available from the

<sup>1</sup>The source code of the original DFO algorithm can be found in the following web page: <http://doc.gold.ac.uk/mohammad/DFO>

the University of California, Irvine (UCI) machine repository<sup>2</sup>. These datasets are imbalanced and they vary in size and class distribution. Moreover, they have been widely used as benchmarks to compare the performance of various methods in the literature. Table I provides a description of the datasets used. In this experiment, the authors have applied the proposed method on the Abalone datasets for the class '9' versus '18' and for the Vehicle dataset, the model is applied on the class 'Van' vs the others. Moreover, normalisation was applied on the datasets to scale each feature values to a [0,1] range, and instances with missing values are removed. Furthermore, to make predictions on new data valid, a train/test split is used, in which 80% of the dataset is used for training and 20% is used for testing. The advantages of train/test split are that the optimised  $c$  and  $\gamma$  are evaluated on unseen dataset. As the datasets are imbalanced, F-measure is used as a fitness value for SVM, in which the goal is to find the  $c$  and  $\gamma$  that will give the maximum F-measure.

#### A. Experiment set up

Fifty flies are set to optimise the SVM's parameters, in which the range for  $c$  that has been defined as  $[2^{-5}, 2^{15}]$  and the range of  $\gamma$  has been defined as  $[2^{-15}, 2^3]$  based on [12]. The iterations allowed is equal to 10. At the *initialisation phase*, each fly is assigned randomly to two values, with the first value being for  $c$  and the second for  $\gamma$ ; using these values the fitness

<sup>2</sup><http://archive.ics.uci.edu/ml/>

value, the F-measure, is generated. The fitness value is stored for each fly, to find the best neighbouring fly and the best fly in the whole swarm. At every iteration, the components of the position vector are independently updated at the *update phase*, considering the components vector for the best neighbouring fly and the components vector for the best fly in the whole swarm. It also considers if the random number,  $r$ , that is generated from the uniform distribution on the range  $[0,1]$ , is less than the disturbance threshold  $dt$ . In the experiment, the  $dt$  is empirically equal to 0.5, which means 50% of the flies' components are randomly initialised to new positions in the search space. This will enhance the diversity of the algorithm and will provide a balance between exploration and exploitation. In order to ensure that the performance of the algorithm is not solely due to the disturbance mechanism, a control algorithm (random algorithm) is also applied to the problem and the results are reported.

#### IV. RESULTS AND DISCUSSION

Table II summarises the results of applying DFO as optimisation algorithm and compares them with other methods on the same datasets. This include PSO, grid search and random search. As shown in the table, the use of DFO was found to improve the F-measure for all datasets and the proposed model outperforms other techniques on the same datasets. For example, for the Ionosphere dataset, the F-measure increased from 94.52%, as obtained by the PSO, to 98.59%. Similar improvements in the F-measure can be seen in the rest of the datasets. As a result, the proposed model which uses DFO to optimise the SVM kernel's parameters  $c$  and  $\gamma$ , demonstrates the ability to improve the classifier performance on imbalanced datasets. As Fig. 1 illustrate, while the other technique exhibit varying performance over different datasets, DFO is shown to provide a consistent outperformance over all datasets. Given the importance of conducting a statistical analysis measuring the presence of any significant difference in the performance of the proposed model and the other techniques including PSO, grid and random search, t-test is applied. This statistical significant test is applied using the outcome of the entire trials (30 runs) on each experiment. Based on the results, the F-measure difference is significant at 5% level. The result of this test indicates that the proposed optimisation technique offers a statistically significant improvement in the classifier's performance on the imbalanced datasets when compared to the other techniques.

##### A. Impact of Disturbance Threshold

The disturbance mechanism in DFO provides a stable independent convergence throughout the optimisation process. It also maintains a balance between exploration and exploitation. At the update phase, the  $dt$  is the only adjustable parameter to set that controls the diversity of the algorithm. A suitable value for this parameter depends on the size of the swarm, the number of iterations and the size of the search space. Therefore, further work needs to be done to find a theoretically suitable value for this parameter. In this experiment,  $dt$  is

Fig. 1. Comparison of F-measure on all datasets

Fig. 2. Negative impact of reducing the disturbance threshold to  $dt = 0.001$

empirically set to 0.5, which allows for an enhanced diversity of the population in covering the search space, as well as the ability to escape local optima.

As stated previously, random algorithm is included in the comparison as a control algorithm to ensure the DFO's performance is not solely attributable to its disturbance mechanism and that the coupled mechanisms of forming and breaking of the swarm, together, give rise to the performance of the algorithm. Equally, in order to demonstrate the impact of the absence or reduction of diversity (induced through the disturbance mechanism), another control algorithm with small disturbance threshold ( $dt = 0.001$ ) is proposed. Fig. 2) illustrates that the sole presence of diversity or the lack of it, negatively impacts the performance of the algorithm.

#### V. CONCLUSION

Class imbalance is a major problem in machine learning. This work investigated the use of DFO to optimise the RBF kernel's parameters to improve the classifier performance without changing the distribution of the dataset by applying data level solutions such as oversampling or undersampling the dataset. The proposed method has performed *statistically significantly* better when compared to other techniques on all datasets. Moreover, the simplicity of this swarm intelligence algorithm adds to its appeal when applied to complex search

**Abstract**—Correlation clustering is a NP-hard problem, and for large graphs finding even just a good approximation of the optimal solution is a hard task. In previous articles we have suggested a contraction method and its divide and conquer variant. In this article we present several improvements of this method (preprocessing, quasi-parallelism, etc.) and prepare it for parallelism. Based on speed tests we show where it helps the concurrent execution, and where it pulls us back.

## I. INTRODUCTION

CLUSTERING is an important tool of unsupervised learning. Its task is to group objects in such a way, that the objects in one group (cluster) are similar, and the objects from different groups are dissimilar. It generates an equivalence relation: the objects being in the same cluster. The similarity of objects are mostly determined by their distances, and the clustering methods are based on distance.

Correlation clustering is an exception, it uses a tolerance (reflexive and symmetric) relation. Moreover it assigns a cost to each partition (equivalence relation), i.e. number of pairs of similar objects that are in different clusters plus number of pairs of dissimilar objects that are in the same cluster. Our task is to find the partition with the minimal cost. Zahn proposed this problem in 1965, but using a very different approach [1]. The main question was the following: *which equivalence relation is the closest to a given tolerance (reflexive and symmetric) relation?* Many years later Bansal et al. published a paper, proving several of its properties, and gave a fast, but not quite optimal algorithm to solve this problem [2]. Bansal have shown, that this is an NP-hard problem.

The number of equivalence relations of  $n$  objects, i.e. the number of partitions of a set containing  $n$  elements is given by Bell numbers  $B_n$ , where  $B_1 = 1$ ,  $B_n = \sum_{i=1}^{n-1} \binom{n-1}{i} B_i$ . It can be easily checked that the Bell numbers grow exponentially. Therefore if  $n > 15$ , in a general case we cannot achieve the optimal partition by exhaustive search. Thus we need to use some optimization methods, which do not give optimal solutions, but help us achieve a near-optimal one.

If the correlation clustering is expressed as an optimization problem, the traditional optimization methods (hill-climbing, genetic algorithm, simulated annealing, etc.) could be used

in order to solve it. We have implemented and compared the results in [3].

In a former article we have shown the clustering algorithm based on the divide&conquer method, which was more effective than our previous methods. But our measurements have pointed out, that this method is not scalable. Hence for large graphs the method will be very slow. Therefore we would like to speed up the method. The *simplest* way to do it is to distribute the calculations between the cores of the processor. Unfortunately, theory and practice often differs.

The structure of the paper is the following: in Section 2 correlation clustering is defined mathematically, Section 3 presents the contraction method and some variants. Next, the best combination of local improvements is selected, and in Section 5 the former divide and conquer method is improved. Later the technical details of the concurrency is discussed

## II. CORRELATION CLUSTERING

In the paper the following notations are used:  $V$  denotes the set of the objects, and  $T \subset V \times V$  the tolerance relation defined on  $V$ . A partition is handled as a function  $p : V \rightarrow \{1, \dots, n\}$ .

The objects  $x$  and  $y$  are in a common cluster, if  $p(x) = p(y)$ . We say that objects  $x$  and  $y$  are in conflict at given tolerance relation and partition iff value of  $c_T^p(x, y) = 1$  in (1).

$$c_T^p(x, y) \leftarrow \begin{cases} 1 & \text{if } (x, y) \in T \text{ and } p(x) \neq p(y) \\ 1 & \text{if } (x, y) \notin T \text{ and } p(x) = p(y) \\ 0 & \text{otherwise} \end{cases} \quad (1)$$

We are ready to define the cost function of relation  $T$  according to partition  $p$ :

$$c_T(p) \leftarrow \frac{1}{2} \sum c_T^p(x, y) = \sum_{x < y} c_T^p(x, y) \quad (2)$$

The task of correlation clustering is to determine the value of  $\min_p c_T(p)$ , and a partition  $p$  for which  $c_T(p)$  is minimal. Unfortunately, this exact value cannot be determined in practical cases, except for some very special tolerance relations. Hence we can only get approximative, near optimal solutions.

Correlation clustering can be defined as a problem of statistical physics [4], where the authors use analogies from physics to solve the problem for small graphs. Here we do

something similar. We can define the attraction between two objects: if they are similar then the attraction between them is 1; if they are dissimilar then the attraction between them is  $-1$  (they repulse each other); otherwise—which can occur at a partial tolerance relation—the attraction is 0.

$$a(x, y) \leftarrow \begin{cases} 1, & \text{if } (x, y) \in T \\ -1, & \text{if } (x, y) \notin T \\ 0, & \text{otherwise} \end{cases} \quad (3)$$

(3) can be generalized for object  $x$  and for clusters  $g$  and  $h$ :

$$a'(x, g) = \sum_{y \in g} a(x, y) \text{ and } \hat{a}(g, h) = \sum_{y \in h} a'(y, g).$$

We leave it to the reader to check that if these sums are positive and we join these element and clusters—by getting a partition  $p'$  containing the clusters  $g \cup \{x\}$  or  $g \cup h$ —then  $c_T(p) \geq c_T(p')$ . This means that by joining attractive clusters, the cost decreases.

### III. CONTRACTION METHOD

The contraction method [5] is based on two operation: the name *contraction* means that we join two attractive clusters. We can treat a cluster as *stable*, if for each of its elements the best position is inside this cluster, because the superposition of the forces (attraction or repulsion between an element and other elements is attraction for each element in the cluster; and there does not exist another cluster which is more attractive for any element in the cluster. But it is possible that the joining of two stable clusters produces a non-stable cluster: the new elements are mostly repulsive for a given element. In this case to get less conflicts this element needs to be *moved* into another cluster. Specially, if one object is repulsed by all clusters, a singleton containing this element needs to be constructed. The process includes calculation of the attractive forces of one object  $x$  for all clusters, and moving nodes based on the maximal attraction we called *movement*.

[5] contains the forces that are needed to be recalculated after a movement or a contraction. These recalculations can be applied for any kind of tolerance relation. If the graph of the tolerance relation is dense—by using the matrices of forces between objects, forces between objects and clusters (for the movements) and forces between clusters (for the contractions)—then the contraction method can be run in an efficient way by adding and subtracting rows and columns of these matrices.

If the graph of the tolerance relation is sparse, then it is a waste to use full matrices for storing the actual forces. (If the tolerance relation contains small amounts of dissimilarity, then the optimal partition consist of only some clusters, so a small matrix is enough to store the forces between clusters.) In our former articles the algorithms were implemented in Python, and we used associative arrays (dict) and associative arrays of associative arrays to store the non-zero objects. But the deletion is problematic for this data type, therefore the implementations based on hash apply only logical deletion. Working

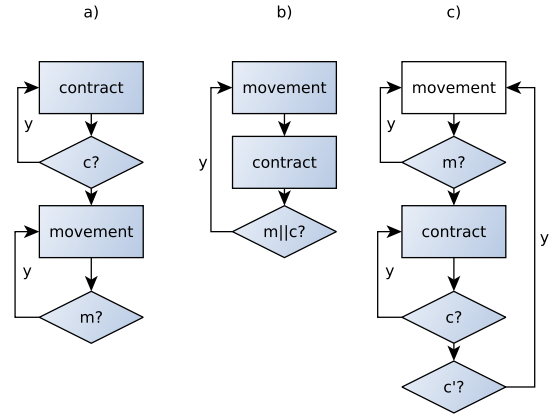

Fig. 1. Different combinations of steps of the local search.

with big tolerance relations, the limit of the implementation is noticeable.

Our new implementation approaches the problem from a new direction. By working with a sparse graph, most of its nodes (the objects) only have a few neighbours. If the forces on a specific node are needed to be calculated (for the movement), only its neighbours need to be checked, not all the objects. Therefore instead of searching for the neighbours of a given object again and again, we store them and the signs of their edges. Of course this means each edge is stored twice i.e. at both of its endpoints, but at a sparse graph ( $|E| = O(|V|)$ ) this is not a serious problem.

To calculate the forces between clusters in the case of a dense graph all edges need to be visited, so the complexity is  $O(n^2)$ . But at sparse graphs the number of edges is proportional to the number of vertices, so the complexity of the calculation of forces is  $O(n)$ .

Correlation clustering can be treated as an optimization problem, where the aim is to minimize the number of conflicts. The steps of contraction and movement can be treated as a local search step. Nevertheless, simple variants of the hill climbing method are not effective for this problem. We have tested this in case of a graph with 13 nodes and from almost 3 million partitions only 2 were global optimum and around ten thousand were local minimum. For bigger graphs the ratio of number of global and local optima will be even smaller, so to find a global optima or a near optimal local optima is a truly difficult task.

The interesting question is how to combine the steps of contraction and movement. Fig. 1/a shows the method we implemented in the former article [6]. A contraction could be a dramatic change, even when two big clusters are joined. This means that with contraction many object get their final positions at the same time. In this variant this contraction step is repeated until it is successful (the number of conflicts decreases). Next, from the unstable clusters some objects are moved to better positions, and this movement is repeated until it is profitable.

This algorithm produced a rather fast method. By rewriting the source we compared this algorithm with some other variants. At first we tested what is the effect of changing the order of contraction and movement. Fig. 1/b shows a variant with a different order, where we execute a contraction after each movement. It is obvious, that the movements only produce local changes, so it takes many cycles to move the objects into their final cluster. Finally we created a variant which moves the objects until it is profitable, then joins the clusters until it is profitable, and if there was a contraction, then it starts a new turn, as Fig. 1/c shows. There is an unbreakable conflict between the speed and efficiency/accuracy: the number of conflicts at method *c* were 13 percent less than at method *a*.

#### IV. QUASI-PARALLEL VARIANT

Formerly we have discussed the quasi-parallel variant of the algorithms [5]. The most naive variant of the *contraction* step calculates all the forces between clusters, and next joins the two most attractive clusters and drops the other calculations. A bit cleverer variant reuses the calculated forces to calculate the forces according to the new (contracted) clusters.

The most costive variant wants to use all the calculations (without any recalculations). Hence it sorts all the calculated forces in decreasing order, and if that value is positive and valid, it joins the suitable clusters. (When can a calculated force be invalid? If some of the clusters it belongs to do not exist any more, because we have already merged them with another, a third cluster.) We named this last variant as *quasi-parallel*, because we practically join the clusters parallel, although not independently.

Of course we can implement similar variants of the *movement* step too. We did, and compared their speed and efficiency. Obviously, the latter variants are faster than the previous ones. The efficiency of the first two variants is the same: we calculated the same values, but the speedier variant needed more technical implementation. Which was surprising is that the last two variants differ in efficiency for contraction and movement.

In case of contraction, the sequential (the first two) variants were better than the quasi-parallel. Maybe the contraction step was so dramatic, that if we join two weakly attractive clusters before we realize that these clusters are more attracted by other clusters, then we cannot redo this action later. Here, based on our tests, the best strategy is to join only the most attractive clusters, and in the next round consider this new joined cluster as well.

In case of movement, the opposite holds. Here the costive (quasi-parallel) version is the best. We can interpret a movement of one object as an engagement. If we allow for a cluster that is getting increasingly stronger to keep on gathering new and new objects, this cluster becomes huge and will not release its objects. With quasi-parallel execution several small clusters grow parallel, and movements can be redone, if there is be a more attractive cluster for an object.

TABLE I  
REMAINING EDGES OF THE SUBGRAPHS (IN PERCENT)

N	no. of subgraphs			
	2	5	10	20
		BA(3,2)		
500	62.8/50.6	45.1/18.9	43.4/9.8	39.1/5.7
1000	63.2/48.9	50.3/21.6	42.8/9.8	40.4/5.2
5000	62.5/50.0	49.3/20.9	45.3/10.0	42.6/4.5
10000	62.6/50.3	49.2/20.0	44.8/10.6	42.8/5.0
20000	62.7/50.2	49.5/20.4	44.7/10.1	42.8/4.9
		ER (p=0.015)		
500	58.6/51.2	39.0/19.7	31.1/9.4	28.2/5.5
1000	53.4/49.9	28.1/20.6	20.8/10.2	16.2/4.8
5000	51.2/50.0	21.7/20.0	11.9/10.0	7.3/4.9
10000	50.5/49.9	20.9/19.9	11.0/10.0	6.2/5.0
20000	50.2/50.0	20.4/20.0	10.5/10.0	5.6/5.0

In the following measurements we will use the algorithm of Fig. 1/c with quasi-parallel movement and sequential contraction.

#### V. DIVIDE AND CONQUER RELOADED

In a former article we have examined whether the divide and conquer approach is useful for correlation clustering [6]. As a reminder, the divide and conquer solution consist of three *simple* steps:

- divide the problem into subproblems,
- solve the subproblems (in a recursive way)
- construct the solution of the original problem from the solutions of the subproblems.

In some cases some of the steps could be left out or are very trivial. In our former article the construction of the subproblems was simple: we divided the graph into same size sub-graphs by the IDs of the objects. It can be checked easily, that with this construction most of the edges are left out from our calculations.

In case of Erdős-Rényi random graphs (ER) the edges are distributed uniformly at random. As the matrices of subgraphs cover only  $n/n^2$  part of the matrix of original graph, only  $1/n$  of the edges are left to work with. We construct slightly better sub-graphs with a little effort i.e. with complexity of  $O(n)$ . The breadth first traversal of the graph is used, and the nodes are taken in that order in which they are deleted from the fringe, i.e. when they get closed. The effectiveness of this trick is shown in Table I. It is not a surprise that in case of ER graphs, where the edges are independent from each other, this trick has no real effect. But at Barabási-Albert type random graphs (BA)—where the construction guaranties that the edges are not independent—the trick works well: when the former method left 5 percent of the edges, this leaves us 40 percent of them.

The other steps of the divide and conquer approach remained the same. The sub-problems were solved by recursion if they were big enough, otherwise a direct solution was used: starting from singleton clusters, the algorithm of Fig. 1/c for the graph of the sub-problem was followed. Finally all the clusters from the solutions of the sub-problems were

collected and put together (as an initial clustering of the whole graph), and we executed the algorithm of Fig. 1/c again. It is surprising, but *solving the original problem, the sub-problems, the subsub-problems, etc. is faster than solving the original problem alone*. This is not a paradox, the key question is the initial clustering of the original problem.

## VI. TECHNICAL DETAILS: CONCURRENCY

The last sentences of the previous chapter are very promising. Moreover at the reimplementing of our software we have taken care of parallelism.

We implemented our software in Python.<sup>1</sup> For calculation intensive tasks this language offers a `multiprocessing` package. At first we used the instruction `map` for each object, which could be familiar to the reader from Google's MapReduce concept. We recall, that *movement* in the algorithm of Fig. 1/c (at top right, emphasized by colour) is inside a double cycle. One task (to calculate the forces on an object) is extremely simple, hence the overhead is huge, it runs thousands of times slower than the original. Next we created a `pool`, and the set of nodes were divided into four, and each core of the processor received one subset, and the role to calculate the forces on nodes that are in that subset. At graphs with hundred nodes the parallel version was 300 times slower than the original. As the number of nodes of the graph increased the running time ratio became smaller and smaller, but at graphs with 20,000 nodes the parallel version was twice slower.

Our framework—constructed for divide and conquer method (D&C)—enables us to break the original problem into sub-problems, and solve them in parallel using the possibilities of a multi-core processor.

One categorisation of tolerance graphs is based on the rate of positive edges. As the edges of BA graphs are dependent, two graphs with the same rate could be very different, but using big samples can help us to discover tendencies. Based on the measurements, the preprocessing for D&C (the trick in the previous section) is useless when this rate is small, and very profitable if this rate is near to 1.

The biggest divergence in number of conflicts was at rate 0.71—where even the number of conflicts was maximal—so we executed speed tests for 3/2 type BA graphs with this rate.

Based on the measurements, the running time the algorithm of Fig. 1/c is near quadratic—a problem with 20,000 nodes was solved within a minute on an i5-6500 processor—and the aim is to solve problems with million of nodes in reasonable time.

We tested the D&C method which gave about 8 percent worse results than solving the problem at once. Does the running time compensate for this penalty? If we only have a few objects, the overhead of solving sub-problems gives a longer running time. At 3000-5000 objects this overhead disappears. But at problematic cases the hardness of solving the sub-problems brings this overhead back. We examined the running time of the subproblems, and we found, that for big

graphs the combination of subsolutions (repeat the contraction method for the whole graph) could take up 98% of the running.

## VII. FUTURE PLANS

Although we have a fast algorithm to solve the problems for large graphs, and some hints about how to choose between them, the research is not over. When solving big graph problems, most of the time only one thread is running, hence we have possibilities to use the concurrency. It is worth to try a manager and a pool of worker processes defined not inside cycles, but at the upper levels. The overhead of the communication between processes could be problematic, but only tests could decide on usefulness of this approach.

The fastest computation is *no* computation. Therefore we need to examine which calculations are necessary, and which can be omitted.

Of course these tricks do not change the quadratic complexity of the algorithm, but we believe, that we can reduce the constant part, which will be very important in practice.

## VIII. CONCLUSION

We introduced a correlation clustering problem, and we presented the contraction method to solve it. We improved our former algorithm in several ways, and we created several variants to it. Some of them used the elements of concurrent execution of the Python code with a small success.

To our knowledge, these are the state of the art algorithms in correlation clustering.

We made several measurements and the results gave hints on how to select amongst them to solve a particular problems. By these measurements our method has quadratic complexity. Finally, we presented the bottleneck of the algorithms. Our next step is to eliminate this, hopefully by using concurrency in a different way.

**Abstract**—Nurse rostering problems are typically too large and hard to be solved exactly. In order to achieve quality solutions to these difficult problems, meta-heuristics are often employed. One such meta-heuristic is Ant Colony Optimisation (ACO), inspired by the pheromone trails left by ants. ACO works by guiding a heuristic solution construction by using these pheromones to direct weighted random choices. When the problem to be solved is highly constrained, finding feasible solutions is difficult, which can result in poor performance for ACO. To address this, we propose an ACO algorithm using an integer programming based solution construction method to ensure feasibility and select from a collection of schedules. The approach also uses a novel solution merging step that combines the information from multiple ants to generate a better final roster. We discuss several challenges inherent in this approach, and how they may be overcome. Computational results on highly constrained nurse rostering problem instances from the literature demonstrate the effectiveness of our proposed new hybrid metaheuristic.

## I. INTRODUCTION

Rostering problems involve the assignment of employees to shifts in order to satisfy cover demands, subject to hard and soft constraints according to rules and preferences respectively. For a review of rostering problems and methods, see [1], or more recently [2].

The Ant Colony Optimisation (ACO) metaheuristic [3] has been applied successfully to a broad range of combinatorial optimisation problems since its inception, including rostering problems. ACO is inspired by the behaviour of real ants that leave trails of pheromones in order to communicate. In ACO, pheromones are used to guide solution construction by encouraging the inclusion of solution components with a higher pheromone presence. Pheromones are left by ants in quantities proportional to solution quality to push future ants towards higher quality solutions. In the past, ACO has been applied to a dynamic version of the Nurse Rostering Problem (NRP) [4] and to a very loosely constrained NRP variant [5]. This is the only ACO and exact algorithm hybrid we have encountered for the NRP.

Various hybrid techniques involving ACO have been implemented in literature, including hybrids with Constraint Programming (CP) [6], [7], Lagrangian Relaxation [8], [9], and Linear Programming [10]. Hybrids of exact methods with other meta-heuristics have also been applied to the NRP, including Tabu Search with CP [11] and Integer Linear

Programming [12], Integer Programming with Variable Neighbourhood Search [13], and Iterated Local Search with CP [14]. More generally, hybridisation of exact algorithms and meta-heuristics is discussed and classified in [15].

What we are proposing in this paper is a new type of hybrid meta-heuristic in which Integer Programming is not only used to handle maintaining feasibility of constraints, but also to make an objective guided selection between a subset of possible schedules during solution construction of work-lines. The ACO framework then provides a way to manage solution diversification and intensification.

Highly constrained rostering problems feature a set of hard constraints that cause many roster combinations to be infeasible, reducing the feasible space of the problem. This can hinder the performance of meta-heuristics such as ACO where the random solution construction cannot achieve feasibility. In some cases this can be addressed by using problem specific knowledge to ensure the construction of only feasible solutions, however this is not always possible. Alternatively, this set of hard constraints (or a subset of) may be relaxed and penalised heavily to discourage violations. Such penalty approaches can be problematic as they distort the fitness landscape, often creating many more local optima so that it is more difficult for the optimisation to find the global optimum.

To address the problem of constructing feasible solutions, we use integer programming to generate feasible work-lines for nurses which can be combined to form a complete roster. This allows us to ensure feasibility in the construction of solutions for our highly constrained NRP, as well as select the best option from a subset of schedules, however the use of Integer Programming can introduce other challenges. Integer programs can be slow to solve for difficult problems. Quick solution construction is desired for use within metaheuristics in order to meaningfully explore the solution space. Optimally solving Integer Programming sub-problems can also lead to less solution diversity and quicker convergence to a local optimum. Our proposed hybrid algorithm addresses this challenge by using ideas from ACO to manage diversification and intensification of the search.

We propose an Integer Programming based ACO method for highly constrained rostering problems, making use of the benefits of this hybrid approach while addressing possible

concerns. While our approach makes use of features that are general to rostering problems, we begin developing this new hybrid method by applying it to instances from a highly constrained NRP dataset to demonstrate its effectiveness at generating good solutions quickly, in a way that scales well for larger problems.

## II. NURSE ROSTERING PROBLEM

The NRP consists of scheduling of nurses in hospitals to satisfy shift requirements. There are several types of shifts each day e.g. Day, Night, Early, Late, each with cover demands. The assignment of nurses to shifts is subject to various work contract constraints, both hard and soft, that determine legal and preferred components of nurse schedules. Individual nurse preferences for shifts on/off are also desired to be satisfied. For reviews of models and methods for NRPs, see [16], [17].

Due to the difficulty inherent in NRPs, in order to achieve good solutions quickly, metaheuristics are often applied to problems. Approaches attempted include Simulated Annealing [18], Variable Neighbourhood Search [19], Genetic Algorithm [20], and Tabu search [12], among others.

As discussed in [21], constraints for the NRP can be put in 3 categories. *Sequence* constraints that are applied within shift sequences (work-stretches), e.g. allowed shift transitions and maximum / minimum consecutive work days. *Schedule* constraints that apply to a work-line for a single nurse (a combination of work-stretches), e.g. maximum number of assignments, maximum weekends worked, personal shift requests on / off. *Roster* constraints that apply across nurse work-lines for the entire roster, e.g. cover requirements.

Various descriptions of the NRP have been presented in literature, featuring different constraints and different combinations of these being considered hard / soft constraints. We explore the NRP as defined in [22], and use their set of benchmark datasets hosted online along with best known bounds<sup>1</sup>.

Three methods are applied to the NRP dataset in [22], the ejection chain and branch-and-price from [23], and solving the formulation provided with the integer programming software Gurobi 5.6.3. The instances of the NRP dataset have also been solved as a partially weighted maxSAT problem [24]. The objective is to minimise the weighted sum of undercover, overcover, and not satisfied nurse shift preferences. This is subject to 10 requirements (with their respective category: *sequence*, *schedule*, or *roster*):

- 1) A nurse cannot be assigned more than one shift on a single day - *sequence*.
- 2) Certain shifts cannot follow each other on consecutive days, i.e. a Day shift cannot immediately follow a Night shift - *sequence*.
- 3) Nurses cannot be assigned more than a certain number each type of shift - *schedule*.
- 4) Nurses cannot work less than a minimum or more than a maximum number of hours in the schedule - *schedule*.

- 5) Nurses cannot work more than a maximum number of days in a row without a day off - *sequence*.
- 6) Nurses cannot work less than a minimum number of days in a row before having a day off - *sequence*.
- 7) Nurses cannot take less than a minimum number of days off in a row - *sequence*.
- 8) Nurses cannot work more than a maximum number of weekends in a schedule - *schedule*.
- 9) Nurses cannot work on days on which they have booked leave - *sequence*.
- 10) There is an ideal cover requirement to be achieved each day, with over cover / under cover penalised - *roster*.

TABLE I  
24 BENCHMARK INSTANCES

Instance	Weeks	Nurses	Shift Types
1	2	8	1
2	2	14	2
3	2	20	3
4	4	10	2
5	4	16	2
6	4	18	3
7	4	20	3
8	4	30	4
9	4	36	4
10	4	40	5
11	4	50	6
12	4	60	10
13	4	120	18
14	6	32	4
15	6	45	6
16	8	20	3
17	8	32	4
18	12	22	3
19	12	40	5
20	26	50	6
21	26	100	8
22	52	50	10
23	52	100	16
24	52	150	32

A summary of the benchmark instances is given in Table I, varying in the 3 problem dimensions: number of weeks, nurses, and shift types. These instances are highly constrained due to requirement 4, which is both an upper and lower bound on hours worked. This requirement is often quite strict, not allowing much variation in the number of shifts each nurse is required to work. As a result, purely random constructions heuristics perform poorly for these problems.

## III. MODEL

Here we will present the Integer Programming formulation for our solution construction method. The solution construction involves solving an integer program (IP) for single nurse's work-line. A typical integer programming formulation for a NRP will utilise variables representing the assignment of a particular nurse to a specific shift on a given day, as in [22], [23].

As solution construction time is of concern, we make use of the concept of work-stretches for the variables of our IP in order to reduce complexity. We define a work-stretch as a

<sup>1</sup><http://www.cs.nott.ac.uk/~psztc/NRP/index.html>

Fig. 1. Definition of a work-stretch as a continuous sequence of work shifts including the following minimum length stretch of off-days (requirement 7).

continual sequence of shift assignments for a specific nurse with no off-days in between, combined with a stretch of off-days of the minimum required length as shown in Figure 1. These work-stretches are able to incorporate all the *sequence* constraints of the problem, as well as the costs due to nurse preferences not satisfied. Only work-stretches that satisfy all of the *sequence* constraints (and so are feasible for our problem) are generated and added to the problem as variables.

There are several examples in literature of the use of work-stretch like structures for the NRP, mainly for use in heuristics, including [21] who also present a brief summary of work-stretches in NRP. For rostering problems more generally, [25] present a general column generation approach based upon work-stretches to reduce complexity. They use a nested resource constrained shortest path that builds work-stretches then uses these to construct columns of work-lines for nurses. Their method is further refined and utilised in a branch-and-price framework [26].

In using work-stretches to model our NRP, we reduce the number of constraints we need to formulate explicitly in our model. Each nurse's schedule is modelled as a network flow with side constraints that cover only the *schedule* and *roster* constraints. By introducing single off-day variables, we can model all combinations of shifts on and off by allowing transitions from work-stretches to other work-stretches or to these single off-day variables. The mathematical formulation of this integer programming model for a given nurse  $i \in I$  is given here in terms of the notation described in Table II.

First, we construct the network flow for this nurse. Equations (1) and (2) set up the source and sink of the flow respectively. Equation (3) defines the flow conservation for all other nodes, that the sum of work-stretches or off days finishing on a given day equals the sum of those starting the next day.

Day 0 flow:

$$\sum_{j \in W_{i0}} x_{ij} + o_{i0} = 1. \quad (1)$$

Day  $h$  (last day) flow:

$$\sum_{j \in W_{ih+1}^E} x_{ij} + o_{ih} = 1. \quad (2)$$

Middle day flows:

$$\sum_{j \in W_{id}^E} x_{ij} + o_{id-1} = \sum_{j \in W_{id}} x_{ij} + o_{id}, \quad \forall d \in D \setminus \{0, h\}. \quad (3)$$

TABLE II  
SETS, VARIABLES AND PARAMETERS FOR WORK-STRETCH NRP FORMULATION

Component	Type	Description
$I$	Set	Set of Nurses $i$
$D$	Set	Set of Days in the schedule period $d$
$T$	Set	Set of Shift types $t$ , e.g. $t \in \{D, A, N\}$
$W_{id}$	Set	Set of all work-stretches $j$ that start on day $d \in D$ for nurse $i \in I$
$W_{id}^E$	Set	Set of all work-stretches $j$ that end the day before day $d \in D$ for nurse $i \in I$
$W_{it}^N$	Set	Set of all work-stretches $j$ that contribute a shift of type $t \in T$ for nurse $i \in I$
$W_{td}^C$	Set	Set of all work-stretches $j$ that contribute a shift of type $t \in T$ on day $d \in D$
$l_t$	Parameter	length of shift type $t \in T$ in hours
$cst_j$	Parameter	penalty cost of assigning work-stretch $j$
$csto_{id}$	Parameter	penalty cost of assigning nurse $i \in I$ an off-day on day $d \in D$
$we_j$	Parameter	1 if work-stretch $j$ involves working a week-end, 0 otherwise
$c_{itj}$	Parameter	number of shifts of type $t \in T$ that work-stretch $j$ contributes for nurse $i \in I$
$a_i^{max}$	Parameter	maximum number of weekends that nurse $i \in I$ can work
$m_{it}^{max}$	Parameter	maximum number of shifts of type $t \in T$ that can be assigned to nurse $i \in I$
$b_i^{min}$	Parameter	minimum number of hours that nurse $i \in I$ must be assigned
$b_i^{max}$	Parameter	maximum number of hours that nurse $i \in I$ can be assigned
$h$	Parameter	last day of the horizon
$u_{dt}$	Parameter	preferred total number of nurses assigned shift type $t \in T$ on day $d \in D$
$v_{td}^{min}$	Parameter	weight if below the preferred cover for shift type $t \in T$ on day $d \in D$
$v_{td}^{max}$	Parameter	weight if exceeding the preferred cover for shift type $t \in T$ on day $d \in D$
$x_{ij}$	Variable	1 if nurse $i \in I$ is assigned work-stretch $j \in \bigcup_{d \in D} W_{id}$ , 0 otherwise
$o_{id}$	Variable	1 if nurse $i \in I$ is assigned an off-day on day $d \in D$
$y_{td}$	Variable	total below the preferred cover for shift type $t \in T$ on day $d \in D$
$z_{td}$	Variable	total above the preferred cover for shift type $t \in T$ on day $d \in D$
$cv_{td}$	Variable	Total cover for shifts of type $t \in T$ on day $d \in D$

Equations (4), (5), and (6) cover the *schedule* requirements 3, 4, and 8 respectively for the nurse. Equation (4) specifies that for each shift type  $t \in T$  the sum of shifts of that type worked by the nurse is less than the maximum allowed. Equation (5) specifies that the sum of hours worked by the nurse is within the allowed bounds. Equation (6) specifies that the sum of weekends worked by the nurse is less than the allowed number.

$$\sum_{d \in D} \sum_{j \in W_{it}^N} c_{itj} x_{ij} \leq m_{it}^{max} \quad \forall t \in T, \quad (4)$$

$$b_i^{min} \leq \sum_{t \in T} \sum_{j \in W_{it}^N} l_t x_{ij} \leq b_i^{max}, \quad (5)$$

$$\sum_{d \in D} \sum_{j \in W_{id}} we_j x_{ij} \leq a_i^{max}. \quad (6)$$

For the *roster* requirement of meeting cover demand, we sum assigned work-stretches for all nurses in the current solution:

$$cv_{td} = \sum_{i' \in I} \sum_{j \in W_{td}^C} x_{i'j}. \quad (7)$$

Assigning under and over-cover variables the correct values:

$$y_{td} \geq u_{td} - cv_{td} \quad \forall t \in T, d \in D, \quad (8)$$

$$z_{td} \geq cv_{td} - u_{td} \quad \forall t \in T, d \in D. \quad (9)$$

The objective function is then the sum of work-stretch and off-day costs with under and over cover:

$$\begin{aligned} \min \sum_{i' \in I} \sum_{d \in D} \sum_{j \in W_{i'd}^C} cst_j x_{i'j}^w + \sum_{i' \in I} \sum_{d \in D} cst_{o_{i'd}} o_{i'd} \\ + \sum_{t \in T} \sum_{d \in D} (v_{td}^{min} y_{td} + v_{td}^{max} z_{td}). \end{aligned} \quad (10)$$

#### IV. ACO-IP ALGORITHM

ACO is a meta-heuristic based upon quality solutions leaving pheromones to encourage future solutions. Generally, the solution construction heuristic that is guided by these pheromones is just a weighted random selection. In the case of highly constrained rostering problems, this weighted random selection may choose shift / off-day combinations early on that means upper or lower bounds for work hours cannot be satisfied. To address this, we use an integer programming based ant construction in our ACO-IP hybrid algorithm.

Our ant construction is still guided by random choices in the ACO fashion, using a heuristic component,  $\eta$ , calculated using problem specific knowledge, and a pheromone component,  $\tau$ . Typically, there is one  $\eta$  and  $\tau$  component per decision made in the ant construction. As our decisions are the assignment of whole work-stretches, the number of which is exponential in number of shift types, we instead use one of each component  $\eta$  and  $\tau$  for each shift for each nurse for each day. Rather than directly informing the choice of work-stretch, the weightings are used to choose the reduced set of shifts that will make the components of the work-stretches. All feasible work-stretches are then generated from this subset of shifts, with integer programming used to select the best schedule from these subset of all work-stretches. From the set of available shifts, each is given a probability of being chosen, then shifts are selected for each day without replacement until the desired number of shifts are chosen. Only work-stretches comprising the chosen set of shifts on their given days will be added to the integer programming problem. Thus we have for each ant:

$$p_{itd}(S) = \frac{\tau_{itd}(S)^\alpha \cdot \eta_{itd}^\beta}{\sum_{u \in T} \tau_{iud}(S)^\alpha \cdot \eta_{iud}^\beta} \quad \forall i \in I, t \in T, d \in D, \quad (11)$$

where  $S$  is the current solution,  $p_{itd}(S)$  is the probability of choosing shift  $t$  for nurse  $i$  and day  $d$  given solution  $S$ ,  $\eta_{itd}(S)$  is the calculated heuristic value of shift  $t$  for nurse  $i$  on day

$d$  given solution  $S$ ,  $\tau_{itd}$  is the pheromone value, and  $\alpha$  and  $\beta$  are parameters to adjust the influence of  $\eta$  and  $\tau$ .

After each iteration, all of the pheromone components are evaporated according to some evaporation rate,  $\rho$ , then updated with an additional pheromone amounts for each solution in that iteration. The amount of pheromone left is proportional to the quality of the solution,  $\frac{1}{objval(S)}$  for a minimisation problem with solution  $S$ , scaled by a constant  $Q$ :

$$\tau_{itd} = (1-\rho) \cdot \tau_{itd} + \sum_{S \in S_n} \frac{Q}{objval(S)} \quad \forall i \in I, t \in T, d \in D, \quad (12)$$

where  $S_n$  is the set of solutions for iteration  $n$ . To avoid extreme pheromone values, it is typical to control the values of pheromones using fixed maximum and minimum pheromone levels. We do not run our algorithm for long enough for this to become necessary.

The approach as described above makes use of the  $\eta$  and  $\tau$  components to choose the work-stretches that are included in the integer programming problem for each nurse, but not to influence the decisions made directly. The decision of what schedule to choose is limited by the options given by the pheromone guided random choice of shifts, but is made to minimise the objective given in Equation 10 for the available options of work-stretches. This limits the influence of the pheromones in directing the search. It is possible to address this by similarly randomly weighting the objective coefficients for undercover of the corresponding shift and day combinations.

---

#### Algorithm 1 Ant Construction: make\_ants()

---

```

for ant in num_ants do
2:   new_sol = best solution copy
   for all nurse in nurses do
4:     remove work-line for current nurse from new_sol
     for all day in horizon do
6:       calculate heuristic weight from new_sol cover
       randomly choose num_shift shifts weighted by
       heuristic weight and pheromone
8:     end for
     make_workstretches(chosen_shifts)
10:    solve_nurse()
    add work-line to new_sol
12:  end for
end for

```

---

Also of interest are the heuristic weights  $\eta$ , which if calculated for the first few nurses of a solution, will give little information as to which shifts should be scheduled as most of the solution is empty. This can be addressed with a pseudo-elitist strategy where the best know solution is assumed to be present for nurses whose work-lines have not yet been constructed. This both gives the  $\eta$  components a more insightful value and encourages solutions closer to the best known solution. The algorithm for the ant construction in this way is shown in Algorithm 1. The construction of multiple

ants is able to parallelised easily, and we make use of this in our application of the method.

---

**Algorithm 2** ACO-IP: ACO meta-heuristic and merge solve

---

```

while not iteration limit & not time limit do
2:   make_ants()
   if new best solution then
4:     store best solution
   end if
6:   update_pheromones()
end while
8: for last n solutions do
   add unique solution work-stretches to merge_stretches
10: end for
   add merge_stretches to merge_IP
12: add best solution to merge_IP (as incumbent)
   solve merge_IP

```

---

Solving single work-lines to optimality in serial can result in less solution diversity than other random construction methods, especially when we do not alter the objective coefficients for undercover of shifts. To consistently achieve good solutions and properly explore the search space, it is desirable to have some diversity in the solutions being constructed.

In order to improve solution quality, we can make use what diversity there is in the solution set, even for solutions of varied quality, by solving an IP as a final merging step for solutions explored. By combining work-stretches from previous solutions into an IP and taking the current best solution as an incumbent solution, we can explore the neighbourhood around our best solution. As we do not consider all possible work-stretches, this keeps the IP a more manageable size.

The overarching ACO algorithm is described in Algorithm 2, with the integer programming merge step as described as a final step to improve solutions.

## V. EXPERIMENTAL RESULTS

To determine the effectiveness of our new approach, we evaluate its performance on the 24 NRP benchmark instances discussed above. Parameter tuning was performed on a subset of the benchmark instances to improve solution quality. Our algorithm was then applied to the full NRP benchmark dataset with the tuned parameters, with ant construction run in parallel. We also analyse the variance of performance of the algorithm on a subset of the NRP dataset. The results are compared with existing results for this NRP dataset from the literature. The ACO-IP hybrid algorithm was implemented in Python to construct 4 ants in parallel for each iteration, using the commercial solver Gurobi 7.0 to evaluate the integer programs. All runs were conducted on 4 threads of an Intel Xeon CPU E5-2680 v3 @ 2.50GHz.

### A. Parameter Tuning

There are several parameters in our algorithm that can affect performance. Here we present a brief study over several choices of parameter values to tune our algorithm. The

selection of some parameters were made explicitly with time or computational hardware considerations in mind.

The termination criteria was set to 50 iterations of the ACO loop then 5 minutes for the integer programming merge step (or until optimality is proven). The iteration limit chosen is aimed at reducing the run time for instances.

The number of shift types to choose as options for building work-stretches in the ant construction was chosen to be 3 for all instances. As the number of work-stretches can be exponential in the number of shift types, this number of shifts was chosen to give a balance of choices available, which influences convergence performance, and also keeping solve times short. For instances with 3 shift types or less, this means that we are reducing greatly the variability in our approach, especially when the number of employees is small and time horizon is short. As such we omitted the 7 smallest instances from our experiments.

The ant construction in our algorithm is able to be done in parallel, this allows multiple ants to be constructed at each iteration without increase in overall solution time (given enough CPUs). The ant population size was chosen to be 4 ants per iteration for all instances. This was mainly due to computational hardware constraints, enabling each ant construction one CPU core in parallel.

The pheromone evaporation rate  $\rho$  was chosen to be 0.05. As we initiate all pheromone values at 1, the evaporation rate was chosen such that after the 50 iteration limit the pheromone values would be reduced by about an order of magnitude.

The parameters selected for tuning were the constant multiplier for pheromone placement,  $Q$ , and the heuristic and pheromone influence parameters,  $\alpha$  and  $\beta$ . These parameters were tuned for the whole of our ACO-IP algorithm, not including the integer programming merge step, as the variation in solutions generated in the ACO-loop of our algorithm also influences the performance of the merge step.

The choice of the constant  $Q$  affects the amount of pheromones placed by ants each iteration. This effects the convergence of pheromone values. As the solution quality ( $\frac{1}{objval}$ ) is instance dependent, this constant  $Q$  was chosen in terms of the objective value of the initial solution, scaled by some constant  $Q_s$ . This gives:

$$Q = \frac{Q_s \cdot inisol}{objval}, \quad (13)$$

where  $inisol$  is the objective value of the initial solution for the solve. This makes the choice of value specific for the instance, without the need for any a priori knowledge.

The  $\alpha$  and  $\beta$  parameters effect the relative influence of the heuristic information and pheromone values on the random solution construction. To determine the best combination of  $Q_s$ ,  $\alpha$ , and  $\beta$ , combinations were evaluated for a subset of instances (instances 12, 15, and 19) for 10 runs each.

The choices of parameters for testing were  $Q_x \in [0.1, 0.5, 1]$ ,  $\alpha \in [0, 0.5, 1]$ , and  $\beta \in [1]$ . The results of these runs are shown in Table III. The use of pheromones to guide the search can be seen to have a beneficial effect as

TABLE III  
AVERAGE BEST SOLUTION AFTER ACO LOOP OF OUR ALGORITHM FOR DIFFERENT  $Q_s$ ,  $\alpha$ , AND  $\beta$  COMBINATIONS AFTER 10 RUNS.

Instance	$Q_s = 0.1, \beta = 1$			$Q_s = 0.5, \beta = 1$			$Q_s = 1, \beta = 1$		
	$\alpha = 0$	$\alpha = 0.5$	$\alpha = 1$	$\alpha = 0$	$\alpha = 0.5$	$\alpha = 1$	$\alpha = 0$	$\alpha = 0.5$	$\alpha = 1$

performance is worse when  $\alpha$  is set to 0 (when pheromone values are ignored). The algorithm tends to perform better with more of an influence on the heuristic values. This may be due to the limited number of iterations not allowing convergence of the pheromone values. For further runs a  $Q_s$  value of 0.1,  $\alpha$  value of 0.5, and  $\beta$  value of 1 were chosen.

### B. Variance of Performance

As with other random searches, the variance in performance of the ACO algorithm can be quite large. Here we aim to analyse the variance of performance for our ACO-IP hybrid algorithm. To do this we tested our algorithm more extensively on a subset of the NRP dataset (instances 12, 15, and 19).

Our algorithm was run 30 times on each instance, with the mean performance and standard deviation presented for both after the ACO loop is complete, and after the final integer programming merge step. The results are summarised in Table V. It is clear that our integer programming merge step leads to a significant improvement in solutions achieved. The standard deviation of solution achieved does not decrease significantly after the merge step, and in fact increases, indicating there is still variability in the performance of the integer programming merge step.

### C. Comparison of Results

Finally our algorithm was run on all instances of the NRP dataset with tuned parameters for comparison with existing results in literature for the dataset used. Existing results on this dataset for comparison are shown in Table IV, including

TABLE V  
AVERAGE (AVG.) AND STANDARD DEVIATION (SD) OF BEST SOLUTION AFTER THE ACO LOOP AND FINAL SOLUTION AFTER THE INTEGER PROGRAMMING MERGE STEP AFTER 30 RUNS OF OUR ACO-IP ALGORITHM.

Instance	ACO Search		Final	
	Avg.	SD	Avg.	SD
12	5577.03	229.23	4347.3	334.76
15	5735.86	220.93	5055.6	326.38
19	4411.22	214.32	3782.22	371.04

the work of [24] who model the NRP using Partial Weighted maxSAT and solve it using the WPM3 algorithm of [27] for 4 hours runtime, both an ejection chain heuristic method (reported after 10 and 60 minutes, solutions after 60 minutes shown) and a branch-and-price method implemented by [22] as in [23], and finally results for a complete integer programming implementation of the problem instances from [22], run on Gurobi 7.0 with a 1 hour runtime limit.

The best results for these methods are compared with the average result of 10 runs of our ACO-IP approach in Table IV. Note that in our parameter tuning we trained on Instances 12, 15, and 19. Other methods were not similarly trained on a subset of the instances used for comparison.

Best results across all methods are highlighted in bold. While Gurobi obtains the best solution for the largest number of test instances, it is clear that it does not scale well with increasing problem size. Indeed, as the problem size increases our method clearly starts to outperform the others presented

here. For the medium to large instances, our method is comparable to or outperforms the best other heuristic method (ejection chain). While the ability to solve larger problems is encouraging for the scalability of our method, further research is required to improve the method. Gurobi is able to generate solutions of better quality for the medium sized instances, and further work is required to ensure we are generating good solutions for the larger instances.

## VI. CONCLUSIONS

We have presented a new ACO-IP hybrid metaheuristic for highly constrained rostering problems. It uses an integer programming based solution construction to avoid problems of finding feasible solutions inherent in other random construction methods typical of ACO when problems are highly constrained, as well as to enhance the quality of the schedule chosen over a subset of all options. Performance of the algorithm is improved by a novel integer programming merge step which uses past solutions to explore the neighbourhood around the best solution achieved. While unable to compete against Gurobi for solution quality in the small to medium sized instances, our method scales well and outperforms Gurobi and all other methods for large instances, and is generally able to achieve good solutions to medium instance comparable to or better than the ejection chain heuristic.

These results show that our ACO-IP hybrid algorithm can be effective for highly constrained problems, this encourages the further improvement of the method and application to rostering problems more generally.

**Abstract**—The workforce planning helps organizations to optimize the production process with aim to minimize the assigning costs. A workforce planning problem is very complex and needs special algorithms to be solved. The problem is to select set of employers from a set of available workers and to assign this staff to the jobs to be performed. Each job requires a time to be completed. For efficiency, a worker must performs a minimum number of hours of any assigned job. There is a maximum number of jobs that can be assigned and a maximum number of workers that can be assigned. There is a set of jobs that shows the jobs on which the worker is qualified. The objective is to minimize the costs associated to the human resources needed to fulfill the work requirements. On this work we propose a variant of Ant Colony Optimization (ACO) algorithm to solve workforce optimization problem. The algorithm is tested on a set of 20 test problems. Achieved solutions are compared with other methods, as scatter search and genetic algorithm. Obtained results show that ACO algorithm performs better than other two algorithms.

**Index Terms**—Workforce Planning, Ant Colony Optimization, Metaheuristics

## I. INTRODUCTION

THE workforce planning is an important industrial decision making problem. It is a hard optimization problem, which includes multiple level of complexity. This problem contains two decision sets: selection and assignment. The first set is selected employees from the larger set of available workers. The second set is assignment the employees to the jobs to be performed. The aim is minimal assignment cost while the work requirements are fulfil. The workforce planing is an essential question of the human resource management.

The problem is very complex with strong constraints and it is impossible to apply exact methods for instances with realistic size. A deterministic workforce planing problem is studied in [9], [14]. In the work [9] workforce planning models that contain non-linear models of human learning are reformulated as mixed integer programs. The authors show that the mixed integer program is much easier to solve than the non-linear program. In [14] a model of workforce planning is considered. The model includes workers differences, as

well as the possibility of workers training and upgrading. A variant of the problem with random demands is proposed in [3], [15]. In [3] a two-stage stochastic program for scheduling and allocating cross-trained workers is proposed considering a multi-department service environment with random demands. In to some problems uncertainty has been employed [10], [12], [13], [17], [18]. In this case the corresponding objective function and given constraints is converted into crisp equivalents and then the model is solved by traditional methods [13] or the considered uncertain model is transformed into an equivalent deterministic form as it is shown in [17]. Most of them simplifies the problem by omitting some of the constraints. Some conventional methods can be applied on workforce planning problem as mixed linear programming [5], decomposition method [15]. However, for the more complex non-linear workforce planning problems, the convex methods are not applicable. On this case is applied some heuristic method including genetic algorithm [1], [11], memetic algorithm [16], scatter search [1]. In this work we propose an Ant Colony Optimization (ACO) algorithm for workforce planning problem. So far the ACO algorithm is proved to be very effecting solving various complex optimization problems [6], [8].

We consider the variant of the workforce planning problem proposed in [1]. Our algorithm performance is compared with genetic algorithm and scatter search.

The rest of the paper is organized as follows. In Section 2 the mathematical description of the problem is presented. In Section 3 the ACO algorithm for workforce planing problem is proposed. Section 4 show computational results and comparison with other methods. In Section 5 some conclusions and directions for future works are done.

## II. THE WORKFORCE PLANNING PROBLEM

On this paper we use the description of workforce planing problem given by Glover et al. [7]. There is a set of jobs  $J = \{1, \dots, m\}$ , which must be completed during a fixed period (week for example). Each job  $j$  requires  $d_j$  hours to be

completed. The set of available workers is  $I = \{1, \dots, n\}$ . For efficiency reason every worker must perform every of assigned to him job minimum  $h_{min}$  hours. The worker  $i$  is available  $s_i$  hours. The maximal number of assigned jobs to a same worker is  $j_{max}$ . The workers have different skills and the set  $A_i$  shows the jobs that the worker  $i$  is qualified to perform. The maximal number of workers which can be assigned during the planed period is  $t$  or at most  $t$  workers may be selected from the set  $I$  of workers and the selected workers can be capable to complete all the jobs. The aim is to find feasible solution that optimizes the objective function.

Every worker  $i$  and job  $j$  are related with cost  $c_{ij}$  of assigning the worker to the job. The mathematical model of the workforce planing problem is as follows:

$$x_{ij} = \begin{cases} 1 & \text{if the worker } i \text{ is assigned to job } j \\ 0 & \text{otherwise} \end{cases}$$

$$y_i = \begin{cases} 1 & \text{if worker } i \text{ is selected} \\ 0 & \text{otherwise} \end{cases}$$

$$z_{ij} = \text{number of hours that worker } i \\ \text{is assigned to perform job } j$$

$$Q_j = \text{set of workers qualified to perform job } j$$

$$\text{Minimize } \sum_{i \in I} \sum_{j \in A_i} c_{ij} \cdot x_{ij} \quad (1)$$

Subject to

$$\sum_{j \in A_i} z_{ij} \leq s_i \cdot y_i \quad i \in I \quad (2)$$

$$\sum_{i \in Q_j} z_{ij} \geq d_j \quad j \in J \quad (3)$$

$$\sum_{j \in A_i} x_{ij} \leq j_{max} \cdot y_i \quad i \in I \quad (4)$$

$$h_{min} \cdot x_{ij} \leq z_{ij} \leq s_i \cdot x_{ij} \quad i \in I, j \in A_i \quad (5)$$

$$\sum_{i \in I} y_i \leq t \quad (6)$$

$$\begin{aligned} x_{ij} &\in \{0, 1\} & i \in I, j \in A_i \\ y_i &\in \{0, 1\} & i \in I \\ z_{ij} &\geq 0 & i \in I, j \in A_i \end{aligned}$$

The objective function of this problem minimizes the total assignment cost. The number of hours for each selected worker is limited (inequality 2). The work must be done in full (inequality 3). The number of the jobs, that every worker can perform is limited (inequality 4). There is minimal number of hours that every job must be performed by every assigned worker to can work efficiently (inequality 5). The number of assigned workers is limited (inequality 6).

Different objective functions can be optimized with the same model. In this paper our aim is to minimize the total assignment cost. If  $\tilde{c}_{ij}$  is the cost the worker  $i$  to performs the job  $j$  for one hour, than the objective function can minimize the cost of the hall jobs to be finished (on hour basis).

$$f(x) = \text{Min} \sum_{i \in I} \sum_{j \in A_i} \tilde{c}_{ij} \cdot x_{ij} \quad (7)$$

Some worker can have preference to perform part of the jobs he is qualified and the objective function can be to maximize the satisfaction of the workers preferences or to maximize the minimum preference value for the set of selected workers.

As we mentioned above in this paper the assignment cost is minimized (equation 1). This problem is similar to the Capacitated Facility Location Problem (CFLP). The workforce planning problem is difficult to be solved because of very restrictive constraints especially the relation between the parameters  $h_{min}$  and  $d_j$ . When the problem is structured ( $d_j$  is a multiple of  $h_{min}$ ), it is more easier to find feasible solution, than for unstructured problems ( $d_j$  and  $h_{min}$  are not related).

### III. ANT COLONY OPTIMIZATION

The ACO is a metaheuristic methodology which follows the real ant colonies behavior when they look for a food and return back to the nest. Real ants use chemical substance, called pheromone, to mark their path ant to can return back. An isolated ant moves randomly, but when an ant detects a previously laid pheromone it can decide to follow the trail and to reinforce it with additional quantity of pheromone. The repetition of the above mechanism represents the auto-catalytic behavior of a real ant colony, where the more ants follow a given trail, the more attractive that trail becomes. Thus the ants collectively can find a shorter path between the nest and source of the food. The main idea of the ACO algorithms comes from this natural behavior.

#### A. Main ACO algorithm

Metaheuristic methods are applied on difficult in computational point of view problems, when it is not practical to use traditional numerical methods. A lot of problems coming from real life, especially from the industry. These problems need exponential number of calculations and the only option, when the problem is large, is to be applied some metaheuristic methods in order to obtain a good solution for a reasonable time [4].

ACO algorithm is proposed by Marco Dorigo [2]. Later some modification are proposed mainly in pheromone updating rules [4]. The artificial ants in ACO algorithms simulates the ants behavior. The problem is represented by graph. The solutions are represented by paths in a graph and we look for shorter path corresponding to given constraints. The requirements of ACO algorithm are as follows:

- Suitable representation of the problem by a graph;
- Suitable pheromone placement on the nodes or on the arcs of the graph;

- Appropriate problem-dependent heuristic function, which manage the ants to improve solutions;
- Pheromone updating rules;
- Transition probability rule, which specifies how to include new nodes in the partial solution.

The structure of the ACO algorithm is shown on Figure 1.

#### Ant Colony Optimization

Initialize number of ants;

Initialize the ACO parameters;

**while not** end condition **do**

**for**  $k = 0$  **to** number of ants

        ant  $k$  choses start node;

**while** solution is not constructed **do**

            ant  $k$  selects higher probability node;

**end while**

**end for**

    Update pheromone trails;

**end while**

Fig. 1: Pseudo-code of ACO algorithm

The transition probability  $p_{i,j}$ , to choose the node  $j$ , when the current node is  $i$ , is a product of the heuristic information  $\eta_{i,j}$  and the pheromone trail level  $\tau_{i,j}$  related with this move, where  $i, j = 1, \dots, n$ .

$$p_{i,j} = \frac{\tau_{i,j}^a \eta_{i,j}^b}{\sum_{k \in \text{Unused}} \tau_{i,k}^a \eta_{i,k}^b}, \quad (8)$$

where *Unused* is the set of unused nodes of the graph.

A node becomes more profitable if the value of the heuristic information and/or the related pheromone is higher. At the beginning, the initial pheromone level is the same for all elements of the graph and is set to a small positive constant value  $\tau_0$ ,  $0 < \tau_0 < 1$ . At the end of every iteration the ants update the pheromone values. Different ACO algorithms adopt different criteria to update the pheromone level [4].

The main pheromone trail update rule is:

$$\tau_{i,j} \leftarrow \rho \tau_{i,j} + \Delta \tau_{i,j}, \quad (9)$$

where  $\rho$  decreases the value of the pheromone, like the evaporation in a nature.  $\Delta \tau_{i,j}$  is a new added pheromone, which is proportional to the quality of the solution. The quality of the solution is measured by the value of the objective function of the solution constructed by the ant.

An ant start to construct their solution from a random node of the graph of the problem. The random start is a diversification of the search. Because the random start a relatively few number of ants can be used, comparing with other population based metaheuristics. The heuristic information represents the prior knowledge of the problem, which we use to better manage the ants. The pheromone is a global experience of the ants to find optimal solution. The pheromone is a tool for concentration of the search around best so far solutions.

#### B. ACO algorithm for Workforce Planning

One of the essential point of the ant algorithm is the proper representation of the problem by graph. In our case the graph of the problem is 3 dimensional and the node  $(i, j, z)$  corresponds worker  $i$  to be assigned to the job  $j$  for time  $z$ . At the beginning of every iteration every ant starts to construct their solution, from random node of the graph of the problem. For every ant are generated three random numbers. The first random number is in the interval  $[0, \dots, n]$  and corresponds to the worker we assign. The second random number is in the interval  $[0, \dots, m]$  and corresponds to the job which this worker will perform. The third random number is in the interval  $[h_{min}, \dots, \min\{d_j, s_i\}]$  and corresponds to the number of hours worker  $i$  is assigned to performs the job  $j$ . After, the ant applies the transition probability rule to include next nodes in the partial solution, till the solution is completed.

We propose the following heuristic information:

$$\eta_{ijl} = \begin{cases} l/c_{ij} & l = z_{ij} \\ 0 & \text{otherwise} \end{cases} \quad (10)$$

This heuristic information stimulates to assign the most cheapest worker as longer as possible. The ant chooses the node with the highest probability. When an ant has several possibilities for next node (several candidates have the same probability to be chosen), then the next node is chosen randomly between them.

When a new node is included we take in to account how many workers are assigned till now, how many time slots every worker is assigned till now and how many time slots are assigned per job till now. When some move of the ant do not meets the problem constraints, then the probability of this move is set to be 0. If it is impossible to include new nodes from the graph of the problem (for all nodes the value of the transition probability is 0), the construction of the solution stops. When the constructed solution is feasible the value of the objective function is the sum of the assignment cost of the assigned workers. If the constructed solution is not feasible, the value of the objective function is set to be equal to  $-1$ .

Only the ants, which constructed feasible solution are allowed to add new pheromone to the elements of their solutions. The new added pheromone is equal to the reciprocal value of the objective function.

$$\Delta \tau_{i,j} = \frac{\rho - 1}{f(x)} \quad (11)$$

Thus the nodes of the graph of the problem, which belong to better solutions (with less value of the objective function) receive more pheromone than others and become more desirable in the next iteration.

At the end of every iteration we compare the iteration best solution with the best so far solution. If the best solution from the current iteration is better than the best so far solution (global best solution), we update the global best solution with the current iteration best solution.

The end condition used in our algorithm is the number of iterations.

TABLE I: Test instances characteristics

Parameters	Value
$n$	20

#### IV. COMPUTATIONAL RESULTS

In this section we report test results and compare them with results achieved by other methods. We analyse the algorithm performance and the quality of the achieved solutions. The software, which realizes the algorithm is written in C and is run on Pentium desktop computer at 2.8 GHz with 4 GB of memory.

We use the artificially generated problem instances considered in [1]. The test instances characteristics are shown in Table I.

The set of test problems consists of ten structured and ten unstructured problems. The structured problems are enumerated from  $S01$  to  $S10$  and unstructured problems are enumerated from  $U01$  to  $U10$ . The problem is structured when  $d_j$  is proportional to  $h_{min}$ .

As a stopping criteria for our ACO algorithm we use the number of iterations. The number of iterations is fixed to be 100. The parameter settings of our ACO algorithm is shown in Table II. This values are fixed experimentally.

The algorithm is stochastic and from a statistical point of view it needs to be run minimum 30 times to guarantee the robustness of the average results. We perform 30 independent runs of the algorithm. After we did statistical analysis of the results applying ANOVA test to guarantee the significance of the difference between the results achieved by different methods.

Lets compare the computational results achieved by our ACO algorithm and those achieved by genetic algorithm (GA) and scatter search (SS) presented in [1]. Table III shows the achieved results for structured instances while Table IV shows the achieved results for unstructured instances. We observe that ACO algorithm outperforms the other two algorithms. The ACO is a constructive method and when the graph of the problem and heuristic information are appropriate and they represent the problem in a good way, they can help a lot of

TABLE III: Average results for structured problems

U09	1055	1173	768
U10	1178	1214	818

for better algorithm performance and achieving good solutions. Our graph of the problem has a star shape. Each worker and job are linked with several nodes, corresponding to the time, for which the worker is assigned to perform this job. The proposed heuristic information stimulates the cheapest workers to be assigned for longer time. It is a greedy strategy. After the first iteration the pheromone level reflects the experience of the ants during the searching process thus affects the strategy. The elements of good solutions accumulate more pheromone, during the algorithm performance, than others and become more desirable in the next iterations.

Now we will compare the execution time of the proposed ACO algorithm with the execution time of the other two algorithms. The algorithms are run on similar computers. In Tables V and VI is reported average execution time over 30 runs of every of the algorithms. It is seen that the ACO algorithm finds the solution faster than GA and SS. Considering the execution time the GA and SS algorithms have similar performance. By the Tables III, IV, V and VI we can conclude that ACO algorithm gives very encouraging results. It achieves better solutions in shorter time than the other two algorithms, SS and GA. If we compare memory use, the ACO algorithm uses less memory than GA (GA population size is 400 individuals [1]) and similar memory to SS (initial population size is 15 and reference set is 8 individuals [1]).

## V. CONCLUSION

In this article we propose ACO algorithm for solving workforce planning problem. We compare the performance of our algorithm with other two metaheuristic methods, genetic algorithm and scatter search. The comparison is done by various criteria. We observed that ACO algorithm achieves better solutions than the other two algorithms. Regarding the execution time the ACO algorithm is faster. The ACO population consists 20 individuals and the used by the algorithm memory is similar to one used by the SS and less than the memory used by the GA. We achieved very encouraging results. As a future work we will combine our ACO algorithm with appropriate local search procedure for eventual further improvement of the algorithm performance and solutions quality.

**Abstract**—Quantum Computing is a field of study in computer science based on the laws of quantum physics. Quantum computing is an attractive subject considering that quantum algorithms proved to be more efficient than classical algorithms and the advent of large-scale quantum computation. In particular, Grover's search algorithm is a quantum algorithm that is asymptotically faster than any classical search algorithm and it is relevant for the design of fast optimization algorithms. This article proposes two algorithms based on Grover's adaptive search for biobjective optimization problems where access to the objective functions is given via two different quantum oracles. The proposed algorithms, considering both types of oracles, are compared against NSGA-II, a highly cited multiobjective optimization evolutionary algorithm. Experimental evidence suggests that the quantum optimization methods proposed in this work are at least as effective as NSGA-II in average, considering an equal number of executions. Experimental results showed which oracle required less iterations for similar effectiveness.

## I. INTRODUCTION

QUANTUM Computing is a field of study in computer science since the 1980's. It is based on the laws of quantum physics as superposition, entanglement and interference, which cannot be efficiently simulated by classical computers [1]. In the middle of the 1990's, after the development of an efficient quantum algorithm for integer factorization [2], the idea of quantum computers became more relevant, considering that the quantum algorithms proved to be asymptotically faster over classical algorithms. In a similar way, another milestone was achieved with a quantum algorithm for search in unstructured databases developed by Grover [3]. This algorithm can find a specific marked element from a finite set of  $N$  elements with a computational complexity of order  $O(\sqrt{N})$ , instead of  $O(N)$  required by classical computers.

After Grover's search algorithm, several researchers proposed diverse methods based on Grover's algorithm applied to global optimization. Dürr and Høyer [4] presented a quantum algorithm for finding the minimum value of an objective function. Another relevant contribution comes from Baritompá, Bulger and Wood [5], who proposed an adaptive search method for minimization problems. Furthermore, Barán and Villagra [6] introduced the first quantum algorithm for

multiobjective combinatorial optimization based on a quantum adiabatic computer.

In this paper, we propose an application of Grover's algorithm to multiobjective optimization problems. Two algorithms are proposed that can query the objective functions via so-called quantum oracles. For comparison purposes, two different oracles are studied. The first oracle "marks" non-dominated solutions from a known feasible solution of the decision space. The second oracle also "marks" non-dominated solutions as the first one but, the difference is that it marks non-comparable solutions too. Both oracles are implemented in an algorithm called MOGAS from *Multiobjective Optimization Grover Adaptive Search*, which is based on the Grover adaptive search algorithm of Baritompá, Bulger and Wood [5].

The experimental results of this work suggest that the proposed MOGAS algorithm (considering both types of oracles) was not only an effective approach for multiobjective optimization problems, but it was also efficient when compared against NSGA-II. In most of the studied cases, MOGAS obtained better or equal results in average for the same number of executions. It is important to note that in spite of the simple adaptive strategies used by MOGAS (considering both types of oracles), the results of this work present a remarkable performance over NSGA-II. Therefore, the experimental results show the efficiency of simple quantum algorithms with respect to classical algorithms.

This paper is organized as follows. In Section 2, a brief introduction to Grover's algorithm is given. In Section 3, an application of Grover's search algorithm to optimization problems and the algorithm of Dürr and Høyer is explained. Section 4 reviews basic definitions of multiobjective optimization. In Section 5 the proposed algorithm MOGAS is presented and Section 6 shows the experimental results and some discussions. Finally, Section 7 concludes the paper.

## II. GROVER'S SEARCH ALGORITHM

In this section we briefly explain Grover's algorithm, which is an integral part of the proposed algorithm of this work. For details refer to the book by Nielsen and Chuang [1].

The fundamental element of information in a quantum computer is the *quantum bit* or qubit. These qubits may be in a superposition state of classical states one and zero, that is, a linear combination of zeros and ones with complex coefficients (or amplitudes). Qubits are represented by basis vector states  $|1\rangle$  and  $|0\rangle$ , usually referred to as the *computational basis*<sup>1</sup>. In quantum computing, quantum states are described using the linear algebra of Hilbert's spaces, and therefore, they are represented using vectors over a complex number field [1].

In classical computation, finding a specific element out from a set of  $N$  elements requires  $N$  tries; that is, the complexity of finding a particular element is  $O(N)$ , which is tight [1].

Grover's search algorithm, however, can find a specific element out from a finite set of  $N$  elements with complexity  $O(\sqrt{N})$ . This is possible because of quantum interference, which the algorithm exploits via a quantum operator  $G$  known as the *Grover operator*. The Grover operator is constructed from an oracle operator  $O_G$  and a phase operator  $W$ .

The number of iterations  $r$  necessary to find a desired item out of  $N$  alternatives is obtained from the equation

$$r = \left\lfloor \frac{\pi}{4} \sqrt{N} \right\rfloor \approx \sqrt{N}, \quad (1)$$

which corresponds to a complexity  $O(\sqrt{N})$  [3].

The input to Grover's algorithm is a set of  $n$  qubits  $|0\rangle^{\otimes n}$ , where  $2^n = N$ , and an ancilla qubit  $|1\rangle$ . The first input  $|0\rangle^{\otimes n}$  is transformed to a superposition state using an  $n$ -fold Hadamard transformation  $H^{\otimes n}$ ,

$$|\zeta\rangle = H^{\otimes n} |0\rangle^{\otimes n} = \frac{1}{\sqrt{N}} \sum_{x \in \{1,0\}^n} |x\rangle. \quad (2)$$

A superposition of basis states is a particular case of linear combination where the square moduli of the complex coefficients (amplitudes) must sum to one. The second register is transformed using a Hadamard gate according to

$$H|1\rangle = |-\rangle = \frac{|0\rangle - |1\rangle}{\sqrt{2}}. \quad (3)$$

Grover's algorithm is based on the ability of an oracle to "mark" a desired solution, which is represented by one of the basis states. Given a superposition state, the marking process of an oracle is a change of the sign of the coefficient in the basis state which corresponds to a desired solution; such a marking process will only be possible if some interaction exists between the oracle operator and the ancilla register. After the marking process, the phase operator performs an increase of the absolute value of the amplitude associated to the solution state while decreasing amplitudes associated to the other non-solution states. This will happen at each iteration, and because of that, it is possible to observe/measure the desired solution state with high probability [1].

<sup>1</sup>The ket notation  $|\cdot\rangle$  is simply a notation for a column vector of a vector space.

### III. DÜRR AND HØYER'S ALGORITHM
