Grover's algorithm is generally used as a search method to find a set of desired solutions from a set of possible solutions. However, Dürr and Høyer presented an algorithm based on Grover's method [4] for optimization. Their algorithm finds an element of minimum value inside an array of  $N$  elements using at most  $O(\sqrt{N})$  queries to the oracle.

Baritompä, Bulger and Wood [5] presented an application of Grover's algorithm for global optimization, which they call *Grover Adaptive Search (GAS)*. Basically, GAS is based on Grover's search with an "adaptive" oracle operator in a minimization context of the objective function. The oracle operator marks all the solutions from a set below a certain threshold value  $y$  given by

$$g(x) = \begin{cases} 1, & \text{if } f(x) < y \\ 0, & \text{if } f(x) \geq y \end{cases}, \quad (4)$$

where  $x$  is a possible solution in the decision space and  $f(x)$  is the value of the objective function (in this case, the value of the objective function of a current known solution  $y$ ). The oracle marks a solution  $x$  if and only if the boolean function  $g(x) = 1$  [5].

The algorithm requires two extra parameters, a currently known solution and an iteration count. This iteration count is a value computed from the number of solutions that are better than the currently known solution. Initially, the algorithm randomly chooses a feasible solution from the decision space which becomes the known solution; however, the number of solutions that are better than this last solution is unknown and an iteration count is required to perform the search. This is due to the black box nature of the oracle [5].

When the algorithm finds a better solution, it becomes the new known solution. This solution is then used as a new threshold for the next iteration of GAS and the sequence of iteration counts must be computed again. In this way, GAS can find improved solutions in an adaptive search framework [5].

Dürr and Høyer introduced a strategy for the selection of the iteration count based on a random selection of a number from a set of integer numbers. This set starts with  $\{0\}$  as the only element. When the search is unsuccessful in finding a better solution, the algorithm adds more elements to a maximum of  $\{0, \dots, \lceil m - 1 \rceil\}$  at each search step, until a solution better than the current known solution is found. In this way, the set incorporates more integer numbers as elements. Thus, the probability of selecting the right iteration count for a successful search increases.

The value of  $m$  is updated at each step by  $\min\{\lambda^i m, \sqrt{N}\}$ , where  $\lambda$  is given as a parameter,  $i$  represents the count of the previous unsuccessful search steps and  $N = 2^n$  is the number of total elements from the decision space based on the number of qubits  $n$ . Therefore,  $m$  is not allowed to exceed  $\sqrt{N}$ , which is the optimal iteration number to find a specific element from a set of  $N$  elements.

The pseudocode of Dürr and Høyer's algorithm based on the GAS algorithm is presented below. This corresponds to an

interpretation that has been described by Baritompa, Bulger and Wood [5], where the parameter  $k$  represents the search process count.

---

**Algorithm 1** Dürre and Høyer's Algorithm
 

---

- 1: Randomly choose  $x$  from the decision space.
  - 2: Set  $x_1 \leftarrow x$ .
  - 3: Set  $y_1 \leftarrow f(x_1)$ .
  - 4: Set  $m \leftarrow 1$ .
  - 5: Choose a value for the parameter  $\lambda$  (8/7 is suggested).
  - 6: For  $k = 1, 2, \dots$  until termination condition is met, do:
    - (a) Choose a random rotation count  $r_k$  uniformly from  $\{0, \dots, \lceil m - 1 \rceil\}$ .
    - (b) Perform a Grover search of  $r_k$  iterations on  $f(x)$  with threshold  $y_k$ , and denote the outputs by  $x$  and  $y$ .
    - (c) If  $y < y_k$  set  $x_{k+1} \leftarrow x$ ,  $y_{k+1} \leftarrow y$  and  $m \leftarrow 1$ ; otherwise, set  $x_{k+1} \leftarrow x_k$ ,  $y_{k+1} \leftarrow y_k$  and  $m \leftarrow \min\{\lambda m, \sqrt{N}\}$ .
- 

#### IV. MULTIOBJECTIVE OPTIMIZATION

The goal of a multiobjective optimization problem is to optimize several objectives (at least two) at the same time. The objectives are frequently in conflict, and therefore, there may exist several “optimal” solutions. The set of optimal solutions is known as a Pareto-optimal set, where solutions provide the best compromise relations between the objective functions considering the entire feasible decision space [7], [8].

The feasible decision space is the set of all feasible solutions, which are compared against each other by means of the *Pareto dominance relation*. Indeed, the relation makes possible to determine if a solution is dominated or not by another solution. One solution  $Y$  is dominated by a solution  $Y'$ , denoted by  $Y' \prec Y$ , if  $Y'$  is better or equal in every objective function and strictly better in at least one objective function. Thus, a non-dominated solution is Pareto-optimal if there is no solution that dominates it. The set of all non-dominated solutions corresponds to the Pareto-optimal set and its mapping to the objective space is known as the Pareto Front. Furthermore, a solution  $Y$  is said to be non-comparable with respect to a solution  $Y''$  and it is denoted  $Y \sim Y''$  if neither  $Y$  dominates  $Y''$  ( $Y \not\prec Y''$ ) nor  $Y''$  dominates  $Y$  ( $Y'' \not\prec Y$ ) [7].

#### V. MULTIOBJECTIVE GROVER ADAPTIVE SEARCH (MOGAS)

In this work, a new adaptative search algorithm based on the heuristic of Dürre and Høyer is proposed named *Multiobjective Grover Adaptive Search (MOGAS)*. MOGAS uses two different oracle operators based on the Pareto dominance relation. The first oracle marks all the non-dominated solutions with respect to a known (current) solution. The second oracle marks

all the non-dominated and non-comparable solutions. These oracles are based on the boolean functions

$$h_1(x) = \begin{cases} 1, & \text{if } \mathbf{F}(x) \prec \mathbf{Y} \\ 0, & \text{otherwise} \end{cases}, \quad (5)$$

$$h_2(x) = \begin{cases} 1, & \text{if } \mathbf{F}(x) \prec \mathbf{Y} \vee \mathbf{F}(x) \sim \mathbf{Y} \\ 0, & \text{otherwise} \end{cases}, \quad (6)$$

where  $x$  is a feasible solution of the decision space,  $\mathbf{F}(x)$  is a vector where each element represents the value of the objective function with respect to solution  $x$ , and  $\mathbf{Y}$  is a vector where each element is the value of each objective function for the current known solution.

The first oracle marks a non-dominated solution if and only if the boolean function  $h_1(x) = 1$ . In a similar way, the second oracle marks a non-dominated or non-comparable solution if and only if the boolean function  $h_2(x) = 1$ .

The pseudocode of the MOGAS algorithm, where the parameter  $k$  represents the search process count, is presented below:

---

**Algorithm 2** MOGAS Algorithm
 

---

- 1: Randomly choose  $x$  from the decision space.
  - 2: Set  $S \leftarrow \{x_1 \leftarrow x\}$
  - 3: Set  $\mathbf{Y}_1 \leftarrow \mathbf{F}(x_1)$ .
  - 4: Set  $m \leftarrow 1$ .
  - 5: Choose a value for the parameter  $\lambda$  (8/7 is suggested).
  - 6: For  $k = 1, 2, \dots$  until termination condition is met, do:
    - (a) Choose a random rotation count  $r_k$  uniformly from  $\{0, \dots, \lceil m - 1 \rceil\}$ .
    - (b) Perform a Grover search of  $r_k$  iterations on  $\mathbf{F}(x)$  with threshold  $\mathbf{Y}_k$ , and denote the outputs by  $x$  and  $\mathbf{Y}$ .
    - (c) If  $\mathbf{Y} \not\prec \mathbf{Y}_k$  set  $x_{k+1} \leftarrow x_k$ ,  $\mathbf{Y}_{k+1} \leftarrow \mathbf{Y}_k$  and  $m \leftarrow \min\{\lambda m, \sqrt{N}\}$ .  
Otherwise, set  $m \leftarrow 1$ ,  $x_{k+1} \leftarrow x$ ,  $\mathbf{Y}_{k+1} \leftarrow \mathbf{Y}$  and with respect to all elements of the set  $S$ , where  $j = 1, \dots, |S|$ , do:
      - If  $\exists x_j \in S : \mathbf{F}(x) \prec \mathbf{F}(x_j)$ , then, set  $S \leftarrow S - \{x_j\}$  and finally set  $S \leftarrow S \cup \{x\}$ .
  - 7: Set  $PF \leftarrow \{\mathbf{F}(x_j) : j = 1, \dots, |S|, \forall x_j \in S\}$ .
- 

The operation of MOGAS is based on the oracle operator. Then, using any of the presented oracles,  $h_1$  or  $h_2$ , MOGAS can find a non-dominated solution with respect to a known solution. In this way, the algorithm can reach the Pareto-optimal set by finding new non-dominated solutions at each iteration. Therefore, with the proposed search process it is possible to incorporate a new element into the Pareto-optimal set or replace some old elements from it each time a non-dominated solution is found.

## VI. EXPERIMENTAL RESULTS

Currently, a general purpose quantum computer has not been implemented. Nevertheless, the basic ideas of quantum algorithms can be fully explored using linear algebra, and therefore, computational performances of quantum algorithms are possible by executing linear algebra operations [9].

To verify the effectiveness of the proposed algorithm, we have tested it by means of simulations against one of the most cited optimization algorithms for multiobjective problems, the Non-dominated Sorting Genetic Algorithm - version two [7], [8] known as NSGA-II. The tests were made considering some biobjective problems based on the well known ZDT test suite [10] and on randomly generated instances.

The randomly generated problems (RG) consist of a random selection of numbers from a set of integer numbers between 1 and 1000 for each of the two objective functions. Then, three different suites of this type of random instances were established for testing. With respect to the ZDT test suite, the ZDT1, ZDT3 and ZDT4 were selected considering two objective functions. For each of these functions, a total of twenty decision variables were used and to each of these decision variables a random real number from the interval  $[0, 1]$  was assigned.

The decision space for each instance consist in a set of  $1024 = 2^{10}$  points. The amount of points is based on the number of qubits ( $n = 10$ ) selected for the proposed MOGAS algorithm. Since the problem has two objective functions that should be minimized, the vector dimension (for  $\mathbf{F}(x)$  and  $\mathbf{Y}$ ) is  $p = 2$ . Table I presents the main characteristics of the considered test suites.

The testing procedure was based on ten executions of both algorithms, that is, MOGAS (considering the two different

types of oracles) and NSGA-II, over all test suites. At each execution, the termination criteria was to complete two hundred generations (with a population size equal to fifty) for NSGA-II and a total of four hundred algorithm consultations for MOGAS. Where the algorithm consultation is exactly to a performed Grover search with regard to  $r_k$  iterations on  $\mathbf{F}(x)$  considering a threshold  $\mathbf{Y}_k$ , and denoting the outputs by  $x$  and  $\mathbf{Y}$  respectively.

The hypervolume was used as the metric for the comparison of the results, considering that it is the most used comparison metric in multiobjective optimization [8]. The hypervolume is an indicator used in the multiobjective optimization of evolutionary algorithms to evaluate the performance of the search, which was proposed by Zitzler and Thiele [11]. It is based on a function that maps the set of Pareto-optimal to a scalar with respect to a reference point. In tables II, III and IV, the obtained experimental results from the testing procedure are presented considering the hypervolume.

The tables are composed of six columns that correspond to each test suite and a column for the order of execution.

TABLE IV

AVERAGE RESULTS OF THE TESTING PROCEDURE - MOGAS (FROM  
100 TO 400 EVALUATIONS AND THE ORACLE BASED ON THE BOOLEAN  
FUNCTION  $h_1$ ).

Test suites	RG <sub>1</sub>	RG <sub>2</sub>	RG <sub>3</sub>	ZDT1	ZDT3	ZDT4
# Evaluations	[%]	[%]	[%]	[%]	[%]	[%]
100	97.7	97.4	98.2	49.2	54.8	57.9
200	98.5	98.2	98.6	51.4	56.8	58.9
300	98.9	98.5	98.8	52.3	57.5	59.7
400	98.9	98.6	98.9	52.5	57.7	60.2

In these six columns, the result of the hypervolume metric in percentage for each execution is given. In this way, each row summarizes the experimental results for every test suite with respect to a specific execution order denoted in the left column. Also, in the last row, an average of these ten executions for all test suites is presented.

Tables II and III correspond to results obtained for MOGAS using  $h_1$  and  $h_2$  respectively. Table IV corresponds to results obtained using NSGA-II with a population size equal to fifty.

From the experimental results obtained, MOGAS presents similar results compared to NSGA-II with a population size of fifty with respect to RG problems; in most cases, however, MOGAS delivers better or equal results. Nevertheless, considering the structured ZDT test suites and compared to NSGA-II results, only MOGAS based on the boolean function  $h_1$  as oracle presents equal or better results, whereas MOGAS based on the boolean function  $h_2$  as oracle presents nearly equal results but not equal or better results.

Nevertheless, considering the algorithm consultations of MOGAS as a single evaluation of the objective function, the results present an important fact to note: MOGAS used only four hundred evaluations of the objective function vector  $F(x)$ , whereas NSGA-II (with a population size of fifty) used 10000 (pop\*gen= 50\*200) evaluations of the same vector to deliver similar results.

Tables V, VI and VII summarize the average results of both

MOGAS algorithms and NSGA-II, considering objective function evaluations. These tables are composed of six columns that correspond to each test suite and a column for the number of evaluations. In these six columns, the average results of the hypervolume metric in percentage corresponding to ten executions are presented. In this way, each row summarizes the average results for every test suite with respect to a specific number of evaluations given in the left column.

The obtained experimental results are presented in figures 1 to 6 as the performance in the hypervolume metric (in percentage) versus the number of evaluations of the objective function vector.

Considering the average number of iterations of the Grover operator needed for MOGAS using both oracles, the presented experimental results reveal that MOGAS using  $h_2$  as oracle, in most cases, uses less iterations compared to MOGAS using  $h_1$  as oracle.

Certainly, the oracle based on  $h_2$  marks more solutions from the decision space. Therefore, the probability to change the threshold at every consultation performed increases. This way, the parameter  $m$  is set to one more often and the iteration number chosen corresponds to a lower number. Thus, the total number of iterations for MOGAS using  $h_2$  is smaller when compared to the oracle based on  $h_1$ .

Tables VIII to XIII summarize the average results of the number of iterations used by MOGAS, considering the number of times the Grover operator is invoked. These tables have two columns that correspond to each different type of oracle and a column for the number of evaluations. In these two columns,

## VII. CONCLUDING REMARKS

This work compared two different types of oracles used in a quantum algorithm for multiobjective optimization problems. The presented multiobjective quantum algorithm, called MOGAS, is a natural extension of previous quantum algorithms for single-objective optimization based on Grover's search method. The experimental results of this work suggests that MOGAS (considering both types of oracles) was not only an effective approach for multiobjective optimization problems, but it was also efficient as was observed when MOGAS was compared against NSGA-II, which is one of the most cited multiobjective optimization algorithms [8]. In most of the studied cases, MOGAS obtained better or equal results in average after comparing it against NSGA-II for the same number of executions especially with respect to the oracle based on the boolean function  $h_1$ ; in regard of  $h_2$ , the results presented in this work are almost equal compared to NSGA-II.

In spite of the simple adaptive strategy used by MOGAS

(considering both types of oracles), the experimental results of this work present a remarkable performance over NSGA-II. Therefore, the presented experimental results show the efficiency of a simple quantum algorithm with respect to a classical more elaborated algorithm.

Another interesting fact to note is the difference between the number of iterations used by MOGAS. The oracle based on the boolean function  $h_2$ , in most cases, employed a smaller number of iterations than the one using  $h_1$ . Hence,  $h_2$  is more efficient than  $h_1$ , which represents a saving in the number of queries to the quantum oracle.

For future research, it is interesting to study other different definitions of oracles for multiobjective problems. It is also very important to lay some theoretical foundations that can show the convergence of MOGAS to the set of Pareto-optimal solutions.

**Abstract**—In the area of applied optimisation, heuristics are a popular means to address computational problems of high complexity. Modelling the problem and mapping all variations of its solution into a so-called *solution space* are integral parts of this process. Representing solutions as graphs is common and, for a special type of graph, *Prüfer Code* (PC) offers a computationally efficient mapping (algorithms of  $\Theta(n)$ -complexity are known) to  $n-2$  dimensional Euclidean space. However, this encoding does not preserve properties such as e.g. locality and therefore PC has been shown to be a bad choice for entire classes of problems. We argue that PC does allow the preservation of some properties (e.g. degree of branching and branching vertices) and that these are sufficiently relevant for certain types of problems to motivate encoding them in PC. We present our investigations and provide an example where PC has been shown to be a useful encoding.

## I. INTRODUCTION & OUTLINE

**H**EURISTICS (from the Greek *εὐρίσκω*: “to find”, “to discover”) are approaches that *find* or *estimate* good solutions to problems, as opposed to reliably determining the best one. For the more complex problems it is often impossible to exhaustively check all possible solutions, motivating the use of a heuristic. Furthermore, many problems require only a certain quality of the solution, and investing resources in improving a solution past this point does not add any benefit.

In one way or another, heuristics use some underlying properties of the solution space to navigate it. This process is *iterative*: heuristics identify acceptable solutions and then continuously try to improve on them in some informed manner.

In order to be able to *move* from one solution to a better one, there has to be some relation between them. Using this relation enables the heuristic to estimate which alternatives to consider (so as to avoid having to consider them all).

*Modelling* a problem and *encoding* its solutions (i.e. the mapping into a domain) are important decisions in the process. There are many ways to represent solutions and we will only focus on one: graphs, and in our case, simple, undirected, connected and acyclic graphs, commonly called *trees* [5]. In §II we provide some background on trees and discuss known complexity results as well as a specific

encoding that allows us to represent trees as unique sequences of numbers: *Prüfer Code* [15].

There is evidence from the literature that mapping a tree to Prüfer Code fails to preserve certain properties, which have been shown to be important for a number of meta-heuristics [10]. We take a closer look at which properties are indeed preserved and then argue in §III that for a certain class of problems the preserved properties are actually sufficient to motivate the use of Prüfer Code. We support this in §IV by referencing to our work, which successfully used Prüfer Code.

## II. GRAPHS

### A. Graphs and trees

A *graph*  $G$  is a pair  $G = (V, E)$  of two sets: the set  $V = \{v_1, \dots, v_n\}$  of  $n$  *vertices* (which are also often referred to as *nodes* or *worlds*) and the set  $E = \{e_1, \dots, e_m\}$  of  $m$  *edges* (often called *lines* or *connections*). Each edge  $e_i$  is a tuple of two vertices, representing the two vertices that this edge connects (cf. [8], [3]). One sub-category of graphs are *connected graph without cycles* (i.e. the number of edges is  $n-1$  for  $n$  vertices), commonly called *trees* [14]. Trees are graphs in which any two vertices are *connected* to each other by a finite path which can not contain cycles. Phrasing it like this makes it intuitively clear why this type of graph can represent a solution to e.g. decision trees or routing problems.

We distinguish vertices that are single end nodes (i.e. *leaves* in the tree) and those that are not (i.e. *branching points*).

### B. Complexities of graphs

Given a set of  $n$  vertices, [4] showed that the family of different trees that can be constructed over this set has  $n^{n-2}$  members. This result is commonly known as *Cayley's Theorem* due to [5] (cf. [6]). The first combinatorial proof provided for this theorem was provided by Prüfer [15] in 1918 [14] using a mapping that represented trees with  $n$  vertices as strings of length  $n-2$  (cf. §II-C). By showing that this set of strings therefore had  $n^{n-2}$  members, Prüfer proved *Cayley's Theorem*.

**Algorithm 1** Encoding a tree-graph to Prüfer Code (cf. [13])

---

```

1:  $L \leftarrow$  leaves of  $T$ 
2: for  $i \leftarrow 1$  to  $(n - 2)$  do do:
3:    $v \leftarrow$  node removed from the head of  $L$ 
4:    $PC[i] \leftarrow$  neighbour of  $v$ 
5:   delete  $v$  from  $T$ 
6:   if  $\deg(PC[i]) = 1$  then
7:     add  $PC[i]$  to  $L$ 

```

---

If we restrict the branching factor for any vertex in the tree to a constant  $k$ , we get  $k$ -ary trees, which have been studied in the literature extensively [16], [9], [7]. The relation between *leafs* ( $n_l$ ) and *branching* vertices  $n_b$  in a  $k$ -ary tree is  $n_l = n_b(k - 1) + 1$  [16].

**C. Encoding graphs as Prüfer Code (PC)**

In addition to providing a proof to [5], Prüfer also provided us with an efficient mechanism to encode trees into sequences of  $n - 2$  integers (and back). Such  $n - 2$  dimensional Euclidean spaces are known to work well with swarm and evolutionary search algorithms and are therefore of potential interest to us.

Fig. 1. The Prüfer codes similar to [2,2,3,3]. All variations (b) to (i) differ from the original string (a) in only one digit and the difference between that digit and the original is 1; the root vertex  $v_3$  is denoted by a double circle.

The specific way in which Prüfer Code (PC) is generated can result in fundamentally different trees being represented as very similar PCs [10] (see Figure 1, above). This is one of the likely sources of problems in the context of using PCs for heuristics, and we address this issue in §III.

1) *Algorithms*: PC encoding and decoding follows a simple linear algorithm (cf. Alg. 1, Alg. 2, respectively), details of which can be found in [12]. From e.g. [13] we know that there are  $\Theta(n)$ -complexity algorithms (i.e. algorithms that can perform the translation either way in linear time) to do this.

Note that Alg. 1, above, assumes that the leaves are stored in a list (initially sorted in ascending order).

2) *Solution space*: Let's consider trees with  $n$  nodes (labelled 1 to  $n$ ), resulting in PCs with  $n - 2$  positions. We use  $\mathbb{PC} = \{pc_1, \dots, pc_{n(n-2)}\}$  to denote the set of all possible PC that meet this description. Clearly, any  $\mathbb{PC}$  can be mapped into

**Algorithm 2** Decoding Prüfer Code to a tree-graph (cf. [13])

---

```

1:  $L \leftarrow$  nodes that do not appear in the Prüfer Code  $PC$ 
2: for  $i \leftarrow 1$  to  $(n - 2)$  do do:
3:    $v \leftarrow$  node removed from the head of  $L$ 
4:   add edge  $\{v, PC[i]\}$  to  $T$ 
5:   if  $i$  is the rightmost position of  $v$  in  $PC$  then
6:     add  $v$  to  $L$ 
7:    $v \leftarrow$  node removed from the head of  $L$ 
8:   add edge  $\{v, PC[n - 2]\}$  to  $T$ 

```

---

a subset of  $\mathbb{N}^+$  by reading individual  $pc_i$  as a number (e.g. for  $n = 7$ : this is  $\{11111, \dots, 26416, 26417, 26421, \dots, 77777\}$ ). We use a PC's position in this set as the its ID (see example).

When exploring the solution space with heuristics we want there to be some correlation between a solution's location that space and its performance value. If we require that *similar* PCs represent trees encoding families of solutions (with regard to certain properties), we have to consider how we define *similar*.

**Example:** Let's consider encoding cooking recipes as trees (representing the order and inter-dependency of individual steps, started with step  $v_1$ ). For a recipe with 7 steps, this can be represented as a tree with 7 nodes (of which there are exactly 16807 unique variations), each corresponding to exactly one PC with 5 positions. If the interpretation of *similar* is numerical distance between two codes (e.g. 24617 is followed immediately by 26421, cf. Figure 2 bottom row) then very similar PCs encode substantially different trees (see Figure 2). As pointed out in [10] this will make PC a sub-optimal choice for interpretations of similarity.

While the variations shown in Fig. 2 differ, they do not differ dramatically. This loose similarity was already enough to produce results of sufficient quality when we used PC to encode solutions representing cable diagrams [1], [2], [11].

**III. NAVIGATING PRÜFER CODE****A. A property-preserving mapping of PC to a solution space**

The way trees are constructed from PC (cf. Alg. 2) implies that the connectivity of a vertex (the number of vertices it is connected to) is equal to the number of its occurrences in the PC + 1. This also means that not occurring vertices are leafs.

However, the positions of the integers matter, and exchanging two integers can result in more than the exchange of the corresponding vertices in the tree (see the example in Fig. 2).

1) *Filtering PC*: Using the above insight we look at certain filters for PCs that characterise properties of interest to us.

These filters, are defined with respect to a specific  $pc_i \in \mathbb{PC}$ :

- $\mathbb{I}_{pc_i}$ , the set of all different integers that occur in  $pc_i$
- $\mathbb{I}_{pc_i}^+$ , the ordered list of all the occurring integers

**Example:** for trees with  $n = 5$ ,  $\mathbb{PC} = \{[1, 1, 1], \dots, [5, 5, 5]\}$ ; for e.g.  $pc_i = [1, 2, 1]$ :  $\mathbb{I}_{[1,2,1]} = \{1, 2\}$  and  $\mathbb{I}_{[1,2,1]}^+ = \{1, 1, 2\}$ .

Fig. 2. Variations on  $pc_{4269}$ . An original graph (middle) is flanked by variations: (**first row**) differing in one position and just by 1 from the original integer (solution space  $(n-2)$ -dimensional) or (**second row**) the previous and the next ID (solution space:  $\mathbb{N}^+$ ); the root vertex is assumed to be  $v_1$ .

2) *Similarity classes*: We use these filters to define the similarity classes  $\mathbb{PC}_{\mathbb{I}}$  and  $\mathbb{PC}_{\mathbb{I}^+}$ , i.e. the subsets of  $\mathbb{PC}$  where all members  $pc_j$  have the same  $\mathbb{I}_{pc_j}$  or  $\mathbb{I}_{pc_j}^+$ , respectively:

- $\mathbb{PC}_{\mathbb{I}_{pc_i}}$ , the subset of  $\mathbb{PC}$  in which members are constructed using only the integers found in  $pc_i$ , and
- $\mathbb{PC}_{\mathbb{I}_{pc_i}^+}$ , where all members have exactly the same integers as  $pc_i$ , but not necessarily in the same order.

$\forall pc_j \in \mathbb{PC}_{\mathbb{I}_{pc_i}} : \mathbb{I}_{pc_i} = \mathbb{I}_{pc_j}$  and  $\forall pc_k \in \mathbb{PC}_{\mathbb{I}_{pc_i}^+} : \mathbb{I}_{pc_i}^+ = \mathbb{I}_{pc_k}^+$  with  $pc_i \in \mathbb{PC}_{\mathbb{I}_{pc_i}}$ ,  $pc_i \in \mathbb{PC}_{\mathbb{I}_{pc_i}^+}$  and  $\mathbb{PC}_{\mathbb{I}_{pc_i}^+} \subset \mathbb{PC}_{\mathbb{I}_{pc_i}}$ .

**Example:** for  $\mathbb{I}_{[1,2,1]} = \{1, 2\}$  and  $\mathbb{I}_{[1,2,1]}^+ = \{1, 1, 2\}$  we get:  $\mathbb{PC}_{\mathbb{I}_{[1,2,1]}} = \{[1, 1, 2], [1, 2, 1], [1, 2, 2], [2, 1, 1], [2, 1, 2], [2, 2, 1], [2, 2, 2]\}$  and  $\mathbb{PC}_{\mathbb{I}_{[1,2,1]}^+} = \{[1, 1, 2], [1, 2, 1], [2, 1, 1]\}$ .

3) *Distance*: To create - individually for each  $pc_i$  - relative  $pc_i$ -solution spaces based on  $\mathbb{I}_{pc_i}$  or  $\mathbb{I}_{pc_i}^+$  we need to define a distance between  $pc_i$  and any  $pc_j$  in  $\mathbb{PC}_{\mathbb{I}_{pc_i}}$  and  $\mathbb{PC}_{\mathbb{I}_{pc_i}^+}$ . Clearly the distance to itself ( $pc_j = pc_i$ ) is zero.

We may either want to define a single neighbour, a certain number of neighbours or sets of neighbours (potentially of varying sizes). This will directly impact the dimensionality of our solutions space: with a single neighbour we can use  $\mathbb{N}^+$  as solution space, otherwise our solution space is  $n$ -dimensional or, in case of sets, of varying dimensionality. After defining a function to determine either a fixed number or a set of immediate neighbours of  $pc_i$  we can calculate the distance  $\delta(i, j)$  between any two  $pc_i$  and  $pc_j$  as the shortest path connecting these two through their neighbours.

**Example:** for both  $\mathbb{PC}_{\mathbb{I}_{pc_i}}$  and  $\mathbb{PC}_{\mathbb{I}_{pc_i}^+}$  neighbourhood could (the choice is problem specific) be defined as, e.g.:

- the element in the respective set that is numerically the closest to  $pc_i$  (reading e.g.  $[1, 3, 2, 4]$  as 1324), or
- all those elements that are created by exchanging two neighbouring digits of the  $pc$ , e.g. for  $pc_i = [1, 2, 3, 4]$  this would be  $[2, 1, 3, 4]$ ,  $[1, 3, 2, 4]$  and  $[1, 2, 4, 3]$ .

## B. Motivation

When optimising cabling structures for e.g. distributed antenna systems or routing network trees, the number of used *splitters* or *routers* (corresponding to branches in the tree) is an important factor as hardware plays a major role in the overall cost. In problems of this type constraints are commonly imposed on all paths from the root to the leaf nodes of the trees (e.g. power attenuation due to cable length which must not exceed a certain value); due to this variations over a fixed set of routers or splitters need to be explored.

On the other hand, having identified nodes in the network that exhibit high potential to become branches we want to consider changing their branching factors (i.e. the equivalent of replacing a splitter with a larger or a smaller one).

Specifically, our subsets of  $\mathbb{PC}$  allow us the following:

- 1)  $\forall pc_i \in \mathbb{PC}_{\mathbb{I}_{pc_i}^+}$ :  $pc_i$  preserves the number of branching nodes, their branching degree as well as which node has how many branches. Only the specific allocation of leafs to these branches changes, as well as how these branching nodes are connected to each other.
- 2)  $\forall pc_j \in \mathbb{PC}_{\mathbb{I}_{pc_i}^+}$ : contrary to the above,  $pc_j$  does not ensure that the number of nodes with a certain branching degree stays the same, i.e. while the branching nodes do not change, their degree might, as does (as above) which leafs / other branching nodes they connect to.
- 3) In addition to the two above, we can explore variations on  $\mathbb{PC}_{\mathbb{I}_{pc_i}^+}$  and  $\mathbb{PC}_{\mathbb{I}_{pc_i}^+}$  by replacing all occurrences of an integer with one that does not occur in the original, or by simply adding or removing integers. As shown in Figure 1, these are more dramatic changes.

#### IV. PROOF OF CONCEPT APPLICATION

Despite the claims made in [10] we successfully used Prüfer Code encoding to optimise cabling to power indoor antenna systems for large buildings [1], where small instances of  $n = 20$  already have  $20^{20-2} = 2.62 \times 10^{22}$  possible connection trees, (cf. Figure 3). Our work, tested for problems of up to 100 floors, showed that using Particle Swarm Optimisation obtained good solutions in short time (minutes)<sup>1</sup>. We also used Genetic Algorithms (GA) which, although inferior to PSO, performed well, indicating that using PC was a feasible approach. Cf. [2] for an overview over the results.

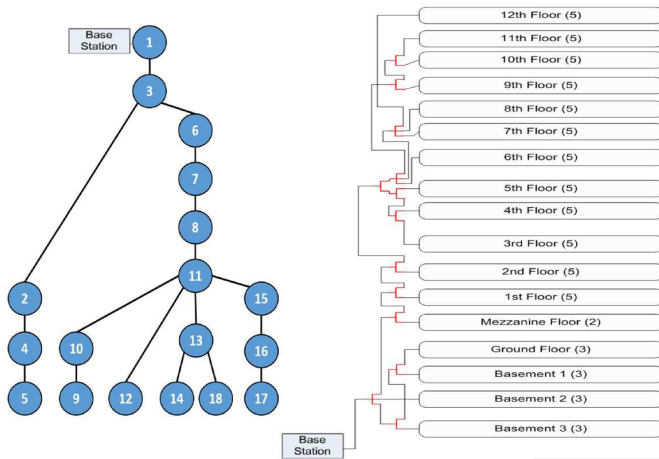

Fig. 3. An example solution for the Distributed Antenna Cabling Problem [1], [2], [11]. The objective is to connect all floors (and antennas on each floor) using splitters and cables, subject to power constraints imposed in the splitters and the antennas. The choice of branching nodes (and their degree) is a primary factor in this problem, making Prüfer Code a useful encoding.

A performance analysis of the algorithm showed that PSO converges towards good solutions. This is suggested by the fact that stagnating improvement over previous generations indicates approaching the best expectable solution (cf. Fig. 4). The argument is straight forward: if our exploration through PC-space were entirely random (and thus void of beneficial *similarities*) we would expect that the potential for finding improved solutions increased with additional searches, while the graph plotted in Figure 4 indicates the opposite.

#### V. CONCLUSION

Our investigations and the suggestions put forward in this paper do not refute the claims made in [10]. Instead, they are to be understood as an addition, in the sense that we have identified a class of problems for which the encoding of trees in PC is beneficial. Specifically, when using trees to represent (a) variations on the branching of a tree (both in identifying the branching nodes as well as their degree of branching) and (b) the allocation of leaf nodes to branching nodes, Prüfer Code has proven to be a useful encoding. We intend to investigate this further by applying PC to other problems in the future.

<sup>1</sup>For comparison, a brute force search for  $n = 8$  required 15 minutes of CPU time; our approach returned the same optimal result after 15 seconds.

Fig. 4. The probability of finding a better solution plotted against the number of PSO generations resulting in unchanged best solution quality.

There have been other investigations into locality properties of PC (e.g. [14]) suggesting that the general results of [10] may not be all there is to PC. We have additional conjectures about this, which would require more space here and further investigations, and are outside the scope of this short paper.

**Abstract**—In this paper, we formulate an *anchored alignment distance* between rooted labeled unordered trees as the minimum cost of the anchored alignment whose anchoring is constructed from the minimum cost isolated-subtree mapping by adding the pairs of non-mapped leaves, and design the algorithm to compute it. Since this algorithm runs in exponential time with respect to the number of leaves in theoretical, we give experimental results for randomly generated trees and for N-glycan data with small degree as real data to evaluate the anchored alignment distance by comparing with the isolated-subtree distance and the alignment distance.

## I. INTRODUCTION

COMPARING tree-structured data such as HTML and XML data for web mining or DNA and glycan data for bioinformatics is one of the important tasks for data mining. The most famous distance measure between *rooted labeled unordered trees* (trees, for short) is the *edit distance* [6], [11], denoted by  $\tau_{\text{Tai}}$ . The edit distance is formulated as the minimum cost of *edit operations*, consisting of a *substitution*, a *deletion* and an *insertion*, applied to transform from a tree to another tree.

It is known that the edit distance is closely related to the notion of a *Tai mapping* (mapping, for short) [11], which is a one-to-one node correspondence between trees preserving ancestor relations. Then, the minimum cost of possible Tai mappings coincides with the edit distance [11]. However, it is known that the problem of computing the edit distance between trees is MAX SNP-hard [18] even if they are binary [2].

An *alignment distance*, denoted by  $\tau_{\text{ALN}}$ , is an alternative distance measure to compare trees [4]. The alignment distance is formulated as the minimum cost of an *alignment* between two trees obtained by first inserting nodes labeled with spaces into two trees such that the resulting trees have the same structure and then overlaying them. The alignment distance is an edit distance such that every insertion proceeds to deletions in operational.

Note first that, whereas the edit distance between strings coincides with the alignment distance between them, the edit distance between trees is different from the alignment distance

between them in general (cf., [6]); The edit distance is smaller than or equal to the alignment distance. The reason is to exist trees not preserving both cycle-free and ancestor relations when every deletion proceeds to insertions.

As another characterization of the alignment distance for trees, Kuboyama [6] has first formulated an *alignable mapping* as the variation of a Tai mapping whose minimum cost coincides with the alignment distance and shown that the alignable mapping coincides with a *less-constrained mapping* [7]. Furthermore, whereas the problem of computing the alignment distance is also MAX SNP-hard, it is tractable if the maximum degree of two trees are bounded by some constant  $D$ , where the detailed time complexity is  $O(n^2 D!)$  time for the maximum number  $n$  of nodes in two trees [4].

In bioinformatics, Schiermer and Giegerich [10] have introduced an *anchored alignment* with respect to a Tai mapping, called an *anchoring*, in the context of forest alignments. The anchored alignment is an alignment (that is, a tree) which contains a node labeled by a pair of labels for every pair of nodes in the anchoring.

However, there arises a problem that an arbitrary anchoring between two trees does not always provide an anchored alignment, since an arbitrary Tai mapping is not always an alignable (that is, a less-constrained) mapping. In order to avoid this problem, Ishizaka *et al.* [3] have designed an efficient algorithm to compute the anchored alignment in  $O(H|M|^2 + n)$  time if an anchoring  $M$  is less-constrained; returns “no” otherwise, where  $H$  is the maximum height of two trees.

In order to compute the anchored alignment, it is necessary to give an anchoring. In this paper, we construct an anchoring from the minimum cost *isolated-subtree* (or *constrained mapping*) [12], [16], [17], because the isolated-subtree mapping is the nearest mapping to the less-constrained mapping in a Tai mapping hierarchy [6], [15] and we can compute an *isolated-subtree distance*  $\tau_{\text{ILST}}$  as the minimum cost of possible isolated-subtree mappings in  $O(n^2 d)$  time, where  $d$  is the minimum of the degrees of two trees [13].

For the minimum cost isolated-subtree mapping  $M$ , we select the set  $M'$  of pairs of non-mapped leaves by  $M$ . Then, we formulate an *anchored alignment distance*  $\tau_{\text{ACH}}$  as the minimum cost of the anchored alignment through an anchoring

$M \cup M'$  if  $M \cup M'$  is less-constrained;  $\tau_{\text{ILST}}$  otherwise. We design the algorithm to compute  $\tau_{\text{ACH}}$  in  $O(n^2(d+H2^v))$  time, where  $v$  is the minimum number of leaves in two trees.

Since this algorithm runs in exponential time with respect to  $v$  in theoretical, we first give experimental results for randomly generated trees to evaluate the anchored alignment distance  $\tau_{\text{ACH}}$  by comparing with the isolated-subtree distance  $\tau_{\text{ILST}}$ . Here, in this experiment, we cannot compute the alignment distance  $\tau_{\text{ALN}}$  of which time complexity is  $O(n^2D!)$  within one day. Next, we give experimental results for N-glycan data as real data provided from KEGG [5] whose  $v$  is small to compute  $\tau_{\text{ACH}}$  efficiently. Then, we compare  $\tau_{\text{ACH}}$  with  $\tau_{\text{ALN}}$  and  $\tau_{\text{ILST}}$ , where it holds that  $\tau_{\text{ALN}} \leq \tau_{\text{ACH}} \leq \tau_{\text{ILST}}$  in general. For N-glycan data, it holds that  $\tau_{\text{ALN}} = \tau_{\text{ACH}} = \tau_{\text{ILST}}$  in more than 94% pairs and  $\tau_{\text{ACH}} = \tau_{\text{ILST}}$  in more than 99% pairs. Furthermore, we investigate the pairs such that  $\tau_{\text{ALN}} < \tau_{\text{ACH}} < \tau_{\text{ILST}}$  and  $\tau_{\text{ALN}} = \tau_{\text{ACH}} < \tau_{\text{ILST}}$ .

## II. PRELIMINARIES

A *tree* is a connected graph without cycles. For a tree  $T = (V, E)$ , we denote  $V$  and  $E$  by  $V(T)$  and  $E(T)$ , respectively. The *size* of  $T$  is  $|V|$  and denoted by  $|T|$ . We sometime denote  $v \in V(T)$  by  $v \in T$ . We denote an empty tree by  $\emptyset$ .

A *rooted tree* is a tree with one node  $r$  chosen as its *root*. We denote the root of a rooted tree  $T$  by  $r(T)$ . For each node  $v$  in a rooted tree with the root  $r$ , let  $UP_r(v)$  be the unique path from  $v$  to  $r$ . If  $UP_r(v)$  has exactly  $k$  edges, then we say that the *height* of  $v$  is  $k$  and denote it by  $h(v) = k$ . We define  $h(T) = \max\{h(v) \mid v \in T\}$  and call it the *height* of  $T$ .

The *parent* of  $v (\neq r)$  is its adjacent node on  $UP_r(v)$  and the *ancestors* of  $v (\neq r)$ , are the nodes on  $UP_r(v) - \{v\}$ . We denote that  $v$  is an ancestor of  $u$  by  $u < v$  that  $u < v$  or  $u = v$  by  $u \leq v$ . Also we denote neither  $u \leq v$  nor  $v \leq u$  by  $u \# v$ . We say that  $w$  is the *least common ancestor* of  $u$  and  $v$ , denoted by  $u \sqcup v$ , if  $u \leq w$ ,  $v \leq w$  and there exists no  $w'$  such that  $w' \leq w$ ,  $u \leq w'$  and  $v \leq w'$ .

We say that  $u$  is a *child* of  $v$  if  $v$  is the parent of  $u$ . The set of children of  $v$  is denoted by  $ch(v)$ . A *leaf* is a node having no children. We denote the set of all leaves in  $T$  by  $lv(T)$ . We define  $d(v) = |ch(v)|$  and  $d(T) = \max\{d(v) \mid v \in T\}$  and call them the *degree* of  $v$  and  $T$ , respectively.

We say that a rooted tree is *labeled* if each node is assigned a symbol from a fixed finite alphabet  $\Sigma$ . For a node  $v$ , we denote the label of  $v$  by  $l(v)$ , and sometimes identify  $v$  with  $l(v)$ . Let  $\varepsilon \notin \Sigma$  denote a special *blank* symbol and  $\Sigma_\varepsilon = \Sigma \cup \{\varepsilon\}$ .

Let  $v \in T$  and  $v_i, v_j \in ch(v)$  such that  $v_i$  (resp.,  $v_j$ ) is the  $i$ -th (resp.,  $j$ -th) child of  $v$ . We say that  $v_i$  is *to the left of*  $v_j$  if  $i \leq j$ . Also, for every  $u, v \in T$ , we define a *sibling order*  $u \preceq v$  if there exist  $u', v' \in ch(u \sqcup v)$  such that  $u \leq u'$ ,  $v \leq v'$  and  $u'$  is to the left of  $v'$ . Hence, we say that a rooted tree is *ordered* if the sibling order  $\preceq$  is fixed; *unordered* otherwise. In this paper, we call a rooted labeled unordered tree a *tree*.

**Definition 1 (Edit operations [11]):** The *edit operations* of a tree  $T$  are defined as follows.

- 1) *Substitution*: Change the label of the node  $v$  in  $T$ .

- 2) *Deletion*: Delete a node  $v$  in  $T$  with parent  $v'$ , making the children of  $v$  become the children of  $v'$ . The children are inserted in the place of  $v$  as a subset of the children of  $v'$ .
- 3) *Insertion*: The complement of deletion. Insert a node  $v$  as a child of  $v'$  in  $T$  making  $v$  the parent of a subset of the children of  $v'$ .

We represent each edit operation by  $(l_1 \mapsto l_2)$ , where  $(l_1, l_2) \in (\Sigma_\varepsilon \times \Sigma_\varepsilon - \{(\varepsilon, \varepsilon)\})$ . The operation is a substitution if  $l_1 \neq \varepsilon$  and  $l_2 \neq \varepsilon$ , a deletion if  $l_2 = \varepsilon$ , and an insertion if  $l_1 = \varepsilon$ .

We define a *cost function*  $\gamma : (\Sigma_\varepsilon \times \Sigma_\varepsilon - \{(\varepsilon, \varepsilon)\}) \mapsto \mathbf{R}^+$  on pairs of labels. We often constrain a cost function  $\gamma$  to be a *metric*, that is,  $\gamma(l_1, l_2) \geq 0$ ,  $\gamma(l_1, l_2) = 0$  iff  $l_1 = l_2$ ,  $\gamma(l_1, l_2) = \gamma(l_2, l_1)$  and  $\gamma(l_1, l_3) \leq \gamma(l_1, l_2) + \gamma(l_2, l_3)$ . We call the cost function that  $\gamma(l_1, l_2) = 1$  if  $l_1 \neq l_2$  a *unit cost function* and denote it by  $\mu$ .

**Definition 2 (Edit distance [11]):** For a cost function  $\gamma$ , the *cost* of an edit operation  $e = l_1 \mapsto l_2$  is given by  $\gamma(e) = \gamma(l_1, l_2)$ . The *cost* of a sequence  $E = e_1, \dots, e_k$  of edit operations is given by  $\gamma(E) = \sum_{i=1}^k \gamma(e_i)$ . Then, an *edit distance*  $\tau_{\text{Tai}}^\gamma(T_1, T_2)$  between trees  $T_1$  and  $T_2$  under  $\gamma$  is defined as follows:

$$\tau_{\text{Tai}}^\gamma(T_1, T_2) = \min \left\{ \gamma(E) \mid \begin{array}{l} E \text{ is a sequence} \\ \text{of edit operations} \\ \text{transforming } T_1 \text{ to } T_2 \end{array} \right\}.$$

**Definition 3 (Tai mapping [11]):** Let  $T_1$  and  $T_2$  be trees and  $M \subseteq V(T_1) \times V(T_2)$ . We say that a triple  $(M, T_1, T_2)$  is a *Tai mapping* between  $T_1$  and  $T_2$  if every pair  $(v_1, w_1)$  and  $(v_2, w_2)$  in  $M$  satisfies the following conditions.

- 1)  $v_1 = v_2$  iff  $w_1 = w_2$  (one-to-one condition).
- 2)  $v_1 \leq v_2$  iff  $w_1 \leq w_2$  (ancestor condition).

We will use  $M$  instead of  $(M, T_1, T_2)$  when there is no confusion. Also we denote the set of all the Tai mappings between  $T_1$  and  $T_2$  by  $\mathcal{M}_{\text{Tai}}(T_1, T_2)$ .

We denote the sets  $\{v \in T_1 \mid (v, w) \in M\}$  and  $\{w \in T_2 \mid (v, w) \in M\}$  by  $M|_1$  and  $M|_2$ , respectively. For  $M \in \mathcal{M}_{\text{Tai}}(T_1, T_2)$ , the *cost*  $\gamma(M)$  of  $M$  is given as:

$$\gamma(M) = \sum_{(v,w) \in M} \gamma(v, w) + \sum_{v \in T_1 - M|_1} \gamma(v, \varepsilon) + \sum_{w \in T_2 - M|_2} \gamma(\varepsilon, w).$$

**Theorem 1 (Tai [11]):**  $\tau_{\text{Tai}}^\gamma(T_1, T_2) = \min\{\gamma(M) \mid M \in \mathcal{M}_{\text{Tai}}(T_1, T_2)\}$ .

**Definition 4 (Less constrained and isolated-subtree mappings):** Let  $T_1$  and  $T_2$  be trees and  $M \in \mathcal{M}_{\text{Tai}}(T_1, T_2)$ .

- 1) We say that  $M$  is a *less-constrained mapping* [7], denoted by  $M \in \mathcal{M}_{\text{LESS}}(T_1, T_2)$ , if  $M$  satisfies that, for every  $(v_1, w_1), (v_2, w_2), (v_3, w_3) \in M$ :

$$v_1 \sqcup v_2 < v_1 \sqcup v_3 \implies w_2 \sqcup w_3 = w_1 \sqcup w_3.$$

Or equivalently [6]:

$$w_1 \sqcup w_2 < w_1 \sqcup w_3 \implies v_2 \sqcup v_3 = v_1 \sqcup v_3.$$

- 2) We say that  $M$  is an *isolated-subtree mapping* [12] (or a *constrained mapping* [16], [17]), denoted by

$M \in \mathcal{M}_{\text{ILST}}(T_1, T_2)$ , if  $M$  satisfies that, for every  $(v_1, w_1), (v_2, w_2), (v_3, w_3) \in M$ :

$$v_3 < v_1 \sqcup v_2 \iff w_3 < w_1 \sqcup w_2.$$

As similar as Theorem 1, we formulate a *less-constrained distance*  $\tau_{\text{LESS}}^\gamma(T_1, T_2)$  and an *isolated-subtree distance*  $\tau_{\text{ILST}}^\gamma(T_1, T_2)$  as follows:

$$\begin{aligned} \tau_{\text{LESS}}^\gamma(T_1, T_2) &= \min\{\gamma(M) \mid M \in \mathcal{M}_{\text{LESS}}(T_1, T_2)\}, \\ \tau_{\text{ILST}}^\gamma(T_1, T_2) &= \min\{\gamma(M) \mid M \in \mathcal{M}_{\text{ILST}}(T_1, T_2)\}. \end{aligned}$$

For  $A \in \{\text{TAI}, \text{LESS}, \text{ILST}\}$ , we define the set  $\mathcal{M}_A^*(T_1, T_2, \gamma)$  of all the minimum cost mappings between  $T_1$  and  $T_2$  under a cost function  $\gamma$  as follows.

$$\mathcal{M}_A^*(T_1, T_2, \gamma) = \operatorname{argmin}\{\gamma(M) \mid M \in \mathcal{M}_A(T_1, T_2)\}.$$

Jiang *et al.* [4] have introduced an alignment distance as an alternative distance measure to compare trees, which is based on an alignment. Here, for two trees  $T_1$  and  $T_2$ , we say that  $T_1$  and  $T_2$  are *isomorphic without labels* if there exists a bijection  $\phi$  from  $V(T_1)$  to  $V(T_2)$ , called an *isomorphism*, satisfying that  $u \leq v$  iff  $\phi(u) \leq \phi(v)$ .

**Definition 5 (Alignment [4]):** Let  $T_1$  and  $T_2$  be trees. Then, an *alignment* between  $T_1$  and  $T_2$  is a tree  $\mathcal{T}$  obtained by the following steps.

- 1) Insert new nodes labeled by  $\varepsilon$  into  $T_1$  and  $T_2$  so that the resulting trees  $T'_1$  and  $T'_2$  are isomorphic without labels and  $l(\phi(v)) \neq \varepsilon$  whenever  $l(v) = \varepsilon$  for an isomorphism  $\phi$  from  $T'_1$  to  $T'_2$  and every node  $v \in T'_1$ .
- 2) Set  $\mathcal{T}$  to a tree  $T'_1$  obtained by relabeling a label  $l(v)$  for every node  $v \in T'_1$  with  $(l(v), l(\phi(v)))$ . (Note that  $(\varepsilon, \varepsilon) \notin \mathcal{T}$ .)

Let  $\mathcal{A}(T_1, T_2)$  denote the set of all possible alignments between  $T_1$  and  $T_2$ . The *cost*  $\gamma(\mathcal{T})$  of an alignment  $\mathcal{T}$  is the sum of the costs of all labels in  $\mathcal{T}$ .

**Definition 6 (Alignment distance [4]):** Let  $T_1$  and  $T_2$  be trees and  $\gamma$  a cost function. Then, an *alignment distance*  $\tau_{\text{ALN}}^\gamma(T_1, T_2)$  between  $T_1$  and  $T_2$  under  $\gamma$  is defined as follows.

$$\tau_{\text{ALN}}^\gamma(T_1, T_2) = \min\{\gamma(\mathcal{T}) \mid \mathcal{T} \in \mathcal{A}(T_1, T_2)\}.$$

In operational, the alignment distance is an edit distance such that every insertion proceeds to deletions [4]. Furthermore, the following theorem is known.

**Theorem 2:** Let  $T_1$  and  $T_2$  be trees. Suppose that  $n = |T_1|$ ,  $m = |T_2|$ ,  $D = \max\{d(T_1), d(T_2)\}$  and  $d = \min\{d(T_1), d(T_2)\}$ .

- 1) ([6], [7])  $\mathcal{M}_{\text{ILST}}(T_1, T_2) \subseteq \mathcal{M}_{\text{LESS}}(T_1, T_2) \subseteq \mathcal{M}_{\text{TAI}}(T_1, T_2)$ , which implies that  $\tau_{\text{TAI}}^\gamma(T_1, T_2) \leq \tau_{\text{LESS}}^\gamma(T_1, T_2) \leq \tau_{\text{ILST}}^\gamma(T_1, T_2)$ . The equation does not always hold in general.
- 2) ([3], [6])  $\tau_{\text{ALN}}^\gamma(T_1, T_2) = \tau_{\text{LESS}}^\gamma(T_1, T_2)$ .
- 3) ([2], [18]) The problem of computing  $\tau_{\text{TAI}}^\gamma(T_1, T_2)$  is MAX SNP-hard, even if  $T_1$  and  $T_2$  are binary trees.
- 4) ([4]) The problem of computing  $\tau_{\text{ALN}}^\gamma(T_1, T_2)$  is MAX SNP-hard. On the other hand, if  $D$  is bounded by some constant, then we can compute  $\tau_{\text{ALN}}^\gamma(T_1, T_2)$  in  $O(nmD!)$  time.
- 5) ([13]) We can compute  $\tau_{\text{ILST}}^\gamma(T_1, T_2)$  in  $O(nmd)$  time.

### III. ANCHORED ALIGNMENT DISTANCE

Let  $T_1$  and  $T_2$  be trees and  $M \in \mathcal{M}_{\text{TAI}}(T_1, T_2)$  called an *anchoring*. Then, Schiermer and Giegerich [10] have introduced an *anchored alignment* between  $T_1$  and  $T_2$  through  $M$ , which we call in this paper, as an alignment  $\mathcal{T}$  containing a node labeled by  $(l(v), l(w))$  for every  $(v, w) \in M$ . We denote it by  $\text{ach}(T_1, T_2, M)$ .

Note that an arbitrary anchoring does not always provide an anchored alignment, since  $M \in \mathcal{M}_{\text{TAI}}(T_1, T_2)$  whenever  $M \in \mathcal{M}_{\text{LESS}}(T_1, T_2)$  but the converse direction does not hold in general (Theorem 2.1). In order to avoid this problem, Ishizaka *et al.* [3] have formulated an *anchored alignment problem* to output an anchored alignment  $\mathcal{T}$  between  $T_1$  and  $T_2$  through  $M$  if  $\mathcal{T}$  exists; return “no” otherwise. Also they have designed an efficient algorithm, called ACHALN in this paper, to solve the problem by using the following cover sequence.

For  $M \in \mathcal{M}_{\text{TAI}}(T_1, T_2)$  and  $(v, w) \in M$ , let  $S_1(v) = V(T_1[v]) \cap M|_1$  and  $S_2(w) = V(T_2[w]) \cap M|_2$ , where  $T[v]$  denotes the complete subtree of  $T$  rooted at  $v \in T$ . Also, by denoting  $UP_{r_1}(v)$  (resp.,  $UP_{r_2}(w)$ ) as a sequence  $[r_1, \dots, v]$  (resp.,  $[r_2, \dots, w]$ ) for  $r_1 = r(T_1)$  (resp.,  $r_2 = r(T_2)$ ), the *cover sequence* of  $v$  in  $T_1$  (resp.,  $w$  in  $T_2$ ), denoted by  $C_1(v)$  (resp.,  $C_2(w)$ ), is a sequence  $[S_1(r_1), \dots, S_1(v)]$  (resp.,  $[S_2(r_2), \dots, S_2(w)]$ ). We say that  $C_1(v)$  and  $C_2(w)$  are *incomparable* if there exist  $s_1 \in C_1(T_1)$  and  $s_2 \in C_2(T_2)$  such that neither  $s_1 \subseteq s_2$  nor  $s_2 \subseteq s_1$ .

Then, the outline of the algorithm ACHALN is illustrated as follows.

- 1) For every  $(v, w) \in M$ , construct cover sequences  $C_1(v)$  and  $C_2(w)$ .
- 2) If there exists  $(v, w) \in M$  such that  $C_1(v)$  and  $C_2(w)$  are incomparable, then set  $\text{ach}(T_1, T_2, M)$  to  $\emptyset$ .
- 3) Otherwise:
  - a) For every  $(v, w) \in M$ , align  $C_1(v)$  and  $C_2(w)$  as  $C'_1(v)$  and  $C'_2(w)$  and construct a path  $P(v, w)$  by pairing each element of  $C'_1(v)$  and  $C'_2(w)$ .
  - b) Set  $\text{ach}(T_1, T_2, M)$  to a tree constructed from merging every path  $P(v, w)$ .

**Theorem 3 (Ishizaka *et al.* [3]):** We can solve the anchored alignment problem in  $O(H|M|^2 + n + m)$  time, where  $n = |T_1|$ ,  $m = |T_2|$  and  $H = \max\{h(T_1), h(T_2)\}$ .

Then, we can formulate an *anchored alignment distance through  $M$*  as follows.

**Definition 7 (Anchored alignment distance through mapping):**

Let  $T_1$  and  $T_2$  be trees,  $M \in \mathcal{M}_{\text{TAI}}(T_1, T_2)$  and  $\gamma$  a cost function. Then, we define an *anchored alignment distance*  $\tau_{\text{ACH}}^\gamma(T_1, T_2, M)$  between  $T_1$  and  $T_2$  through  $M$  under  $\gamma$  as follows.

$$\begin{aligned} \tau_{\text{ACH}}^\gamma(T_1, T_2, M) &= \begin{cases} \gamma(\text{ach}(T_1, T_2, M)), & \text{if } \text{ach}(T_1, T_2, M) \neq \emptyset, \\ |T_1| + |T_2|, & \text{otherwise.} \end{cases} \end{aligned}$$

By Theorem 2.2,  $M \in \mathcal{M}_{\text{LESS}}(T_1, T_2)$  iff  $\text{ach}(T_1, T_2, M) \neq \emptyset$ . The statements 1 and 2 in ACHALN can determine whether or not  $M \in \mathcal{M}_{\text{LESS}}(T_1, T_2)$  in  $O(H|M|)$  time. Also, by Theorem 2.1,  $M \in \mathcal{M}_{\text{LESS}}(T_1, T_2)$  whenever  $M \in \mathcal{M}_{\text{ILST}}(T_1, T_2)$ .

**Theorem 4:** For trees  $T_1$  and  $T_2$  and a cost function  $\gamma$ , suppose that  $M_1 \in \mathcal{M}_{\text{ILST}}^*(T_1, T_2, \gamma)$  and  $M_2 \in \mathcal{M}_{\text{LESS}}^*(T_1, T_2, \gamma)$ . If  $M_1 \subset M_2$ , then, for every  $(v, w) \in M_2 \setminus M_1$ , there exist  $(v_1, w_1), (v_2, w_2) \in M_1$  satisfying each of the following statements.

- 1)  $v < v_1 \sqcup v_2$  and  $w \# w_1 \sqcup w_2$ .
- 2)  $v \# v_1 \sqcup v_2$  and  $w < w_1 \sqcup w_2$ .

*Proof:* Suppose that neither the statements 1 nor 2 holds. Then, for every  $(v_1, w_1), (v_2, w_2) \in M_1$ , it holds that (1)  $v < v_1 \sqcup v_2$  and one of  $w \leq w_1 \sqcup w_2$ ,  $w = w_1 \sqcup w_2$  or  $w_1 \sqcup w_2 \leq w$  and (2)  $w < w_1 \sqcup w_2$  and one of  $v \leq v_1 \sqcup v_2$ ,  $v = v_1 \sqcup v_2$  or  $v_1 \sqcup v_2 \leq v$ . By the ancestor condition, it holds that  $v < v_1 \sqcup v_2 \iff w < w_1 \sqcup w_2$ , which implies that  $M_2 \in \mathcal{M}_{\text{ILST}}(T_1, T_2)$ . Since  $M_1 \subset M_2$  and  $M_1 \in \mathcal{M}_{\text{ILST}}^*(T_1, T_2, \gamma)$ , it is a contradiction. ■

**Theorem 5:** There exist trees  $T_1$  and  $T_2$  and a cost function  $\gamma$  such that neither  $M_1 \subset M_2$  nor  $M_2 \subset M_1$  for  $M_1 \in \mathcal{M}_{\text{ILST}}^*(T_1, T_2, \gamma)$  and  $M_2 \in \mathcal{M}_{\text{LESS}}^*(T_1, T_2, \gamma)$ . This statement also holds even if trees  $T_1$  and  $T_2$  are unlabeled (or equivalently unique-labeled).

*Proof:* Let  $\mu$  be the unit cost function. First consider the trees  $T_1$  and  $T_2$  in Figure 1 (left). Figure 1 (right) illustrates  $M_1 \in \mathcal{M}_{\text{ILST}}^*(T_1, T_2, \mu)$  and  $M_2 \in \mathcal{M}_{\text{LESS}}^*(T_1, T_2, \mu)$ . Then, it holds that  $\mu(M_1) = 3$  and  $\mu(M_2) = 2$ , but neither  $M_1 \subset M_2$  nor  $M_2 \subset M_1$ .

Also consider the unique-labeled trees  $T_3$  and  $T_4$  in Figure 2 (left). Figure 2 (right) illustrates  $M_3 \in \mathcal{M}_{\text{ILST}}^*(T_3, T_4, \mu)$  and  $M_4 \in \mathcal{M}_{\text{LESS}}^*(T_3, T_4, \mu)$ . Then, it holds that  $\mu(M_3) = 4$  and  $\mu(M_4) = 2$ , but neither  $M_3 \subset M_4$  nor  $M_4 \subset M_3$ . ■

Fig. 1. Trees  $T_1$  and  $T_2$  (upper),  $M_1 \in \mathcal{M}_{\text{ILST}}^*(T_1, T_2, \mu)$  and  $M_2 \in \mathcal{M}_{\text{LESS}}^*(T_1, T_2, \mu)$  (lower) in the proof of Theorem 5.

Theorem 5 claims that the minimum cost less-constrained mapping is not always comparable with the minimum cost isolated-subtree mapping (as set inclusion). On the other hand,  $\mathcal{M}_{\text{ILST}}$  is the nearest mapping class to  $\mathcal{M}_{\text{LESS}}$  in a Tai mapping hierarchy [6], [15] and  $\tau_{\text{ILST}}$  is the most general tractable variation of  $\tau_{\text{Tai}}$  [13]. Hence, in this paper, we construct candidates of an anchoring by adding pairs of non-mapped leaves to  $M \in \mathcal{M}_{\text{ILST}}^*(T_1, T_2, \gamma)$  by Theorem 4.

For  $M \in \mathcal{M}_{\text{ILST}}^*(T_1, T_2, \gamma)$ , let  $\bar{M}$  be a complement of  $M$ , that is,  $\{(v, w) \in T_1 \times T_2 \mid (v, w) \notin M\}$ . A *total leaf mapping* of  $M$ , denoted by  $lm(M)$ , is defined as  $\bar{M} \cap (lv(T_1) \times lv(T_2))$  and we call  $M' \subseteq lm(M)$  (possibly  $M' = \emptyset$ ) a *leaf mapping* of  $M$ . Whereas every leaf mapping is always a Tai

Fig. 2. Unique-labeled trees  $T_3$  and  $T_4$  (upper),  $M_3 \in \mathcal{M}_{\text{ILST}}^*(T_3, T_4, \mu)$  and  $M_4 \in \mathcal{M}_{\text{LESS}}^*(T_3, T_4, \mu)$  (lower) in the proof of Theorem 5.

mapping,  $M \cup M'$  is not always a Tai mapping. Then, for  $M \in \mathcal{M}_{\text{ILST}}^*(T_1, T_2, \gamma)$  and  $M' \subseteq lm(M)$ , by applying the algorithm ACHALN for an anchoring  $M \cup M'$  as input, we can obtain the anchored alignment  $ach(T_1, T_2, M \cup M')$ .

**Definition 8 (Anchored alignment distance):** Let  $T_1$  and  $T_2$  be trees and  $\gamma$  a cost function. Then, an *anchored alignment distance*  $\tau_{\text{ACH}}^\gamma(T_1, T_2)$  between  $T_1$  and  $T_2$  under  $\gamma$  is defined as follows.

$$\tau_{\text{ACH}}^\gamma(T_1, T_2) = \min \left\{ \gamma(ach(T_1, T_2, N)) \mid \begin{array}{l} M \in \mathcal{M}_{\text{ILST}}^*(T_1, T_2, \gamma), \\ M' \subseteq lm(M), \\ N = M \cup M', \\ N \in \mathcal{M}_{\text{LESS}}(T_1, T_2) \end{array} \right\}.$$

If no  $M'$  such that  $M' \subseteq lm(M)$  and  $M \cup M' \in \mathcal{M}_{\text{LESS}}(T_1, T_2)$  exists, then it holds that  $\tau_{\text{ACH}}^\gamma(T_1, T_2) = \tau_{\text{ILST}}^\gamma(T_1, T_2) = \gamma(ach(T_1, T_2, M))$ , by regarding  $M'$  as  $\emptyset$  and since  $M \in \mathcal{M}_{\text{ILST}}^*(T_1, T_2, \gamma)$ . Hence, we can avoid to the case that  $|T_1| + |T_2|$  in Definition 7 and it holds that  $\tau_{\text{ALN}}^\gamma(T_1, T_2) \leq \tau_{\text{ACH}}^\gamma(T_1, T_2) \leq \tau_{\text{ILST}}^\gamma(T_1, T_2)$ .

For every alignment  $\mathcal{T}$ , we can construct a mapping which consists of a pair  $(v, w)$  for every node  $(l(v), l(w)) \in \mathcal{T}$ . We call it an *alignable mapping* constructed from  $\mathcal{T}$  [6]. Then, we denote the set of all the alignable mappings constructed from  $ach(T_1, T_2, N)$  such that  $M \in \mathcal{M}_{\text{ILST}}^*(T_1, T_2, \gamma)$ ,  $M' \subseteq lm(M)$ ,  $N = M \cup M'$ ,  $N \in \mathcal{M}_{\text{LESS}}(T_1, T_2)$  and the cost is minimum under  $\gamma$  by  $\mathcal{M}_{\text{ACH}}^*(T_1, T_2, \gamma)$ .

**Theorem 6:** We can compute  $\tau_{\text{ACH}}^\gamma(T_1, T_2)$  in  $O(nm(d + H2^v))$  time, where  $n = |T_1|$ ,  $m = |T_2|$ ,  $d = \min\{d(T_1), d(T_2)\}$ ,  $H = \max\{h(T_1), h(T_2)\}$  and  $v = \min\{|lv(T_1)|, |lv(T_2)|\}$ .

*Proof:* Consider the algorithm ACHALNDIST in Algorithm 1. Here, the algorithm  $\text{ILST}(T_1, T_2, \gamma)$  in line 1 returns a pair of the isolated-subtree distance  $\tau_{\text{ILST}}^\gamma(T_1, T_2)$  and its minimum cost isolated-subtree mapping in  $\mathcal{M}_{\text{ILST}}^*(T_1, T_2, \gamma)$  [13], which runs in  $O(nmd)$  time. By line 4, we ignore the case that  $M \cup M'$  is not less-constrained. By Definition 8, if no  $M' (\neq \emptyset)$  such that  $M \cup M' \in \mathcal{M}_{\text{LESS}}(T_1, T_2)$  exists, then it holds that  $\tau_{\text{ACH}}^\gamma(T_1, T_2) = \tau_{\text{ILST}}^\gamma(T_1, T_2)$  as the case that  $M' = \emptyset$ , realized by the selection of the minimum value of  $d$  and  $\gamma(\mathcal{T})$  in lines 1 and 5. Since the running time of line 3 is  $O(H|M|^2 + n + m) = O(mnH)$  by Theorem 3 and the

number of  $M'$  in line 2 is at most  $2^v$ , the time complexity also holds. ■

```

procedure ACHALNDIST( $T_1, T_2, \gamma$ )
  /*  $T_1, T_2$  : tree,  $\gamma$ : cost function */
  1  ( $d, M$ )  $\leftarrow$  ILST( $T_1, T_2, \gamma$ );
  /*  $d = \tau_{\text{ILST}}^\gamma(T_1, T_2)$ ,  $M \in \mathcal{M}_{\text{ILST}}^*(T_1, T_2, \gamma)$  */
  2  foreach  $M' \subseteq \text{lm}(M)$  s.t.  $M \cup M' \in \mathcal{M}_{\text{TAI}}(T_1, T_2)$ 
    do
  3     $\mathcal{T} \leftarrow \text{ACHALN}(T_1, T_2, M \cup M')$ ;
    /*  $\mathcal{T} = \emptyset$  if  $M \cup M'$  is not less-constrained */
  4    if  $\gamma(\mathcal{T}) > 0$  then
      /*  $\gamma(\mathcal{T}) = 0 \iff \mathcal{T} = \emptyset$  */
      5     $d \leftarrow \min\{d, \gamma(\mathcal{T})\}$ ;
  6  output  $d$ ;

```

**Algorithm 1:** ACHALNDIST.

#### IV. EXPERIMENTAL RESULTS

In this section, we assume a cost function is always the unit cost function  $\mu$ , so the subscript of a cost function is omitted. Also the computer environment is that CPU is Intel Xeon E51650 v3 (3.50GHz), RAM is 1GB and OS is Ubuntu Linux (64bit).

##### A. Randomly generated trees

The running time of the algorithm ACHALNDIST is exponential with respect to the number of leaves in Theorem 6, that is,  $O(nm(d + H2^v))$  time. Here,  $v$  depends on the number of  $M'$  in line 2 of the algorithm ACHALNDIST, which is the minimum value of  $|lv(T_1)| - |(M|_1) \cap lv(T_1)|$  and  $|lv(T_2)| - |(M|_2) \cap lv(T_2)|$ . Then,  $\tau_{\text{ACH}}$  is possible to be computed efficiently between trees if such a value is small.

First, we evaluate the above situation by using randomly generated trees. In this experiment, by using the algorithm PTC [8], we generate 10 rooted labeled trees with from 100 to 200 nodes when varying the maximum degree for 2, 3, 4, 5 and 10 and then compute  $\tau_{\text{ACH}}$  and  $\tau_{\text{ILST}}$  for all of the pairs of 10 trees, that is, 45 pairs. Table I illustrates the running time to compute  $\tau_{\text{ACH}}$  and  $\tau_{\text{ILST}}$ , the average value of  $\tau_{\text{ACH}}$  and  $\tau_{\text{ILST}}$  and the number of different pairs of  $\tau_{\text{ILST}}$  and  $\tau_{\text{ACH}}$ . Note that, under this setting, we cannot compute  $\tau_{\text{ALN}}$  even if the maximum degree is 2 within one day.

TABLE I

THE RUNNING TIME TO COMPUTE  $\tau_{\text{ACH}}$  AND  $\tau_{\text{ILST}}$ , THE AVERAGE VALUE OF  $\tau_{\text{ACH}}$  AND  $\tau_{\text{ILST}}$  AND THE NUMBER OF THE DIFFERENT PAIRS OF  $\tau_{\text{ILST}}$  AND  $\tau_{\text{ACH}}$ .

max. degree	2	3	4	5	10
$\tau_{\text{ACH}}$ time (ms)	926	1,720	14,221	14,892	71,399
$\tau_{\text{ILST}}$ time (ms)	719	635	609	545	552
$\tau_{\text{ACH}}$ average	121.93	130.87	133.30	126.51	133.89
$\tau_{\text{ILST}}$ average	121.93	131.22	133.20	127.60	136.00
$\tau_{\text{ACH}} < \tau_{\text{ILST}}$	0	10	21	25	34
	0%	22.22%	46.67%	55.56%	75.56%

Table I shows that, when the maximum degree is increasing, whereas the average value is independent from the maximum degree, the running time is increasing exponentially and the pairs such that  $\tau_{\text{ACH}} < \tau_{\text{ILST}}$  is increasing.

##### B. N-glycan data

Next, as real data for trees with small  $v$ , we adopt N-glycan data provided from KEGG [5] and evaluate  $\tau_{\text{ACH}}$  by comparing with  $\tau_{\text{ILST}}$  and  $\tau_{\text{ALN}}$  and their mappings in more detail.

Here, the number of N-glycan data is 2,142 and then the number of pairs is 2,293,011. Furthermore, Table II illustrates the minimum, the maximum and the average values of the number of nodes, the number of leaves, the degree and the height of N-glycan data.

TABLE II

THE MINIMUM, THE MAXIMUM AND THE AVERAGE VALUES OF THE NUMBER OF NODES, THE NUMBER OF LEAVES, THE DEGREE AND THE HEIGHT OF N-GLYCAN DATA.

	min.	max.	ave.
nodes	2	38	11.0696
leaves	1	12	3.2876
degree	1	3	2.0724
height	1	5	5.3838

Table III illustrates the running time to compute  $\tau_{\text{ALN}}$ ,  $\tau_{\text{ACH}}$  and  $\tau_{\text{ILST}}$  for all the pairs of N-glycan data.

TABLE III

THE RUNNING TIME TO COMPUTE  $\tau_{\text{ALN}}$ ,  $\tau_{\text{ACH}}$  AND  $\tau_{\text{ILST}}$ .

distance	time(ms)
$\tau_{\text{ALN}}$	50,503,659
$\tau_{\text{ACH}}$	595,188
$\tau_{\text{ILST}}$	274,425

Table III shows that, for N-glycan data, the total running time of computing  $\tau_{\text{ACH}}$  is not so large and nearer the running time of computing  $\tau_{\text{ILST}}$  whose complexity is  $O(mnd)$  time than the running time of computing  $\tau_{\text{ALN}}$  whose complexity is  $O(nmD!)$  time. The total running time of computing  $\tau_{\text{ACH}}$  is less than thrice of the total running time of computing  $\tau_{\text{ILST}}$ .

Table IV illustrates the number of pairs for every inequality between  $\tau_{\text{ALN}}$ ,  $\tau_{\text{ACH}}$  and  $\tau_{\text{ILST}}$ . Note that  $\tau_{\text{ALN}} \leq \tau_{\text{ACH}} \leq \tau_{\text{ILST}}$ .

In contrast to Table I, Table IV shows that the number of pairs that  $\tau_{\text{ALN}} = \tau_{\text{ACH}} = \tau_{\text{ILST}}$  is 2,116,005, which is 94.4612% for all the pairs, and the number of pairs that  $\tau_{\text{ACH}} = \tau_{\text{ILST}}$  is 2,275,260, which is 99.2259% for all the pairs. Also, the number of pairs that  $\tau_{\text{ALN}} = \tau_{\text{ACH}} < \tau_{\text{ILST}}$ , which improve  $\tau_{\text{ILST}}$  as  $\tau_{\text{ACH}}$  is 17,144, which is 0.7477% for all the pairs. On the other hand, the number of pairs that  $\tau_{\text{ALN}} < \tau_{\text{ACH}}$ , which is corresponding to Theorem 5, is 109,862, which is 4.7912% pairs for all the pairs.

Concerned with Table III and IV, Table V illustrates the number of  $M'$  satisfying the condition of line 2 in the algorithm ACHALNDIST for all the pairs.

Table V claims that no  $M'$  in line 2 in the algorithm ACHALNDIST is selected in 2,275,201 pairs, which is

TABLE IV  
THE NUMBER OF PAIRS FOR EVERY INEQUALITY BETWEEN  $\tau_{ALN}$ ,  $\tau_{ACH}$   
AND  $\tau_{ILST}$ .

inequality	#pairs	%
$\tau_{ALN} = \tau_{ACH} = \tau_{ILST}$	2,166,005	94.4612
$\tau_{ALN} < \tau_{ACH} = \tau_{ILST}$	109,255	4.7647
$\tau_{ALN} = \tau_{ACH} < \tau_{ILST}$	17,144	0.7477
$\tau_{ALN} < \tau_{ACH} < \tau_{ILST}$	607	0.0265

inequality	#pairs	%
$\tau_{ALN} < \tau_{ILST}$	127,006	5.5388
$\tau_{ALN} < \tau_{ACH}$	109,862	4.7912
$\tau_{ACH} < \tau_{ILST}$	17,751	0.7741

TABLE V  
THE NUMBER OF  $M'$  SATISFYING THE CONDITION OF LINE 2 IN  
ACHALNDIST.

# $M'$	#pairs	# $M'$	#pairs	# $M'$	#pairs
0	2,275,201	5	110	11	1
1	11,107	6	88	12	15
2	3,699	7	2	20	3
3	2,408	8	2	42	3
4	372				

99.2233% for all the pair. Then, the number of  $M'$  is too smaller than the theoretical worst case  $O(2^v)$ , which implies the experimental efficiency of the algorithm ACHALNDIST illustrated in Table III. This is also the reason why the number of pairs that  $\tau_{ACH} = \tau_{ILST}$  is very close to the number of all the pairs illustrated in Table IV. Furthermore, for the 24 pairs such that  $\#M' \geq 8$ , it holds that  $\tau_{ALN} = \tau_{ACH} < \tau_{ILST}$ .

For the three cases in Table IV that (1)  $\tau_{ALN} < \tau_{ACH} < \tau_{ILST}$ , (2)  $\tau_{ALN} < \tau_{ACH} = \tau_{ILST}$  and (3)  $\tau_{ALN} = \tau_{ACH} < \tau_{ILST}$ , Table VI summarizes the average and the maximum values of difference in the inequalities and the pairs whose difference is maximum. Here, the subscript of the glycan number denotes its number of nodes. Table VI claims that the number of nodes in the pairs in the above inequalities is not always large, that is, near to 38 and at most one tree in the pairs is large.

TABLE VI  
THE AVERAGE AND THE MAXIMUM VALUES OF DIFFERENCE IN THE  
INEQUALITIES AND THE PAIRS WHOSE DIFFERENCE IS MAXIMUM.

case	inequality	ave.	max.	#pairs	pairs
(1)	$\tau_{ALN} < \tau_{ACH}$	1.0644	7	2	(G06867 <sub>28</sub> , G11335 <sub>19</sub> ), (G06867 <sub>28</sub> , G11339 <sub>20</sub> )
(2)	$\tau_{ACH} < \tau_{ILST}$	1.0319	4	4	(G03669 <sub>17</sub> , G04570 <sub>11</sub> ), (G04186 <sub>20</sub> , G04570 <sub>11</sub> ), (G04570 <sub>11</sub> , G04972 <sub>19</sub> ), (G04570 <sub>11</sub> , G06997 <sub>18</sub> )
(3)	$\tau_{ALN} < \tau_{ACH}$	1.0115	3	1	(G04045 <sub>36</sub> , G05896 <sub>19</sub> )
	$\tau_{ACH} < \tau_{ILST}$	1.0537	3	4	(G04191 <sub>18</sub> , G04570 <sub>11</sub> ), (G04206 <sub>37</sub> , G04570 <sub>11</sub> ), (G04570 <sub>11</sub> , G11846 <sub>38</sub> ), (G04570 <sub>11</sub> , G11847 <sub>37</sub> )
	$\tau_{ALN} < \tau_{ILST}$	2.0659	5	3	(G04206 <sub>37</sub> , G04570 <sub>11</sub> ), (G04570 <sub>11</sub> , G11846 <sub>38</sub> ), (G04570 <sub>11</sub> , G11847 <sub>37</sub> )

Consider the glycan G04570<sub>11</sub>, which occurs most frequently in Table VI. Then, the glycans of G04191<sub>18</sub>, G04206<sub>37</sub>, G11846<sub>38</sub> and G11847<sub>37</sub> consist of all the pairs with G04570<sub>11</sub> satisfying that  $\tau_{ALN} < \tau_{ACH} < \tau_{ILST}$ . All the 4 pairs coincide with the pairs that  $\tau_{ACH} < \tau_{ILST}$  in case (3) in Table VI.

Figure 3 illustrates the glycans  $T_1 = G04191_{18}$  and  $T_2 = G04570_{11}$ , and the minimum cost mappings  $M_1 \in \mathcal{M}_{LESS}^*(T_1, T_2, \mu)$ ,  $M_2 \in \mathcal{M}_{ACH}^*(T_1, T_2, \mu)$  and  $M_3 \in \mathcal{M}_{ILST}^*(T_1, T_2, \mu)$ . Here, nodes with the different shapes or colors represent different stereochemistry in glycan structures, so we treat them as different labels. Note that  $\tau_{ALN}(T_1, T_2) = 9$ ,  $\tau_{ACH}(T_1, T_2) = 10$  and  $\tau_{ILST}(T_1, T_2) = 13$ .

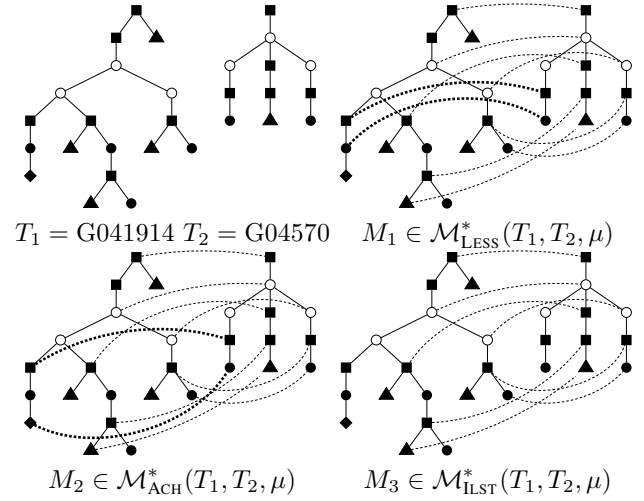

Fig. 3. The glycans  $T_1 = G04191$  and  $T_2 = G04570$ , and the minimum cost mappings  $M_1 \in \mathcal{M}_{LESS}^*(T_1, T_2, \mu)$ ,  $M_2 \in \mathcal{M}_{ACH}^*(T_1, T_2, \mu)$  and  $M_3 \in \mathcal{M}_{ILST}^*(T_1, T_2, \mu)$ .

In Figure 3, we depict the difference between  $M_1$ ,  $M_2$  and  $M_3$  by thick lines. Then, for  $M_3 \in \mathcal{M}_{ILST}^*(T_1, T_2, \mu)$  as input, the algorithm ACHALNDIST returns  $M_2$  by adding not only the pair of leaves whose labels are different as an anchoring, depicted as the lower thick line, but also the pair of their ancestors, depicted as the upper thick line, to  $M_3$ .

On the other hand, since the node in  $T_1$  in the pair in  $M_1$  depicted by the lower thick line is not a leaf in  $T_1$ , the algorithm ACHALNDIST cannot find  $M_1 \in \mathcal{M}_{LESS}^*(T_1, T_2, \mu)$ . The algorithm ACHALNDIST cannot replace a leaf in pairs given as an anchoring with its ancestor.

Finally, consider the successful cases such that  $\tau_{ALN} = \tau_{ACH} < \tau_{ILST}$ , that is, the case (2) in Table VI. Figure 4 illustrates the mappings  $M_i \in \mathcal{M}_{ACH}^*(T_i, T, \mu)$  ( $1 \leq i \leq 4$ ) for  $T_1 = G03669$ ,  $T_2 = G04186$ ,  $T_3 = G04972$ ,  $T_4 = G06997$  and  $T = G04570$ . Then, every  $M_i$  is obtained by adding the pairs depicted by thick lines to the mapping in  $\mathcal{M}_{ILST}^*(T_i, T, \mu)$ .

In contrast to Figure 3, the algorithm ACHALNDIST succeeds to find the minimum cost less-constrained mappings in Figure 4. The reason is that the pair of leaves given as an anchoring is also contained in the minimum cost less-

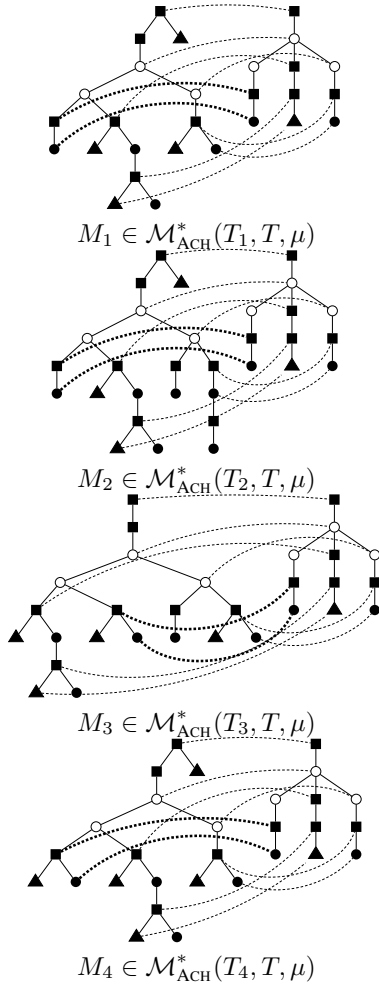

Fig. 4. The mappings  $M_i \in \mathcal{M}_{\text{ACH}}^*(T_i, T, \mu)$  ( $1 \leq i \leq 4$ ) for  $T_1 = \text{G03669}$ ,  $T_2 = \text{G04186}$ ,  $T_3 = \text{G04972}$ ,  $T_4 = \text{G06997}$  and  $T = \text{G04570}$ .

constrained mapping, which is not necessary to replace a leaf in pairs given as an anchoring with its ancestor.

## V. CONCLUSION AND FUTURE WORKS

In this paper, we have formulated the anchored alignment distance  $\tau_{\text{ACH}}$  based on the minimum cost isolated-subtree mapping and designed the algorithm to compute  $\tau_{\text{ACH}}$ . Then, we have given experimental results for randomly generated trees and for N-glycan data to evaluate  $\tau_{\text{ACH}}$  by comparing with  $\tau_{\text{ILST}}$  and  $\tau_{\text{ALN}}$ .

In particular, for N-glycan data, the running time of computing  $\tau_{\text{ACH}}$  have been much smaller than the theoretical worst case and it has been nearer to the running time of computing  $\tau_{\text{ILST}}$  than one of computing  $\tau_{\text{ALN}}$ . The reason is that the number of leaves in N-glycan data is not large. On the other hand, the number of pairs that  $\tau_{\text{ALN}} < \tau_{\text{ACH}}$  is larger than one that  $\tau_{\text{ALN}} = \tau_{\text{ACH}} < \tau_{\text{ILST}}$ , but even the former is less than 5%. It holds that  $\tau_{\text{ALN}} = \tau_{\text{ACH}} = \tau_{\text{ILST}}$  in more than 94% pairs. Furthermore, concerned with Figure 3 and 4, we have just observed the improvement that  $\tau_{\text{ACH}} < \tau_{\text{ILST}}$  by adding at

most two pairs of nodes along a path to the minimum cost isolated-subtree mapping.

Hence, it is a future work to analyze whether or not there are cases that at least three pairs are added by containing some branches for other data.

Concerned with Section IV-B, Mori *et al.* [9] and Yoshino *et al.* [14] have designed the algorithms to compute unordered tree edit distance  $\tau_{\text{TAI}}$  exactly for a part of N-glycan data. Section IV-B claims that the number of pairs that  $\tau_{\text{ALN}} < \tau_{\text{ACH}}$  and  $\tau_{\text{ALN}} < \tau_{\text{ACH}}$  is much smaller than the number of pairs that  $\tau_{\text{ALN}} = \tau_{\text{ACH}}$  and  $\tau_{\text{ALN}} = \tau_{\text{ILST}}$ . Then, the number of pairs that  $\tau_{\text{TAI}} < \tau_{\text{ALN}}$  is possible be much smaller than the number of pairs that  $\tau_{\text{TAI}} = \tau_{\text{ALN}}$ . In fact, all of the less-constrained mappings in Figure 3 and 4 are the minimum cost TAI mappings, and then it holds that  $\tau_{\text{ALN}} = \tau_{\text{TAI}}$  in all the cases. On the other hand, as similar as Figure 2, we provide an example of the unique-labeled trees  $T_1$  and  $T_2$ ,  $M_1 \in \mathcal{M}_{\text{TAI}}^*(T_1, T_2, \mu)$  and  $M_2 \in \mathcal{M}_{\text{LESS}}^*(T_1, T_2, \mu)$  in Figure 5 such that, for a unit cost function  $\mu$ ,  $\tau_{\text{TAI}}^\mu(T_1, T_2) = 2 < 4 = \tau_{\text{ALN}}^\mu(T_1, T_2)$ .

Fig. 5. Trees  $T_1$  and  $T_2$ ,  $M_1 \in \mathcal{M}_{\text{TAI}}^*(T_1, T_2, \mu)$  and  $M_2 \in \mathcal{M}_{\text{LESS}}^*(T_1, T_2, \mu)$ .

Hence, it is a future work to investigate whether or not the difference between  $\tau_{\text{TAI}}$  and  $\tau_{\text{ALN}}$  exists for N-glycan data and other experimental data.

Concerned with Theorem 4 and 5, it is a future work to investigate the properties of less-constrained mappings to construct an anchoring. In particular, in order to find the minimum cost less-constrained mapping, it is necessary to replace a leaf in pairs given as an anchoring with its ancestor as illustrated in Figure 3. This replacement is possible to be essential for the intractability of the problem of computing  $\tau_{\text{ALN}}$  [4]. Furthermore, concerned with Theorem 6 and Section IV-A, to apply the algorithm ACHALNDIST to trees with many leaves, it is necessary to decrease the number of leaf mappings, by using the number of connected components in the mapping [1], for example.

Hence, it is a future work to improve leaf mappings, to introduce other mappings instead of leaf mappings or to improve the definition of  $\tau_{\text{ACH}}$  and the algorithm ACHALNDIST independent from leaf mappings.

**Abstract**—Human-like characters can be modeled by suitable skeletal structures, which basically consist in trees where edges represent bones and vertices are joints between two adjacent bones. Motion is then defined as variations of the joints' configuration (i.e., partial rotations) over time, which also influences joint positions. However, this representation does not allow to easily represent the relationship between joints that are not directly connected by a bone. This work is therefore based on the premise that variations of the relative distances between such joints are important to represent complex human motions. While the former representations are currently used in practice for playing and analyzing motions, the latter can help in modeling a new class of problems where the relationships in human motions need to be simulated. Our main interest in this work is in adapting previously captured human postures (one frame of a given motion) with the aim of satisfying a certain number of geometrical constraints, which turn out to be easily definable in terms of distances. We present a novel procedure for approximating the relative inter-joint distances for skeletal structures having arbitrary features and respecting a predefined posture. This set of inter-joint distances defines an instance of the Distance Geometry Problem (DGP), that we tackle with a non-monotone spectral gradient method.

## I. INTRODUCTION

IN COMPUTER animation, human characters are typically modeled by a skeletal structure, which is a weighted tree  $S = (V, E_{skel}, b_{skel})$ , where every vertex  $v \in V$  represents a joint of the character, and where every edge connecting two joints  $u$  and  $v$  represents a bone. Weights are associated to the bones, that indicate their length  $\delta_{uv}$  through the function:

$$b_{skel} : \{u, v\} \in E_{skel} \longrightarrow \delta_{uv} \in \mathbb{R}_+.$$

In this setup, a motion for a given character can be represented by the joints' orientations over time, which influence joint positions [4], [9]. While this representation is commonly used in domains such as video games or human motion analysis, it does not allow, however, to easily represent the relationship between joints that are not directly connected by a bone (e.g., how a wrist moves in relation to the hip of the character).

We focus our attention on a novel methodology to describe a character and its motion by relative inter-joint distances. In the current literature, the simulation of character motions is generally performed either by modifying existing captured motions, where character and/or motion features may be manipulated [8], or by simulating motions from physical equations [3]. By exploiting distance information, it is our aim to study novel methods that are able to distinguish the geometrical information regarding a character, and the motion associated to it. In this way, the simulation of a modified motion for a modified character becomes trivial to model, and solely based on distance constraints.

In first analysis, we focus in this paper on human *postures*, that is, on only one “frame” of a given human motion. The main problem that we address is the following. How to adapt a given posture, extracted from a certain skeletal structure, to another skeletal structure having arbitrary bone lengths? The methods proposed in this paper can potentially be integrated in tools for motion simulation, and applied to all frames (all postures) of a given motion.

A posture  $x$  for the skeletal structure  $S$  in the Euclidean space  $\mathbb{R}^3$  is a mapping  $x : V \longrightarrow \mathbb{R}^3$ , so that every  $x_v = x(v)$  provides the coordinates of the joint  $v$  in the posture. If an ordering is associated to the joints (some possible orderings can be deduced from the tree structure of  $S$ ), then the posture can also be expressed in matrix form by  $X = [x_1 x_2 \dots x_n]^T$ , where  $n = |V|$  and every  $x_v$  is a column vector. The matrix  $X$  has  $n$  rows and 3 columns (corresponding to the dimension of the Euclidean space). From a known posture  $X$  for  $S$ , the distance matrix  $D = [D_{uv}]$  can be defined such that:

$$\forall \{u, v\} \in V \times V, \quad D_{uv} = \|x_u - x_v\|, \quad (1)$$

where  $\|\cdot\|$  is the Euclidean norm.

Given a distance matrix  $D = [\delta_{uv}]$ , the Distance Geometry Problem (DGP) in dimension 3 asks whether a *realization*  $X$  in the three-dimensional space for  $D$  exists so that all distances

$\delta_{uv}$  are satisfied [6]. Notice that, the distance matrix  $D$  is said a *Euclidean Distance Matrix* (EDM<sup>1</sup>), in dimension 3, when the DGP admits at least one solution. In our context, a realization  $X$  corresponds to a posture for the corresponding skeletal structure  $S$ .

A common approach to the DGP is to reformulate it as an unconstrained global optimization problem, where a penalty function is utilized for measuring the violation of the distance constraints [6]. The terms of the penalty function, one for each constraint, measure the absolute difference between the computed value  $\|x_u - x_v\|$  and the expected value  $\delta_{uv}$ . One example of penalty function, that also takes into consideration the fact that priority levels  $\pi_{uv}$  can be associated to the distances, is given by

$$\sigma_w(X) = \frac{1}{2} \sum_{\{u,v\} \in E} \pi_{uv} (\|x_u - x_v\| - \delta_{uv})^2. \quad (2)$$

After the reformulation of a DGP as a global optimization problem, its solution consists in finding a global optimum for the chosen penalty function. When the matrix  $D$  is an EDM, the value of the objective function in the solution is supposed to be zero. Otherwise, this value is strictly positive because of the error introduced on some of the distances. In our particular DGP application, the magnitude of the constraint violations cannot be a priori estimated.

In this work, we propose a novel procedure for manipulating distance matrices  $D$  with the aim of imposing a predefined set of geometrical constraints to the postures  $X$  to be simulated. Our procedure is based on the idea of separating the geometrical information concerning the character (the tree  $S$ ) from the posture  $X$ . The modified distance matrix  $D = [\delta_{uv}]$ , containing an approximated set of distances, is then *realized* by using an ad-hoc approach to the DGP.

It is important to remark that, after performing some modifications on distance matrix  $D$  obtained by applying (1), it is likely that this distance matrix is no longer an EDM, so that approximate posture  $X$ , in a least squares sense, need to be searched. This is equivalent to searching for the EDM that is the nearest to  $D$  [1]. In such a case, associating a priority level  $\pi_{uv}$  to every distance  $\delta_{uv}$  becomes fundamental: we seek and select in fact approximate postures that are able to privilege higher priority distances.

The rest of this short paper is organized as follows. In Section II, we will present our original method for manipulating a distance matrix  $D$ , initially representing a posture for a given skeletal structure  $S$ , so that it represents the same posture for a skeletal structure having modified bone lengths. This distance matrix will be used for creating new DGP instances that we will solve by employing a spectral gradient method implementing a non-monotone line search. Some preliminary computational experiments on a predefined human walking posture are presented in Section III, and Section IV will briefly conclude the paper.

<sup>1</sup>In some articles, EDMs are distance matrices where the entries are squared distances. In this paper, the distance matrix  $D$  contains *non-squared* distances.

## II. SKELETON-INDEPENDENT DISTANCE MATRICES

Let us suppose that the matrix  $X_1$  of positions for the joints of the skeletal structure  $S_1$  is known.  $X_1$  is a possible realization of the skeletal structure  $S_1$  which satisfies all bone-length constraints in the set  $b_{skel}(E_{skel})$ . The other inter-joint distances, that are not pre-defined in  $S_1$ , give a possible posture of the skeletal structure. Our main idea is to capture the distance information related to this posture, independently from the features of the skeletal structure (i.e. the bone lengths). This way, this distance-based information about the posture can be subsequently associated to a skeletal structure having different bone lengths.

Since  $X_1$  is known for  $S_1$ , all inter-joint distances  $D_{uv}$  can be computed by applying equ. (1), so that an initial distance matrix  $D$  can be defined. Naturally, all bone-length constraints in  $b_{skel}(E_{skel})$  are satisfied by  $X_1$ . The realization of this initial matrix  $D$  can be performed in polynomial computational time, and a high-quality approximation of the unique solution can be easily obtained [2]. Naturally, this unique solution corresponds to the original posture  $X_1$  of  $S_1$  (modulo rotations, translations and reflections).

We propose to extract the information about the posture of  $S_1$  represented by  $X_1$  with the following procedure. Our procedure is based on the idea to compute all shortest paths  $P_{uv} = \{p_1, \dots, p_k\}$  between pairs of distinct joints, where  $p_1 = u$ ,  $p_k = v$  and, for every  $i = 1, \dots, k-1$ , we have  $\{p_i, p_{i+1}\} \in E_{skel}$ . The term “shortest” makes reference to the number of edges that need to be crossed by the path to walk from the vertex  $u$  to the vertex  $v$  of the skeletal structure  $S$ ; it is not related neither to the distances  $\delta$ , not to priority levels  $\pi$ . We refer to the sum of the distance values  $\delta$  over a path  $P_{uv}$  as the *weight*  $\tau_{uv}$  of the shortest path  $P_{uv}$ , computed as:

$$\tau_{uv} = \sum_{i=1}^{(|P_{uv}|-1)} \delta(p_i, p_{i+1}).$$

We will use the superscript “(1)” for indicating that shortest paths  $P_{uv}$  and weights  $\tau_{uv}$  are related to the skeletal structure  $S_1$ ; the superscript “(2)” will be employed below when referring to  $S_2$ .

Once all shortest paths  $P_{uv}^{(1)}$  over the skeletal structure  $S_1$  are computed, we normalize the computed distances  $D_{uv}$  with the weights  $\tau_{uv}^{(1)}$  of the corresponding shortest path. In other words, instead of considering the distances computed by equ. (1), we apply the following formula:

$$\forall \{u, v\} \in V \times V, \quad D_{uv} = \|x_u - x_v\| / \tau_{uv}^{(1)},$$

where  $x_v$  is the position of the generic vertex  $v$  in the posture  $X_1$ . Notice that all distances related to bone lengths are equal to 1 after the normalization, and that distances close to 0 indicate an inter-joint contact, while non-bone distances close to 1 are related to completely extended configurations. We point out that the idea to normalize relative distances is not completely new, and that it was partially exploited for example in [5] in a morphology-independent representation of

Fig. 1. The posture  $X_1$  of the original skeletal structure  $S_1$ .

the motions, which is however not solely based on distance information.

In order to impose the posture in  $X_1$  to another skeletal structure  $S_2$ , we apply first of all the formula for computing a new distance matrix:

$$\forall \{u, v\} \in V \times V, \quad \delta_{uv} = \tau_{uv}^{(2)} \cdot D_{uv},$$

where  $\tau_{uv}^{(2)}$  is the weight of the shortest path  $P_{uv}^{(2)}$  over  $S_2$ . This formula makes it possible to reconstruct correctly the bone lengths of  $S_2$  while modifying accordingly the original distances in  $X_1$ , for them to be adapted to the new bone lengths of  $S_2$ .

Intuitively, distances between joints that are close in the skeletal structure (i.e. corresponding to shortest paths  $P_{uv}$  over fewer bones) can be approximated better than others (for example the distance between a hand and a foot is more difficult to approximate). For this reason, every computed distance  $\delta_{uv}$  is coupled with the priority level  $\pi_{uv}$ , that is based on the cardinality  $|P_{uv}|$  of the corresponding shortest path:

$$\pi_{uv} = (|P_{\max}| - |P_{uv}| + 2) / |P_{\max}|,$$

where  $P_{\max}$  is the longest shortest path that can be defined over the two skeletal structures  $S_1$  and  $S_2$ . Notice that, in correspondence with the bone lengths, the priority  $\pi_{uv}$  is maximal and equal to 1; the smallest possible priority value is given by  $2/|P_{\max}|$ . This distance information, together with the associated priority levels, defines a DGP instance for the simulation of human postures.

### III. COMPUTATIONAL EXPERIMENTS

In our computational experiments, we consider a human walking posture extracted from a walking motion. This section shows the results obtained by constructing an approximated distance matrix by the method detailed in Section II, and by looking for the corresponding posture by implementing the spectral gradient method with non-monotone line search described in [7]. All codes were written in Matlab 2016b and the experiments were carried out on an Intel Core 2 Duo @ 2.4 GHz with 2GB RAM, running Mac OS X.

A graphical representation of the original skeletal structure is displayed in Fig. 1, together with the initial posture from which we extract the distance information. Table I shows the list of short labels for all joints forming the skeletal structure, together with the original distances from the corresponding joint parents (bone lengths).

TABLE I  
SOME DETAILS ABOUT THE CONSIDERED SKELETAL STRUCTURE  $S$ , WITH THE ORIGINAL BONE DISTANCES (DISTANCE OF EVERY JOINT FROM ITS PARENT, IN PARENTHESIS).

Joint label	Joint name	distance to parent
H	Hips	/
C	Chest	0.160 (H)
CA	Chest2	0.179 (C)
CB	Chest3	0.069 (CA)
N	Neck	0.069 (CB)
HD	Head	0.106 (N)
RC	RightCollar	0.072 (CB)
RS	RightShoulder	0.158 (RC)
RE	RightElbow	0.273 (RS)
RW	RightWrist	0.258 (RE)
LC	LeftCollar	0.072 (CB)
LS	LeftShoulder	0.158 (LC)
LE	LeftElbow	0.273 (LS)
LW	LeftWrist	0.258 (LE)
RH	RightHip	0.108 (H)
RK	RightKnee	0.435 (RH)
RA	RightAnkle	0.453 (RN)
RT	RightToe	0.125 (RA)
LH	LeftHip	0.108 (H)
LK	LeftKnee	0.435 (LH)
LA	LeftAnkle	0.453 (LK)
LT	LeftToe	0.125 (LA)

Table II shows some preliminary experiments, where the parameters of the non-monotone spectral gradient method, are the same of the experiments presented in [7]. The distance matrix is generated by applying the procedure detailed in Section II. As a starting point  $X_0$  in the spectral gradient method, we considered the original posture with the original bone lengths. All experiments took less than 1 second of CPU time.

As the table shows, the method is able to reproduce quite well the original posture in the new skeletal structures. It is possible to remark, however, that when very important changes in the bone lengths are imposed, the obtained posture can show some slight deformations w.r.t. the original one (see for example the posture obtained when imposing a 60% longer spine). In order to avoid such undesired effects, we are currently working on a more advance method for the definition of the approximated distance matrices and of the associated priority levels.

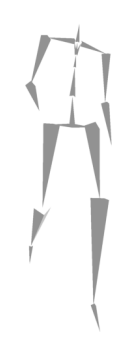

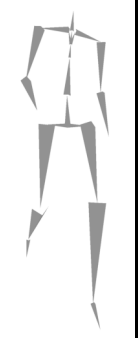

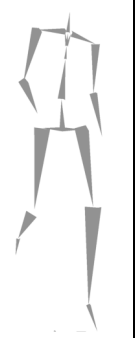

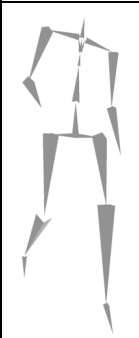

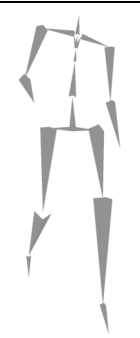

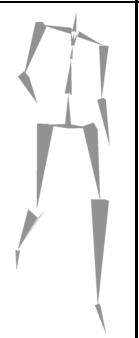

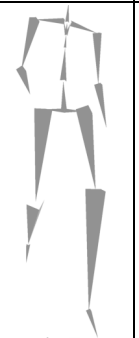

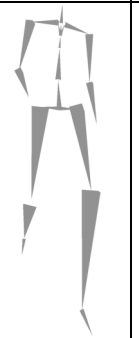

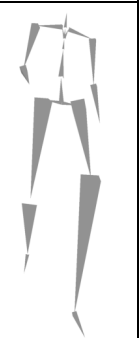

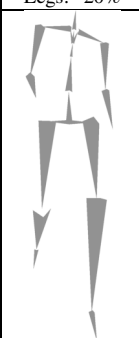

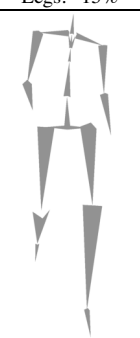

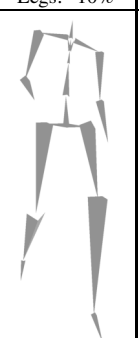

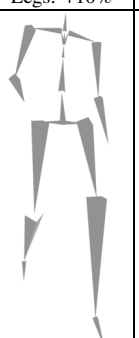

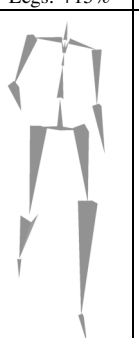

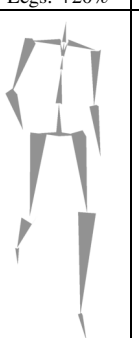

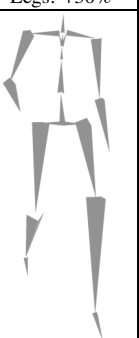

### IV. CONCLUSIONS

We have presented a novel approach, solely based on distance information, for simulating a given human posture of a skeletal structure having arbitrary bone lengths. Once an approximated distance matrix is defined, the problem to be solved is a classical one in the context of distance geometry, where an EDM near to the approximated matrix needs to be identified, by revealing in this way the posture for the new skeletal structure. Our computational experiments show that the presented methodology is promising when the corresponding distance geometry problem is solved by using the non-monotone spectral gradient method proposed in [7] in the context of the *dynamical* distance geometry. Future works will mostly be aimed at improving and at performing a

{coti,leclercq,roupin,butelle}@lipn.univ-paris13.fr

**Abstract**—In this paper we present *MLTBiqCrunch*, a hierarchically parallelized version of the open-source solver *BiqCrunch* [1]. More precisely, this version has two levels of parallelization: a coarse grain, assigning a thread to a node evaluation and a fine grain, parallelizing a node evaluation when some threads are not busy. We present experiments on some classical binary quadratic optimization problems with comparison of their scalability and raw performance. In particular, we obtain a superlinear speedup for some of the most difficult instances.

## I. INTRODUCTION

*BiqCrunch* [1] is a full open-source solver (publicly available online) for binary quadratic optimization problems. Such problems can be stated as 0-1 quadratic programs with  $m_I$  inequality constraints and  $m_E$  equality constraints:

$$\begin{cases} \max & z^T S_0 z + s_0^T z \\ \text{s.t.} & z^T S_i z + s_i^T z \leq a_i, \quad i \in \{1, \dots, m_I\} \\ & z^T S_i z + s_i^T z = a_i, \quad i \in \{m_I + 1, \dots, m_I + m_E\} \\ & z \in \{0, 1\}^n \end{cases} \quad (1)$$

where the  $S_i$ 's are real symmetric  $n \times n$  matrices, the  $s_i$ 's are vectors in  $\mathbb{R}^n$ , and the  $a_i$ 's are real numbers. Note that if all  $S_i = 0$  then one gets a 0–1 linear program. *BiqCrunch* requires the objective value of (1) to be integer for any feasible solution.

Many optimization problems can be stated as (1), for further details about applications and solvers the reader is referred to [2], [3]. A vast majority of solvers for continuous, mixed or integer problems, even to solve special cases (e.g. [4]) or relaxations of (1) (e.g. [5]) are multithreaded. Designing parallel versions is especially useful for Branch-and-Bound-like algorithms (e.g. [6]), and several authors investigated sophisticated approaches to take advantage of various architectures (e.g. [7], [8]). Other authors proposed approaches to provide a more general framework to design such parallel Branch-and-Bound algorithms (e.g. [9]). Some specific softwares are specialized to design this type of solvers, such as the COIN-OR High-Performance Parallel Search Framework [10] which provides a base layer of a hierarchy consisting of implementations of various tree search algorithms for specific problem types.

*BiqCrunch* uses sophisticated high-quality semidefinite bounds [11] and automatically sets the tightness of its bounding procedure node by node in the search tree. Moreover, triangle inequalities are dynamically added and removed from the underlying nonlinear relaxations in order to obtain stronger bounds. A complete description of the solver is given in [1] as

well as its mathematical background. The *BiqCrunch* website is <http://lipn.univ-paris13.fr/BiqCrunch/>, where the source code, numerical results for several classical combinatorial problems and related papers can be downloaded. The distribution also includes converters and heuristics for some specific problems.

The evaluation of each node can be made independently from the other ones, making *BiqCrunch* a good candidate for parallel computing. However, the shape of the search tree developed by the branch-and-bound procedure does not immediately extract an optimal level of parallelism.

In this paper, we propose a two-level parallel execution, mixing parallel, low-level computation kernels and task-based, coarser-grained parallelism, to adapt the degree of parallelism at each level of granularity. After a quick review of the literature on related works, we describe *BiqCrunch* and how it can be parallelized in section II. We evaluate the performance exhibited by each level of parallelism, and its consequence on the overall performance (including the numerical effects of the reorganization of the computation) in section III. Moreover, we compare the new parallel version with the sequential version of the solver by solving three classical NP-hard combinatorial problems (Max-Cut, Max-Independent-Set, and Max- $k$ -Cluster). Last, we discuss the results and open perspectives in section IV.

## II. MULTITHREADED BRANCH-AND-BOUND

The choices we made for *MLTBiqCrunch* are inspired by previous works. For instance, a performance comparison is available in [12] between multi-core and many-core systems by solving big optimization problems with a Branch-and-Bound algorithm. Another branch-and-bound implementation is described in [8] using multi-GPU systems. While the previous papers are related to multi-CPU systems on one hand and to multi-GPU systems on another hand, [13] implements a Branch-and-Bound for heterogeneous architectures (both multi-CPU systems with GPU accelerators).

Nevertheless, the solver *BiqCrunch* has specific characteristics and features that should be taken into account. First, it was initially designed to be used on a standard personal computer, i.e. with a limited amount of memory and up to 8 cores. Second, the nonlinear relaxations used in *BiqCrunch* have a higher computational cost (from several seconds to several minutes) compared to other bounds used generally in Branch-and-Bound-like algorithms (such as linear programming for

instance). On the other hand, high-quality bounds are obtained here and therefore one can expect a small number of nodes to evaluate. Previous experiments with *BiqCrunch*2.0 show that actually, even for difficult combinatorial problems, this number is at most a few hundred. This means that the communication cost will be limited in a parallel version if the grain corresponds to one node evaluation.

However, the bounding procedure of *BiqCrunch* can be very fast since the quality of the relaxation is adjustable. Thus it may be hazardous to allocate many threads to evaluate a given node if other nodes are ready to be evaluated.

#### A. Single-threaded branch-and-bound

*BiqCrunch* is mainly written in C, and makes calls to Fortran libraries. The code actually makes heavy use of linear algebra functions (LAPACK [14] or the Intel Math Kernel Library (MKL)), it includes the nonlinear optimization routine L-BFGS-B [15], [16], and it is provided with an updated version of the branch-and-bound platform BOB [17]. Nevertheless, the current version of *BiqCrunch* uses only the serial features of the platform BOB (i.e. one core is used), although the latter is precisely designed to implement Branch-and-Bound-like algorithms that take advantage from the benefits of parallelism.

When branching on variable  $z_i$  in problem (1), the BOB branch-and-bound platform [17] creates two new subproblems (nodes of the search tree), one where  $z_i$  is fixed to 0 and the other where  $z_i$  is fixed to 1. The subproblem that has the weakest bound (among all the nodes previously inserted into the global priority queue) is then selected to be the next subproblem to branch on. In the case of a tie, BOB selects the subproblem which is lower in the search tree (i.e., having the larger number of fixed variables).

At iteration  $k$  of the bounding procedure, the algorithm computes a bound  $F_k$  of all the feasible solutions of the subtree, and takes advantage of the fact that the optimal value of the combinatorial problem is an integer. Hence, if  $F_k < \beta_k + 1$ , then the node of the branch-and-bound tree is pruned, where  $\beta_k$  is the current best feasible solution (since all feasible solutions of the subproblem have an objective value no better than  $\beta_k$ ). If this is not the case, then the branch-and-bound tree needs to be explored further.

The bounding procedure of *BiqCrunch* enjoys some nice features. It can actually be fast to run if the node is easy to prune, but is also able to provide tighter but more expensive bounds if necessary. Moreover, it stops when it is likely that a bound which is lower than  $\beta_k + 1$  cannot be reached within a reasonable amount of time. The bounding procedure can be stopped anytime and will always return a valid upper-bound for the problem, thanks to duality properties (see [11]). Therefore, the computation times to evaluate the nodes are bounded, and this bound can be chosen. In addition, generic or specific heuristics take advantage of the fractional solution computed by the relaxation to build a feasible solution for the initial combinatorial problem (1), in order to try improving the current best feasible solution. This is done several times

in the bounding procedure (for further details see Section 4.2. and Algorithm 3 in [1]).

The *BiqCrunch* solver stores the input problem matrices in a sparse format in memory to keep its memory requirements small. Moreover the memory usage of the nonlinear optimization routine L-BFGS-B is very low and optimized. Typically, a problem with 225 variables and 32206 constraints (which involves a  $226 \times 226$  symmetric matrix, i.e. 25425 variables, to store the underlying relaxation variables) requires at most 32 MB to be solved. In order to design a parallel version of *BiqCrunch*, thanks to this very limited amount of memory, allocating a private working memory space for each thread is a simple and still low-cost solution, even on a standard personal computer.

#### B. Multithreaded computation kernels

*BiqCrunch* uses linear algebra kernels intensively: in particular, profiling data showed that it spends about 60% of execution time in `dsyevr`, which is itself spending about 20% of the total execution time in `dsytrd`. Therefore, the most basic step to take advantage of multicore architectures is to use multithreaded routines.

This is a fine-grain, low-level parallelism. This approach follows a *fork/join model*. Computation outside of the BLAS/LAPACK routines is sequential. Besides, each call to a routine has to pay the cost of spawning new threads and joining them at the end. Therefore, this parallelization model might not be sufficient.

#### C. Task-parallelism

We have seen in section II-A that the branch-and-bound procedure creates a tree: the branch-and-bound search tree. Each node of this tree can create (or not) subproblems. Each of these subproblems forms a node, that can be computed independently from the other ones. Compared with the approach using multithreaded computation kernels, this is a coarser-grain parallelism.

When generated, nodes of the search tree are put in a queue. When an idle thread is available, it pops a node from the queue and evaluates it. Therefore, this approach follows a *task-based parallelism model*. The priority system provided by BOB handles different priorities between the different nodes and, therefore, the different parallel tasks.

When the current best solution is updated (e.g. when an optimal solution is found), nodes with a evaluation which is not as good are removed from the queue by the BOB platform. Moreover, the other threads that are working may also stop their evaluation if their node can be pruned using this new bound (since the bounding procedure provides valid bounds during all the evaluation process : see remark section II-A).

At the beginning of the computation, only one node exists and therefore, only one thread is computing. As new nodes are generated, more threads can compute them in parallel. Therefore, the level of parallelism increases as nodes are generated. This approach is efficient when the problem generates

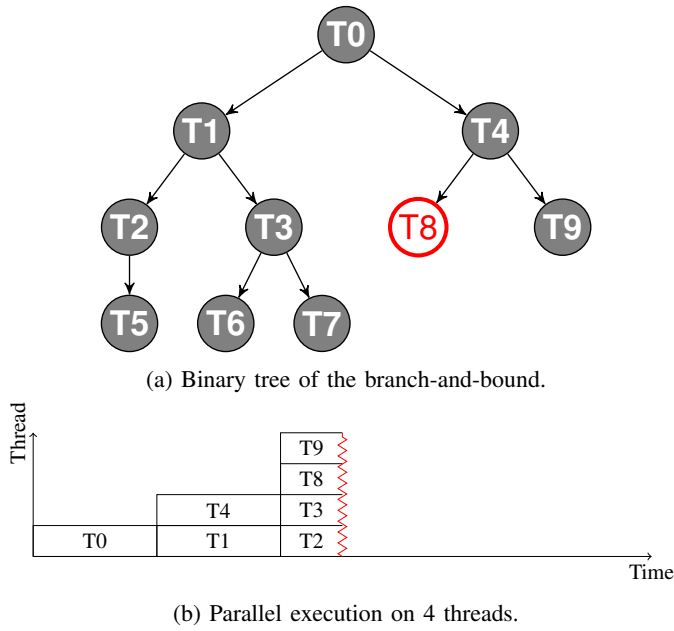

Fig. 1: Computation of a tree that generates 7 tasks, where the optimum is found on task T8.

a large number of nodes, in order to amortize the low level of parallelism of the initial phase.

A short example is given in Figure 1. The initial node T0 generates two nodes T1 and T4. The sequential version (represented by the tree in Figure 1a) computes the nodes in the numerical order indicated (from 1 to 9) if we assume that the value of their evaluation implies it : the branch-and-bound does a best-first search, so if T2 has a better evaluation than T4, T2 will be chosen first. The optimum is found on T8 : the sequential version has already evaluated T5, T6 and T7 whereas the parallel version (Figure 1b) has not, and potentially stops the execution of T2, T3 and T9 because the best solution has been updated.

A drawback of this approach is possible load unbalance. If a node takes significantly longer than the other ones to be computed, it can delay the whole computation while the other threads are waiting for it to complete. However, in practice, this case does not happen and several mechanisms guarantee bounded evaluation times and roughly equivalent computation time (see section II-A).

#### D. Two-level parallelization

In order to improve the exploitation of the multiple core platform when the branch-and-bound tree has not generated enough nodes to keep them all busy, both previous approaches can be combined together in a *hierarchical parallelization*. The core idea is to use multiple threads to evaluate a node when threads are idle, and one thread when there are enough nodes to assign one to each thread.

A possible schedule is given by Figure 2 (note that the tasks are not necessarily related to the ones on Figure 1). At the beginning of the computation, only one node exists

Fig. 2: Possible (perfect) thread occupation of 9 tasks on 4 threads with hierarchical parallelism.

in the branch-and-bound tree. Therefore, all the threads are used to evaluate it. It generates two nodes: each of them is evaluated on two threads. These nodes generate four nodes in total, which is equal to the number of threads: each node is evaluated on a single thread. At the end, the tree narrows and only two nodes are generated, evaluated on two nodes each.

Choosing the number of threads to evaluate a node is not trivial. If some threads are idle when a node evaluation begins, later during the evaluation of this node, other nodes might be generated and need these threads to compute them. In our system, coarse-grain parallelism has a higher priority than the fine-grain one on thread occupation. Therefore, idle threads are assigned to new node evaluation rather than on multithreaded node evaluation. Various heuristics can be defined to determine the number of threads to be used to compute a given task.

### III. PERFORMANCE EVALUATION

We evaluated and compared the performance of our implementation of the algorithms described in section II. In particular, we compared their scalability and raw performance. The problem instances are described thoroughly and the numerical results obtained with the current version of *BiqCrunch* are given on the *BiqCrunch* website.

#### A. Scalability

We limited the number of cores used by the multithreaded *BiqCrunch* and multithreaded BLAS in order to avoid using too many cores. In particular, if our heuristic makes *BiqCrunch* choose to use a number of cores for the BLAS routines such that, later, new tasks are executed and the total number of threads used exceeds the number assigned to *BiqCrunch*, the system limits *BiqCrunch* in such a way that it does not use more cores than indicated.

We used a 32-core machine that features two Intel Xeon CPU E5-2630 v3 running at 2.4 GHz and 32 GB of RAM. The machine runs a Linux 3.16.0 kernel. All the code was compiled using the GNU gfortran and gcc 4.9.2 compilers with -O3 optimization flag. We compiled the code against OpenBLAS 0.2.12 and LAPACK 3.5.0. *BiqCrunch* provides L-BFGS-B version 3.0, that calls LINPACK and BLAS routines provided

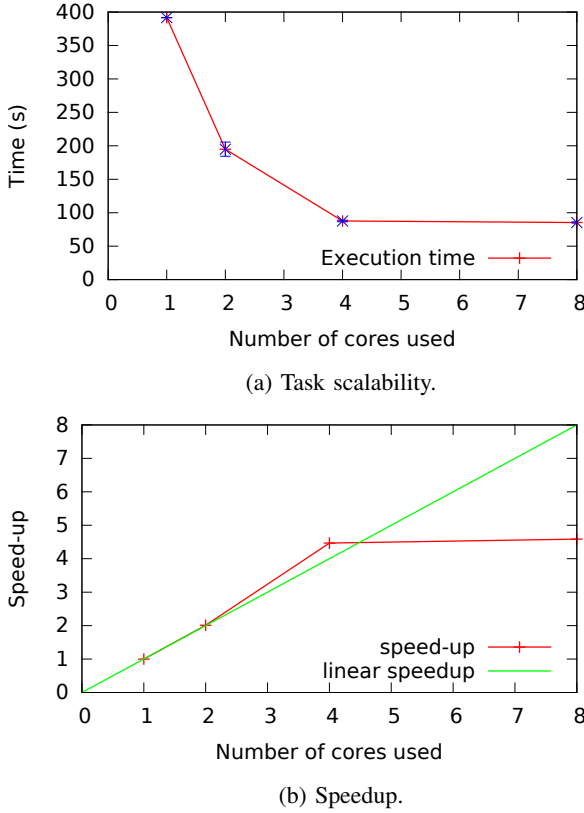

Fig. 3: Scalability with the brock-200-4 problem.

with the source code. We modified it in order to call routines from the BLAS and LAPACK libraries installed on our system (with a wrapper to call equivalent LAPACK routines instead of the LINPACK ones).

*a) Task parallelism:* The performance of *BiqCrunch* increases when threads are added to the computation (see section III-C). We evaluated the scalability of the multithreaded computation (one thread per node of the search tree) on various problems. For instance, Figure 3 presents the scalability (Figure 3a) and the speedup (Figure 3b) obtained by the computation of *brock-200-4*, a Max-Independent Set problem with  $n = 200$  issued from the DIMACS challenge that maximizes the total weight of the vertices in the independent set.

We can see that it scales well, up to a certain number of threads. Unlike small problems, this problem is not limited by the number of nodes in the search tree: it evaluates 185 nodes. Therefore we believe that the scalability is limited by thread management and synchronization costs.

However, this approach faces a strong limitation: in practice, some problems generate only a few nodes, or even only one. If the optimal solution is found on the first node, evaluating nodes in parallel is completely useless, because the one and only node is evaluated by one thread.

*b) Multithreaded computation kernels:* In order to take advantage of the multiple cores available even when the structure of the search tree does not allow enough parallel

tasks (as described in section II-C), we called the BLAS routines using multiple threads. However, on small instances, experimentally, the performance is roughly the same using 1 to 10 threads.

*c) Hybrid parallelism:* We evaluated the performance of the hybrid approach in two contexts: with a number of tasks (used to evaluate the nodes) equal to the number of cores used (a configuration similar to the one presented by Figure 2), and with a number of nodes smaller than the number of cores and several threads per node. The latter configuration tries to scale beyond the scalability limits of the node parallelism by assigning several threads to evaluate one node: if solving the problem scales up to 16 node evaluations in parallel, we assigned two threads per node in order to use 32 cores in total: it is a nested parallelism approach. The former uses several threads per node when some threads are idle because the search tree has not generated enough nodes to keep them busy: it is close to a greedy approach.

Figure 4 presents the scalability of solving the *bqp-250-6* problem (a pure binary quadratic problem with  $n = 250$ , available in the OR-library and *BiqMac* libraries, and used in [18], [19]) using half of the idle threads per node evaluation. We can see that it scales poorly. We have limited to 8 threads, since the nodes' queue list is never longer. We analyzed the execution of *BiqCrunch* and we noticed that, because of the asynchronous nature of the scheduling of the threads that evaluate the nodes, *BiqCrunch* tends to use more threads than the number of cores assigned to the computation (recall that we limited the number of cores available for each run, for fairness purpose).

In Figure 6, we are presenting the performance obtained by the *brock-200-4* problem with 2 threads per node evaluation.

We can see that it “extends” the scalability of the parallel implementation, but the overall performance is only a few percent better than with one thread per node evaluation (Figure 3a). It can possibly be explained by the relatively small speedup obtained by using multithreaded node evaluation in general.

In order to set the balance between the two levels of parallelism, we used performance profiles [20]. Figure 5 gives the performance profiles obtained for a set of 45 Max- $k$ -Cluster problems with  $n = 100$  used in several papers (e.g. [21]) and publicly available on the *BiqCrunch* website. The number of threads assigned to BLAS during the node evaluation ranges from 1 (sequential BLAS) up to 8 (in this case all the nodes are evaluated sequentially and BLAS uses all the cores). If one considers a set  $\mathcal{S}$  of problems used to benchmark the solvers, then for each problem  $p \in \mathcal{S}$ , we define  $t_p^{\min}$  as the minimum time required to solve  $p$  over all the solvers. Then, for each solver, we consider the performance profile function  $\theta$ , which is defined as

$$\theta(\tau) = \frac{1}{|\mathcal{S}|} |\{p \in \mathcal{S} : t_p \leq \tau t_p^{\min}\}|, \quad \text{for } \tau \geq 1, \quad (2)$$

where  $t_p$  is the time required for the solver to solve problem  $p$ .

(a) Task scalability.

(b) Speedup.

Fig. 4: Scalability with the bq-p250-6 use-case with half of the idle threads per node evaluation.

(a) Task scalability.

(b) Speedup.

Fig. 6: Scalability with the brock-200-4 problem with 2 threads per node evaluation.

Fig. 5: Performance profiles using different balancings of the hybrid approach. Each curve  $\theta(\tau)$  corresponds to a given setting (from 1 up to 8 threads assigned to BLAS).

The function  $\theta$  is therefore a cumulative distribution function, and  $\theta(\tau)$  represents the probability of the solver to solve a problem from  $\mathcal{S}$  within a multiple  $\tau$  of the minimum time required by all solvers considered. These results confirm the one obtained in Figure 6: the best choice is to run the BLAS

routines using at most two threads.

### B. Numerical issues

For now, the two-level parallelism is still not fully satisfactory. We have noticed that using the current parameters (e.g. tolerance) of the linear algebra functions, the multithreaded version of BLAS tends to be numerically unstable when the underlying nonlinear relaxation is very tight (see [11] for further details about how adjusting the tightness of the relaxation). We have improved this stability by setting new values, but a lot of factors come into play here.

First, there is a "giving up" function in the bounding procedure that stops the evaluation of a node when the progress of L-BFGS is too small compared to the value of the best current feasible solution. Consequently, this can occur at a different moment of the computation if a different number of threads are allocated to the BLAS functions.

Second, the branching procedure actually depends on the fractional solution to select the variable to branch on, and these values can be slightly different when using the multithreaded version of BLAS. Nevertheless, for most problems, it must be pointed out that this second parallelization level does not improve a lot the solver performance. Indeed, the proportion of computation time during which the number of nodes in the queue is smaller than the number of threads is often negligible (except for "easy" problems). Consequently, for

difficult problems (i.e. that require a large number of node evaluations), each thread will be kept busy most of the time. Hence, it is possible to avoid these issues by using only a one-level parallelization (i.e. one thread corresponds to one node evaluation). But of course, we must investigate in depth the reasons behind this numerical instability to address the problem: this is an ongoing work.

### C. Performance comparison and computational results

In this section, we present computational results obtained for three classical NP-hard combinatorial problems that can be stated as 0-1 quadratic programs. All the tests are run using the same computer: a DELL T-1600 equipped with an Intel Xeon E3-1270 CPU running at 3.40GHz with 8 cores. The same parameters (see the *BiqCrunch* documentation) are set for both solvers except for the number of cores: *BiqCrunch2.0* uses a single core and *MLTBiqCrunch* uses four cores (except in Figure 7 where the number of cores ranges from two to eight).

We chose instances that are not solved at the root of the search tree by *BiqCrunch*, and thus are relevant in our context. All the problems are publicly available and have been used by several authors [18], [21] (see the *BiqCrunch* website <http://lipn.univ-paris13.fr/BiqCrunch/> for further details and references).

In the Max-Independent-Set (MIS) problem (see Table I), we are given a graph  $G = (V, E)$  with vertex weights  $w_i$ , and the objective is to maximize the total weight of the vertices in an independent set (a set  $S$  of vertices having no two vertices joined by an edge in  $E$ ):

$$\begin{aligned} & \text{maximize} && \sum_i w_i z_i \\ \text{(MIS)} & \text{subject to} && z_i z_j = 0, \quad \forall (i, j) \in E \\ & && z \in \{0, 1\}^n. \end{aligned} \quad (3)$$

In the Max- $k$ -Cluster problem (see Tables II, III), we are given an edge-weighted graph with  $n$  vertices and a natural number  $k$ , and the objective is to find a subgraph of  $k$  nodes having maximum total edge weight:

$$\begin{aligned} & \text{maximize} && \frac{1}{2} \sum_{i,j} w_{ij} z_i z_j \\ \text{(Max-}k\text{-Cluster)} & \text{subject to} && \sum_{i=1}^n z_i = k \\ & && z \in \{0, 1\}^n. \end{aligned} \quad (4)$$

In the Max-Cut problem (see Tables IV, IV, VI, VII, VIII, IX), we are given an edge-weighted graph with  $n$  vertices, and the objective is to maximize the total weight of the edges between a subset of vertices and its complement:

$$\begin{aligned} \text{(Max-Cut)} & \text{maximize} && \sum_{i,j} w_{ij} z_i (1 - z_j) \\ & \text{subject to} && z \in \{0, 1\}^n. \end{aligned} \quad (5)$$

*MLTBiqCrunch* is always faster and in some cases it generates fewer nodes. In some other cases (for example *brock200\_1*) the optimal solution is found late in the traversal of the search tree; that explains the much larger number of nodes for *MLTBiqCrunch*. Let us to point out that solving this problem requires only 47 MB with *MLTBiqCrunch*. It involves 200 binary variables (20 100 for the underlying relaxations) and 5267 equality constraints.

When using *MLTBiqCrunch*, we have observed a super-linear speedup for several problems, especially for the most difficult instances (see Table III). Actually, as pointed out in Section II-C, the current best feasible solution can be updated earlier (maybe several times) and therefore, fewer nodes are generated in the search tree. Moreover, since the bounding procedure can be interrupted at any time, a superlinear speedup can even occur with the same number of nodes in the search tree when several bounding procedures are stopped earlier at the same time.

Fig. 7: Performance profiles of *BiqCrunch2.0* and *MLTBiqCrunch* (each curve  $\theta(\tau)$  corresponds to a given number of threads).

In Figure 7, we illustrate the expected performance from a standard user point of view when using *MLTBiqCrunch* instead of *BiqCrunch* (the current version is *BiqCrunch2.0*). This figure gives the performance profiles [20] obtained for the set of problems used in Figure 5. Obviously, increasing the number of threads improves the performance profiles of the solver. Recall that now BLAS uses at most two threads, and thus all the additional free cores are assigned to evaluate the available nodes in the queue.

branch-and-bound solver. We have seen that a coarse-grain, task-based approach gives a satisfying speed-up, but is limited by the start-up phase of the computation, when the search tree is not wide enough to take advantage of all the available cores. On the other hand, we have seen that a fine-grain, kernel-level parallelization is too fine-grained to give a good speed-up, even in these phases.

Although the evaluation of each node is hardly data-parallel, parallelizing the evaluation of each node is an interesting approach that deserves some consideration. The bigger granularity of this approach might give better results than the one

based on multithreaded computation routines, would the data dependencies allow it.

Overall, the coarse-grain, node-level parallelization presents good results, with a satisfying speed-up on large problems that generate a non-trivial number of nodes. Large instances can be solved in less than an hour, which is very positive: these instances can be solved in reasonable time on a desktop workstation. Smaller instances can already be solved in reasonable time, so they are not the core target of *MLTBiqCrunch*, which aims at making it possible to solve 0-1 quadratic problems on mainstream desktop computers. In that sense, the multi-threaded version we are presenting here fulfills this goal.

Quite surprisingly, we have noticed that the small loss of precision suffered by parallel computation routines, due to the reorganization of the computation in the kernels, can affect the branch-and-bound computation dramatically, causing a slower convergence or, more annoyingly, creating extra nodes in the search tree. The numerical stability and accuracy of the parallel computation routines is therefore of major importance. Another perspective for future works consists in exploring the gain provided by extended-precision or arbitrary-precision routines, such as MPACK [22] or xBLAS [23].

**Abstract**—The berth allocation problem (BAP) in marine container terminals is defined as the feasible berth allocation to the incoming vessels. In this work, we develop a model of fully fuzzy linear programming (FFLP) for the continuous and dynamic BAP. The vessel arrival times are assumed to be imprecise, meaning that the vessel can be late or early up to a threshold permitted. Triangular fuzzy numbers represent the uncertainty of the arrivals. The model proposed has been implemented in CPLEX and evaluated for different instances. The results obtained show that the model proposed is helpful to the administrators of a marine container terminal, since a plan supporting imprecision in the arrival time of vessels, optimized with respect to the waiting time and easily adaptable to possible incidents and delays, is available to them.

## I. INTRODUCTION

In this work, we approach the berth allocation problem (BAP), a NP-hard problem of combinatorial optimization [1], consisting in the allocation for every incoming vessel its berthing position at the quay. Once the vessel arrives to the port, it comes a waiting time to be berthed at the quay. The administrators of Marine Container Terminal (MTC) must face with two related decisions: where and when the vessels have to be berthed.

The actual times of arrivals for each vessel are highly uncertain depending this uncertainty, for example, on the weather conditions (rains, storms), technical problems, other terminals that the vessel have to visit and other reasons. The vessels can arrive earlier or later their scheduled arrival time [2], [3]. This situation affects the operations of load and discharge, other activities at the terminal and the services required by costumers. The administrators of MTC change or reviews the plans, but a frequent review of the berthing plan is not a desirable thing from a planning of resources point of view. Therefore, the capacity of adaptation of the berthing plan is important for a good system performance that a MTC manages. As a result, a robust model providing a berthing plan that supports the possible early or lateness in the arrival time of vessels and easily adaptable is desirable.

There are many types of uncertainty such as the randomness, imprecision (ambiguity, vagueness), confusion. Many of them can be categorized as stochastic or fuzzy [4].

The fuzzy sets are specially designed to deal with imprecision.

The simulation is done in the MTC of the port of Valencia, the use of stochastic optimization models is difficult because there are no distributions of probabilities of the delays and advances of the vessels. We assume that the arrival times of vessels are imprecise, for every vessel it is necessary to request the time interval of possible arrival, as well as the more possible time the arrival occurs.

In this work, we present a model of fuzzy optimization for the continuous and dynamic BAP. This paper is organized as follows: In Section II, we present a review of literature related to the BAP under imprecision. Subsequently, in Section III, we describe the basic concepts of the work procedure. In Section IV, we propose the model of fuzzy optimization to the berth allocation problem with imprecision in the arrival of vessels. In Section V, we employ a methodology to resolve the model. In Section VI, we evaluated the model. Finally, in Section VII, we present the conclusions and future lines of research.

## II. STATE OF THE ART

There are many attributes to classify the models related to the BAP [5]. The most important are: spatial and temporal. The spatial attribute can be discrete or continuous. In the discrete case, the quay is considered as a finite set of berths, where segments of finite length describe every berth and usually a berth just works for a vessel at once; for the continuous case, the vessels can berth at any position within the limits of the quay. The temporal attribute can be static or dynamical. In the static case, all the vessels are assumed to be at the port before performing the berthing plan; for the dynamical case, the vessels can arrive to the port at different times during the planning horizon.

In [5], the authors make an exhaustive review of the literature existing about BAP. To our knowledge, there are very few studies dealing with BAP and with imprecise (fuzzy) data.

A fuzzy MILP (Mixed Integer Lineal Programming) model for the discrete and dynamic BAP was proposed in [6]. Triangular fuzzy numbers represent the arrival times of vessels. The model and design of a method for parametric

MILP-based solutions are presented there, but the evaluation is not shown. In the previous model, they do not address the continuous BAP. According to Bierwith [5], to design a continuous model, the planning of berthing is more complicated than for a discrete one, but the advantage is a better use of the space available at the quay.

In [7], a MILP fuzzy model for the continuous and dynamic BAP was proposed, this model assigns slacks to support possible delays or earliness of vessels but it also has an inconvenience: if a vessel arrives early or on time, the next vessel has to wait all the time considered for the possible earliness and delay. This represent a big waste of time without the use of the quay and the vessel has to stay longer than is necessary at the port.

In this work, we present a new model for the continuous and dynamic BAP that solves the problem of the previous model. This model is formulated as a fully fuzzy linear programming problem (FFLP), wherewith we obtain robust berthing plans supporting imprecision (earliness or delay) of vessels without generating unnecessary waiting times.

### III. PRELIMINARIES

The concepts about fuzzy sets, fuzzy arithmetic and possibility distributions are taken from [8].

#### A. Fuzzy Sets

**Definition 1.** Let  $X$  be the universe of discourse. A fuzzy set  $\tilde{A}$  in  $X$  is a set of pairs:  $\tilde{A} = \{(x, \mu_{\tilde{A}}(x)), x \in X\}$ , where  $\mu_{\tilde{A}}: X \rightarrow [0,1]$  is called the membership function and  $\mu_{\tilde{A}}(x)$  represents the degree that  $x$  belongs to the set  $\tilde{A}$ .

In this work, we use the fuzzy sets defined on real numbers,  $\mathbb{R}$ . A membership function can be triangular, trapezoidal, sigmoidal, quadratic, etc.

**Definition 2.** A fuzzy set  $\tilde{A}$  in  $\mathbb{R}$  is normal if  $\max_x \mu_{\tilde{A}}(x) = 1$ .

**Definition 3.** The fuzzy set  $\tilde{A}$  in  $\mathbb{R}$  is convex if and only if the membership function of  $\tilde{A}$  satisfies the inequality  $\mu_{\tilde{A}}(\beta x_1 + (1 - \beta)x_2) \geq \min[\mu_{\tilde{A}}(x_1), \mu_{\tilde{A}}(x_2)]$ ,  $\forall x_1, x_2 \in \mathbb{R}, \beta \in [0,1]$ .

**Definition 4.** A fuzzy number is a normal and convex fuzzy set in  $\mathbb{R}$ .

**Definition 5.** A triangular fuzzy number (TFN) (see Fig. 1) is represented by  $\tilde{a} = (a_1, a_2, a_3)$

Fig. 1. Triangular fuzzy number

#### B. Fuzzy Arithmetic

If we have the nonnegative triangular fuzzy numbers  $\tilde{a} = (a_1, a_2, a_3)$  and  $\tilde{b} = (b_1, b_2, b_3)$ , the operations of sum and difference are defined as follows:

$$\text{Sum: } \tilde{a} + \tilde{b} = (a_1 + b_1, a_2 + b_2, a_3 + b_3)$$

$$\text{Difference: } \tilde{a} - \tilde{b} = (a_1 - b_3, a_2 - b_2, a_3 - b_1)$$

#### C. Comparison of Fuzzy Numbers

The comparison of fuzzy numbers allows deciding between two fuzzy numbers  $\tilde{a}$  and  $\tilde{b}$  which is greater, but fuzzy numbers not always provide a totally ordered set just like real numbers do. All methods for the comparison of fuzzy numbers have advantages and disadvantages.

In this work, we use the method called First Index of Yagger [9]. This method uses the ordering function

$$\mathfrak{R}(\tilde{a}) = \frac{a_1 + a_2 + a_3}{3}$$

As a result,  $\tilde{a} \leq \tilde{b}$  when  $\mathfrak{R}(\tilde{a}) \leq \mathfrak{R}(\tilde{b})$ , that is,

$$a_1 + a_2 + a_3 \leq b_1 + b_2 + b_3$$

#### D. Distributions of Possibility

Imprecision can be represented by distributions of possibility [10]. These distributions allow us to formalize, in a reliable way, a very large amount of situations estimating magnitudes located in the future. The measure of possibility of an event can be interpreted as the degree of possibility of his occurrence. Among the various types of distributions, triangular and trapezoidal ones are most common. Formally, the distributions of possibility are fuzzy numbers; in this work, we use triangular distributions of possibility  $\tilde{a} = (a_1, a_2, a_3)$ , which are determined by three quantities:  $a_2$  is value with the highest possibility of occurrence,  $a_1$  and  $a_3$  are the upper and lower limit values allowed, respectively (see Fig. 1).

#### E. Fully Fuzzy Linear Programming

Fuzzy mathematical programming is useful to handle situations within optimization problems including imprecise parameters [11]. There are different approaches to the fuzzy mathematical programming. When the parameters and decision variables are fuzzy, the problem is formulated as a Fully Fuzzy Lineal Programming Problem (FFLP). There are many methodologies of solution to a FFLP [12]. Mostly of them, convert the original fuzzy model in a classical satisfactory model.

In this work, we use the method of Nasser et al. [13]. Given the FFLP problem

$$\max \sum_{j=1}^n \tilde{c}_j \tilde{x}_j$$

Subject to

$$\sum_{j=1}^n \tilde{a}_{ij} \tilde{x}_j \leq \tilde{b}_i, \forall i = 1 \dots m \quad (1)$$

Where parameters  $\tilde{c}_j, \tilde{a}_{ij}, \tilde{b}_j$  and the decision  $\tilde{x}_j$  are nonnegative fuzzy numbers.

$$\forall j = 1 \dots n, \quad \forall i = 1 \dots m$$

If all parameters and decision variables are represented by triangular fuzzy numbers,

$$\tilde{c}_j = (c1_j, c2_j, c3_j), \quad \tilde{a}_{ij} = (a1_{ij}, a2_{ij}, a3_{ij}),$$

$$\tilde{b}_i = (b1_i, b2_i, b3_i), \quad \tilde{x}_j = (x1_j, x2_j, x3_j)$$

Nasseri's Method transforms (1) into a classic problem of mathematical programming.

$$\max \Re \left( \sum_{j=1}^n (c1_j, c2_j, c3_j)(x1_j, x2_j, x3_j) \right)$$

Subject to:

$$\begin{aligned} \sum_{j=1}^n a1_{ij}x1_{ij} &\leq b1_i, \quad \forall i = 1 \dots m \\ \sum_{j=1}^n a2_{ij}x2_{ij} &\leq b2_i, \quad \forall i = 1 \dots m \\ \sum_{j=1}^n a3_{ij}x3_{ij} &\leq b3_i, \quad \forall i = 1 \dots m \end{aligned}$$

$$x2_j - x1_j \geq 0, \quad x3_j - x2_j \geq 0, \quad \forall j = 1 \dots n$$

Where  $\Re$  is an ordering function (See Section III.C.)

#### IV. FFLP MODEL FOR THE BERTH ALLOCATION PROBLEM

In this section, we present the notation to the main parameters used in the model (see Fig. 2).

$L$ : Total length of the quay at the MTC

$H$ : Planning horizon

Let  $V$  be the set of incoming vessels, the problem data for each vessel  $i \in V$  are given by:

$a_i$ : Arrival time at port.

$l_i$ : Vessel length

$h_i$ : Handling time of the vessel in the berth. (service time).

With these data, the decision variables  $m_i$  and  $p_i$  must be obtained

$m_i$ : Berthing time of vessel.

$p_i$ : Berthing position where the vessel will moor.

With the data and decision variables are obtained  $\omega_i$  and  $d_i$

$\omega_i = m_i - a_i$ : Waiting time of vessel since the arrival to the berthing.

$d_i = m_i + h_i$ : Departure time

We consider the next assumptions: All the information related to the waiting vessels is known in advance, every vessel has a draft that is lower or equal to the draft of the quay,

Fig. 2. Representation of a vessel according to the time and position

the berthing and departures are not time consuming, simultaneous berthing is allowed, safety distance between vessels is not considered.

The objective is to allocate all vessels according to several constraints minimizing the total waiting time, for all vessels.

The arrival times, berthing times and departure times of the vessel are considered to be of fuzzy nature (imprecise) and denoted by  $\tilde{a}$ ,  $\tilde{m}$ , and  $\tilde{h}$ , respectively.

Based on the deterministic model [14] and assuming the imprecision of some parameters and decision variables, we propose the following fuzzy model optimization.

$$\min \sum_{i \in V} (\tilde{m}_i - \tilde{a}_i) \quad (2)$$

Subject to:

$$\tilde{m}_i \geq \tilde{a}_i \quad \forall i \in V \quad (3)$$

$$p_i + l_i \leq L \quad \forall i \in V \quad (4)$$

$$p_i + l_i \leq p_j + M(1 - z_{ij}^x) \quad \forall i, j \in V, i \neq j \quad (5)$$

$$\tilde{m}_i + \tilde{h}_i \leq H \quad \forall i \in V \quad (6)$$

$$\tilde{m}_i + \tilde{h}_i \leq \tilde{m}_j + M(1 - z_{ji}^y) \quad \forall i, j \in V, i \neq j \quad (7)$$

$$z_{ij}^x + z_{ji}^x + z_{ij}^y + z_{ji}^y \geq 1 \quad \forall i, j \in V, i \neq j \quad (8)$$

$$z_{ij}^x, z_{ij}^y \in \{0,1\} \quad \forall i, j \in V, i \neq j \quad (9)$$

In order to assign a vessel to the quay, the following constraints must be accomplished:

(3), the berthing time of vessel must be at least the same as the arrival time; (4), there must be enough space at the quay for the berthing; (5), at the quay, a vessel must be to the left or right side of another vessel; (6), the berthing plan must be within the planning horizon; (7), with regard to the time, a vessel berths after or before another one; (8), the constraints (5) y (6) must be accomplished.

Where  $z_{ij}^x$  is a decision variable indicating if the vessel  $i$  is located to the left of vessel  $j$  at the berth, ( $z_{ij}^x = 1$ ).

$z_{ij}^y = 1$  indicates that the berthing time of vessel  $i$  is before than vessel  $j$ .  $M$  is a large integer constant.

The planning horizon is given by

$$H = \sum_{i \in V} h_i + \max_{i \in V} a_{3i}$$

## V. SOLUTION TO THE FUZZY BAP MODEL

We assume that all the parameters and decision variables are linear and some diffuse, thus, we have a FFLP problem.

The arrival of every vessel is represented by a triangular possibility distribution  $\tilde{a} = (a1, a2, a3)$  (see Fig. 1), indicating the possibility of arrival in  $a2$ , but not before  $a1$ , or after  $a3$ . In a similar way, the berthing time is represented by  $\tilde{m} = (m1, m2, m3)$  and  $\tilde{h} = (h, h, h)$  is considered a singleton.

When representing parameters and variables by triangular fuzzy numbers, we obtain a solution to the fuzzy model proposed applying the methodology proposed by Nasseri, (see section III. E).

To apply this methodology, we use the operation of fuzzy difference on the objective function and the fuzzy sum on the constraints (see Section III.B.) and the First Index of Yagger as an ordering function on the objective function (see Section III.C.) obtaining the next auxiliary MILP model.

$$\min \sum_{i \in V} \frac{1}{3} ((m1_i - a3_i) + (m2_i - a2_i) + (m3_i - a1_i)) \quad (10)$$

Subject to:

$$m1_i \geq a1_i \quad \forall i \in V \quad (11)$$

$$m2_i \geq a2_i \quad \forall i \in V \quad (12)$$

$$m3_i \geq a3_i \quad \forall i \in V \quad (13)$$

$$p_i + l_i \leq L \quad \forall i \in V \quad (14)$$

$$p_i + l_i \leq p_j + M(1 - z_{ij}^x) \quad \forall i, j \in V, i \neq j \quad (15)$$

$$m1_i + h_i + M(1 - z_{ij}^y) \leq m1_j \quad \forall i, j \in V, i \neq j \quad (16)$$

$$m2_i + h_i + M(1 - z_{ij}^y) \leq m2_j \quad \forall i, j \in V, i \neq j \quad (17)$$

$$m3_i + h_i + M(1 - z_{ij}^y) \leq m3_j \quad \forall i, j \in V, i \neq j \quad (18)$$

$$m2_i - m1_i > 0 \quad \forall i \in V \quad (19)$$

$$m3_i - m2_i > 0 \quad \forall i \in V \quad (20)$$

$$z_{ij}^x + z_{ji}^x + z_{ij}^y + z_{ji}^y \geq 1 \quad \forall i, j \in V, i \neq j \quad (21)$$

$$z_{ij}^x, z_{ij}^y \in \{0, 1\} \quad \forall i, j \in V, i \neq j \quad (22)$$

## VI. EVALUATION

The experiments were performed in 50 instances, having each of them the data arrivals for 8 vessels during a day; the instances have been generated with a uniform distribution, in order to simulate the berths at TMC of Valencia's Port (Spain). In this TMC, the quay has an approximate length of 700 meters. All the instances have the same features for all vessels (time of service and length), as well as the most possible arrival time  $a_2$ . However, all instances have different values to the minimum and maximal arrival time allowed,  $a_1$  and  $a_3$ , respectively. The method has been coded and solved, in an optimum way, by using CPLEX. The instances were solved in a desk computer equipped with a Core (TM) i5-4210U CPU 2.4 Ghz with 8.00 GB RAM. The experiments were performed within a "timeout" of 60 minutes.

To report the data we use a new parameter also considered as fuzzy; the departure time of a vessel  $\tilde{d} = (d1, d2, d3)$ .

One instance is shown in Table I.

TABLE I  
EXAMPLE OF ONE INSTANCE

Vessels	Arrival time			$h$	$l$
	$a1$	$a2$	$a3$		
V1	4	8	34	121	159
V2	0	15	36	231	150
V3	18	32	50	87	95
V4	9	40	46	248	63
V5	32	52	72	213	219
V6	55	68	86	496	274
V7	62	75	90	435	265
V8	45	86	87	146	94

For example, the most probably arrival of vessel V1 is at 8 units of time, but it could be early or late up to 4 and 34 units of time, respectively.

The berthing plan obtained with the model is showed in Table II, and polygonal-shaped are showed in Fig. 3.

The berthing plan showed in Table II provides three berthing plans. The one we could call the most optimistic assuming all the vessel arrival occurring at the minimum time allowed, is showed in columns  $m1$  and  $d1$  from Table II. The optimum plan, when all vessels arrive precisely on time, is given by columns  $m2$  and  $d2$  from Table II. The pessimistic plan assuming that all vessels are delayed the maximum allowed time is given by columns  $m3$  and  $d3$  from Table II.

TABLE II  
BERTHING PLAN

Vessel	Berthing time			Service time $e$	Departure time			$l$	$p$
	$m1$	$m2$	$m3$		$d1$	$d2$	$d3$		
V1	4	8	34	121	125	129	155	159	63
V2	0	15	36	231	231	246	267	150	222
V3	18	32	50	87	105	119	137	95	605
V4	9	40	46	248	257	288	294	63	0
V5	32	52	52	213	245	265	285	219	372
V6	245	265	265	496	741	761	781	274	332
V7	231	246	246	435	666	681	702	265	63

Fig. 3. Fuzzy berthing plan in polygonal-shape

An appropriate way to observe the robustness of the fuzzy berthing plan is the polygonal-shape representation (see Fig. 3). The red line represents the possible early Berthing time; the green line, the possible late berthing time, the small triangle represents the optimum berthing time (with a greater possibility of occurrence) and the blue line represents the time that vessel will stay at the quay.

In the circle of Fig. 3, we observe an apparent conflict between the departure of vessel V2 and the berthing of vessel V6. The conflict is not such, if the vessel V2 is late, the vessel V6 has slack times supporting delays. For example, assume that vessel V2 is late 10 units of time; according to the Table II, the berthing occurs at  $m=15 + 10 = 25$  units of time and its departure occurs at  $d=25 + 231 = 256$  units of time. The vessel V6 can moor during this space of time, since according to Table II, its berthing can occurs between 245 and 285 units of time. This fact is observed in Fig. 4.

In order to analyze the robustness of the fuzzy berthing plan, we simulate the incidences showed in Table III.

Fig. 4. Delayed berthing of vessel V2

TABLE III  
INCIDENCES IN THE VESSEL ARRIVAL TIMES

Vessel	Time	Incidence
V1	13	delay
V2	15	delay
V3	0	on time
V4	18	earliness
V5	10	earliness
V6	8	earliness
V7	9	delay
V8	21	earliness

To obtain a feasible and optimum berthing plan supporting the incidences, we realize a rescheduling, obtaining the berthing plan shown in Table IV. In Fig. 5, we observe that the berthing plan obtained, is a part of the fuzzy plan obtained initially.

Fig. 6 illustrates the variation of the objective function (waiting time) for 50 instances. The average of the objective function is 409.76, that is, every day the 8 vessels have to wait a total of 409.76 units of time.

TABLE IV  
BERTHING PLAN WITH RESCHEDULING

Vessel	Berthing time (m)	Service time (h)	Departure time (d)	Length (l)	Position (p)
V1	21	121	142	159	63
V2	30	231	261	150	222
V3	32	87	119	95	605
V4	22	248	270	63	0
V5	42	213	255	219	372
V6	261	496	757	274	332
V7	261	435	696	265	63
V8	119	146	265	94	606

On the other hand, Fig. 7, shows the computer time variation to solve the 50 instances. The average computer time that uses CPLEX to solve one instance is 2.96 seconds.

Fig. 5. Berthing with rescheduling

Fig. 6. Objective function for 50 instances

## VII. CONCLUSION

Even though many investigations about BAP have been carried out, most of them assume that vessel arrivals are deterministic. This is not real, in practice there are earliness or delays in vessel arrivals. Thus, the adaptability of a berthing plan is important for the global performance of the system in a MTC.

The results obtained showed that the model, is useful to the MTC managers in decision-making, since they have different plans in case the vessels arrive late, on time or early up to the maximum allowed time. In case the vessels arrive early or late a shorter time of the maximum tolerance, the optimum plan can be adapted by making a rescheduling.

The model has been evaluated for 50 instances, each consisting of 8 vessels. The number of vessel is for illustrative purposes only, the model works in the same way for a large number of vessels.

The proposed model can be used when sufficient information is not available to obtain probability distributions on the arrival time of vessels that will allow posing a stochastic model.

Fig. 7: Computer time of 50 instances

Likewise it could be used when we want to do berthing plans on the basis of inaccurate information obtained in advance about the vessel arrivals. For every vessel it is necessary to request the time interval of possible arrival, as well as the more possible time the arrival occurs.

Finally, because of this research, we have open problems for future researches:

- To extend the model that considers the quay cranes to be assigned to every vessel.
- To use meta-heuristics to solve the fuzzy BAP model more efficiently, when the number of vessels is greater.

**Abstract**—This study introduces an electronic market model for secondary book markets in which each market participant can put up books for sale, and simultaneously place requests for book purchase. The model allows participants to declare a budget limit so that for each participant, the difference between the cost of purchased books and the revenue obtained from sold books stays within the declared budget limit. The model also allows participants to declare sets of substitutable books along with their preferences so that they can purchase at most one book from each of these sets. In this study, the mathematical definition of the market model is introduced, and the corresponding winner determination problem is formulated as a multi-objective linear integer program. Since this problem is NP-Hard, three heuristic methods are proposed and the performances of these methods are demonstrated on a comprehensive test suite. The results indicate that the model can be used efficiently in large-scale electronic markets in which durable goods are exchanged with tens of thousands of participants.

## I. INTRODUCTION

RECENT advances in information technology provided a shift from traditional physical markets where the participants meet at a certain place for exchanging commodities to the electronic markets. Electronic markets provide a platform bringing multiple buyers and sellers in contact by weakening space and time restrictions [1]. Therefore, an electronic market has the potential of attracting more participants than a physical market. For instance, eBay, the world's largest online market, has more than 160 million buyers globally [2] and Alibaba.com, the world's biggest business-to-business market has more than 400 million active buyers [3]. As the number of participants increases, the higher competition level among the suppliers causes increased supplier innovation [4]. An e-market can reduce buyers' search costs to obtain information about the product offerings of sellers [5], [6]. This increases the allocative efficiency of the market, i.e. the efficiency with which a market is allocating resources [7].

This study focuses on secondary electronic book markets, that is electronic markets for both used and new book trading. Secondary book markets play an important role in overall

economic activity with multi-billion dollars of transaction volumes. For instance, in the U.S., the transaction volume of the used book market was approximately \$2.2 billion in 2004, and online booksellers are responsible for two-thirds of the general interest used book sales [8]. Also, compared to physical markets, electronic book markets provide increased book variety. For instance, according to the study of Brynjolfsson et al. [9], amazon.com and barnesandnoble.com have 2.3 million books listed on their online markets whereas a typical brick-and-mortar bookstore has only 40,000 to 100,000 titles. Similarly, Wal-Mart supercenters which occupy an area of up to 230,000 square-feet have at most one-sixth of the available books in their online version, walmart.com.

In this paper, an electronic market model, called *EMBook model*, is proposed which is designed especially for secondary book markets for the trading of used books as well as new ones. In this model, market participants can have both buyer and seller roles, meaning that each participant can simultaneously put forward books for sale as well as declare requests for purchase. Thus, the market allows participants to spend the revenue to be obtained from the books they want to sell for the books they want to buy. The model also offers a budget limiting mechanism such that for each participant the amount spent on purchased books minus the revenue to be obtained from sold books does not exceed the declared budget limit of the participant. Thus, this model enables participants with limited budgets to purchase new books using the revenue from their books to be sold and also encourages them to participate in the market without a risk of having a budget deficit. Additionally, a participant may also be indifferent to multiple books, for instance there may be multiple sellers of the same book or the participant may be interested in a specific set of novels in a book market. The EMBook model further provides a mechanism for handling such situations so that in her purchase request, a participant can declare a list of substitutable books among which she wants to purchase only one. Furthermore, she is also allowed to indicate her preferences for the books she wants to purchase. By means of these features, the EMBook model aims to attract more participants to the used book

This work is supported by Marmara University, Scientific Research Projects Committee (BAPKO) under D-Type Project.

markets and to increase the allocative efficiency of such markets.

In the next section, the EMBook model is explained in detail on an example book market scenario. In Section III, the mathematical definition of the EMBook model is given, and the corresponding winner determination problem is formulated using multi-objective linear integer programming. The complexity results are also presented. Since the winner determination problem is NP-Hard, three heuristic methods are designed which are introduced in Section IV. The experimental results demonstrating the performances of the heuristic methods on a comprehensive test suite are presented in Section V. Finally, the paper is concluded in Section VI.

## II. THE EMBOOK MODEL

In this section, the EMBook market model and its rules are going to be introduced. In the EMBook model, each participant may sell and purchase books simultaneously, that is each participant may have a seller role, a buyer role or both. First of all, the participants with a seller role declare the books they want to sell along with the prices they request which are called *sales requests*. Thus, in this model, each book to be sold is considered as a unique item and its price is determined by its owner. This feature allows buyers to differentiate between the copies of the same book sold by different sellers, since, for instance, condition of the book, reputation of its seller, location of the seller and the associated transfer cost may vary.

Secondly, the participants with a buyer role declare the books they want to purchase which are called *purchase requests*. However, there may be multiple instances of the same book in the market (e.g. multiple copies sold by possibly different participants), or a participant may be indifferent to a number of different books (e.g. a set of novels). Considering these cases, the participants are allowed to declare one or more sets of books (called *request sets*) among which the participant can buy only one book. Each request set constructed by a participant indicates that the participant is interested in any book in this set, however, she is willing to buy only one of the books inside this set. Furthermore, if the participant is not totally indifferent to the books in the request set she declared, the request set may also be defined as an ordered set indicating the relative preferences of the participant for the books inside this set. That is, if the request set of a participant contains  $\{Book A, Book C, Book B\}$  in this particular order, the participant is assumed to prefer *Book A* over *Book C*, and *Book C* over *Book B*. Note that although the participant is limited to purchase only one book, this is not a limitation for a participant who wants to purchase more, since the model also allow submission of the same request more than once, that is the purchase requests are not needed to be unique in this model.

Thirdly, after the sale and purchase requests are collected, each participant with a buyer role declares a budget limit. The budget limit indicates the maximum amount of money that the participant is willing to spend in the market. If the participant has also a seller role, the budget limit indicates the maximum

difference between the expenditure and the revenue. In other words, for each participant the amount spent on the purchased books minus the revenue obtained from the sold books cannot exceed the budget limit of the corresponding participant.

In order to make the market process easier to understand, an example scenario which is illustrated in Figure 1 is provided. In this scenario, there are four participants who put up six books (*Book A* to *Book F*) for sale with prices ranging from €15 to €40. For instance, *Participant 1* wants to sell two books, *Book A* and *Book B*, for €30 and €20, respectively. Additionally, she wants to purchase either *Book C* or *Book D* indicating that she prefers *Book C* over *Book D*. For all possible outcomes, she declares that she is willing to spend at most €10. Since the price of each of *Book C* and *Book D* exceeds the budget limit of *Participant 1*, this participant cannot purchase any of these two books unless at least one of her books is sold in the market. Similarly, *Participant 2*, wants to sell two books, *Book C* and *Book D*. However, this participant has two purchase requests. She wants to purchase both *Book A* and one of the books from the set containing *Book E*, *Book F* and *Book B*. She also declares that she prefers *Book E* over *Book F*, and prefers *Book F* over *Book B*. Declaring a budget limit of 0 implies that her two purchase requests can only be satisfied if both of her books are sold.

The primary aim of the EMBook model is to increase the allocative efficiency of the book market by allowing participants to use revenue to be obtained from sold books for purchasing new books. The benefit of this feature can also be seen in this scenario. The budget limits of the participants do not allow them to purchase the books they want. Therefore, in traditional book markets, first they would have to sell their books, and then they would be able to purchase new books using the obtained budget. Thus, in this particular scenario, no participants would be able to buy a book. However, the market outcome of the EMBook model for this scenario is as follows:

- *Participant 1* sells *Book A* and buys *Book C* while spending €10 with a final budget of €0,
- *Participant 2* sells *Book C*, *Book D* and buys *Book A*, *Book E* while earning €25 with a final budget of €25,
- *Participant 3* sells *Book E* and buys *Book F* while spending €10 with a final budget of €0,
- *Participant 4* sells *Book F* and buys *Book D* while spending €5 with a final budget of €10

which yields a total transaction volume of €140. As also seen from the example, the model does not allow any participant to have a budget deficit after the market is cleared.

The implementation of the model is also straightforward. Within a predefined time period, sales and purchase requests are collected from the participants. At the end of this period, the market is cleared by solving the winner determination problem which is introduced in the next section. Unsatisfied requests of a participant can be transferred to the next round if the participant wants. The length of the rounds can be

	 wants to sell	 wants to buy	 with a budget limit
<b>Participant 1</b>	 Book A for €30 and Book B for €20	One of {Book C, Book D}	€10
<b>Participant 2</b>	 Book C for €40 and Book D for €30	{Book A} and One of {Book E, Book F, Book B}	€0
<b>Participant 3</b>	 Book E for €15	{Book F}	€10
<b>Participant 4</b>	 Book F for €25	One of {Book D, Book C}	€15

Fig. 1. An example scenario illustrating the EMBook electronic market model for book trading.

determined according to the number of participants and the rate of submission of requests in the market. The longer periods result in better allocative efficiency but they also cause less trading volume to occur per unit time, i.e. reduces the market throughput.

### III. MATHEMATICAL DEFINITION AND FORMULATION OF THE EMBOOK MODEL

The EMBook model is formally defined as follows: Let  $T = \{t_1, t_2, \dots, t_m\}$  be the set of  $m$  participants in the market and  $B_i$  be the set of books to be sold by participant  $t_i$  ( $1 \leq i \leq m$ ). The set of all books,  $B = \{b_1, b_2, \dots, b_n\}$ , is defined as  $B = \bigcup_{i=1}^m B_i$  ( $\forall i, i' \mid B_i \cap B_{i'} = \emptyset$ ). Note that in this model, each book is considered as a unique item. The tuple  $P = (p_{b_1}, p_{b_2}, \dots, p_{b_n})$  denotes the prices of the books where  $p_{b_j}$  is the price of the book  $b_j$  as declared by its owner ( $1 \leq j \leq n$ ,  $p_{b_j} \in \mathbb{R}^+ \cup \{0\}$ ). The budget limits of the participants are denoted by the tuple  $L = (l_1, l_2, \dots, l_m)$  where  $l_i$  is the budget limit of the participant  $t_i$  ( $l_i \in \mathbb{R}^+ \cup \{0\}$ ).

In the EMBook model, a purchase request,  $r_k = (r_{k1}, r_{k2}, \dots, r_{kz})$ , is an ordered set consisting of  $z$  books which are ordered according to the preferences of the request owner ( $1 \leq l \leq z, r_{kl} \in B$ ). That is,  $(r_{k1} \succ r_{k2} \succ \dots \succ r_{kz})$ ,

where  $r_{kx} \succ r_{ky}$  means that the request owner prefers book  $r_{kx}$  over book  $r_{ky}$ . The set of purchase requests submitted by the participant  $t_i$  is denoted as  $R_i$ , and the set of all purchase requests,  $R = \{r_1, r_2, \dots, r_v\}$ , is defined as  $R = \bigcup_{i=1}^m R_i$ .

The meaning of a purchase request can be stated as follows: By submitting a purchase request  $r_k$ , the participant  $t_i$  declares that she wants to purchase at most one of the books in  $r_k$ . The purchase request  $r_k$  is called *satisfiable* if there exists at least one book in the purchase request  $r_k$  which is available for purchase and the price of the book is within the budget of the participant. The budget of the participant  $t_i$  is defined as *proceeds of the sold books of  $t_i$  + budget limit of  $t_i$  - expenses of  $t_i$  for purchased books*. The *winner determination problem (WDP)* of the EMBook model is defined as finding the maximum cardinality set of mutually satisfiable purchase requests such that the weighted sum of the traded books is maximized.

In order to formulate the problem using linear integer programming, a binary variable  $x_{kl}$  is introduced. It denotes whether the book  $r_{kl}$  is purchased in the purchase request  $r_k$  (1) or not (0). The linear integer programming formulation of the winner determination problem is as follows:

$$\text{First Level: max } \sum_{\substack{r_k \in R \\ r_{kl} \in R_k}} w'_{kl} \cdot x_{kl}, \quad (1)$$

$$\text{Second Level: max } \sum_{\substack{r_k \in R \\ r_{kl} \in R_k}} w''_{kl} \cdot x_{kl} \quad (2)$$

$$\text{s.t. } \sum_{\substack{r_k \in R \\ r_{kl} \in R_k \\ r_{kl}=b_j}} x_{kl} \leq 1 \quad (b_j \in B) \quad (3)$$

$$\sum_{r_{kl} \in R_k} x_{kl} \leq 1 \quad (r_k \in R) \quad (4)$$

$$\sum_{\substack{r_k \in R_i \\ r_{kl} \in R_k}} p_{r_{kl}} x_{kl} - \sum_{\substack{r_k \in R \\ r_{kl} \in R_k \\ r_{kl} \in B_i}} p_{r_{kl}} x_{kl} \leq l_i \quad (t_i \in T) \quad (5)$$

$$x_{kl} \in \{0, 1\} \quad (\forall k, l) \quad (6)$$

where

$$w'_{kl} = \begin{cases} p_{r_{kl}} & \text{if } l = 0 \text{ or } w'_{k(l-1)} > p_{r_{kl}} \\ w'_{k(l-1)} & \text{otherwise} \end{cases}$$

and

$$w''_{kl} = \max_k |r_k| - l$$

In this formulation, Eq.(1) is the first level objective function which maximizes the weighted sum of the traded books according to the weights values  $w'_{kl}$ , and Eq.(2) is the second level objective function which again maximizes the weighted sum of the traded books, however, according to the weights values  $w''_{kl}$ . The objective functions are hierarchical, that is, the model should be optimized according to the first level objective, and then the second level objective. When optimizing the second level objective, only the solutions that would not degrade the objective value of the first level objective are considered. These two level objective functions cause the total trading volume to be maximized while taking the preferences of the participants in consideration which are declared in their purchase requests. This is achieved by assigning prices of the books as the weight values  $w'_{kl}$ , i.e. the weight values for the first level objective function, in order to maximize the total trading volume. However, if a participant prefers a cheap book over an expensive one in her purchase request, assigning the price of the expensive book as the weight value of that book would cause the model to assign the expensive book to the participant even if the cheaper one is also assignable. In order to prevent this kind of situations, the weight values  $w'_{kl}$  are determined such as they monotonically decrease for the books requested in the purchase request. Thus, the weight value of the expensive book would be same as the weight value of the cheaper alternative given that the participant prefers the cheaper book over the expensive one. The second level objective function breaks the tie between the books requested in a purchase request in which two or more books exist with the same weight value  $w'_{kl}$ .

Regarding the constraints, Eq.(3) ensures that each book can be purchased by at most one participant. Eq.(4) enforces that in each purchase request, at most one book will be purchased by the request owner. Finally, Eq.(5) is the budget constraint, that is for each participant the total cost of the purchased books minus the proceeds of the sold books should not exceed the budget limit of that participant.

The subset sum problem [10, p. 243] can be reduced in polynomial time to the winner determination problem, proving that the winner determination problem is NP-hard. Moreover, when the budget limits of all participants are 0, then the problem also becomes inapproximable. However, it is obvious that if at least one participant has enough budget to purchase at least one of the books in one of her requests, then finding a nonzero feasible solution becomes a polynomial-time problem. Also, at the other end, if budget limits of all participants allow them to purchase every book they want without using the revenue obtained from sold books, then the problem becomes a network problem and thus can be solved in polynomial-time. The proofs for these statements are provided for a similar model in the author's previous work [11].

#### IV. SOLUTION METHODS

Since the winner determination problem of the EMBook model is NP-hard, three heuristic methods were designed. The pseudocode for the first heuristic method, called *Forward-Satisfy (FS)*, can be seen in Alg. 1. In this method, first a list  $S$  of subrequests is generated based on the list of all of purchase requests  $R$  in the problem instance  $P$ . For instance, if a participant's request is  $\{\text{Book } C, \text{Book } A\}$ , two subrequests one for *Book C* and one for *Book A* are included in  $S$ . A subrequest is a data structure comprising the owner of the subrequest (*owner*), the requested book (*book*), the index of the subrequest in  $S$  (*index*), and the flag indicating whether the subrequest is satisfied or not (*satisfied*). After the list  $S$  is generated, all the subrequests in the list is marked as unsatisfied and the list is sorted in descending order according to a given sorting criterion. In this study, four different sorting criteria are tested. These criteria are:

- (i) the weights of the subrequests (Weight),
- (ii) the prices of the books (Price),
- (iii) weight-price ratios (Weight / Price), and
- (iv) the weight times price values (Weight \* Price).

In these sorting criteria, the value  $w'_{kl}$  is used as the weight value for each subrequest. However, if  $w'_{kl}$  values are equal for different subrequests, then comparisons are done based on the values  $w''_{kl}$  instead.

After the list  $S$  is sorted, the first subrequest in the list  $S$  (marked as the current subrequest) is checked whether it can be satisfied or not. A subrequest is satisfiable if:

- (i) the subrequest is not already satisfied,
- (ii) the owner of the subrequest has enough budget to purchase the book requested in the subrequest,
- (iii) any other subrequest in the same request is not already satisfied,

**Algorithm 1** ForwardSatisfy

---

**Input:** An EMBook problem instance  $P$ , a *SortingCriteria* for sorting subrequests

**Output:** A list  $S_{sol}$  of satisfiable subrequests

```

1: Generate a list  $S$  of subrequests in  $P$ .
2:  $S_{sol} \leftarrow \{\}$ 
3: Sort  $S$  according to SortingCriteria
4: Mark all subrequests in  $S$  as unsatisfied
5:  $sIndex \leftarrow 0$

(iv) the book requested in the subrequest is not already sold.

If the current subrequest is satisfiable (which is checked using *satisfiable* method), then it is committed, meaning that the budget of the request owner is decreased and the budget of the book owner is increased by the price of the book. Furthermore, the book requested in the current subrequest is also marked as sold. After that, the minimum index of the satisfiable subrequests of the owner of the book is found and compared to the index of the current subrequest. If the former is smaller, then the algorithm jumps to the former subrequest. If the latter is smaller, or if the current subrequest is not satisfiable at all, then the algorithm moves to the next subrequest in the list  $S$ . The algorithm terminates after the list  $S$  is traversed to the end.

In the FS method, a subrequest is enabled if the owner of the subrequest has enough budget to purchase the book requested in the subrequest. In the second proposed method, called *ForwardSatisfyWithIncome* (FSWI), if the subrequest owner has not enough budget to purchase the book, then the method tries to improve the income of the subrequest owner. The pseudocode of the FSWI method can be seen in Alg. 2. Thus, in the FSWI method, *satisfiabilityNBC* method (NBC stands

---

for NoBudgetCheck) is used to check the satisfiability of the current subrequest instead of *satisfiability* method used in the FS method. The *satisfiabilityNBC* method checks only satisfiability conditions (i), (iii) and (iv) listed above. Then, if the owner of the current subrequest does not have enough budget to purchase the book in the subrequest, the FSWI method tries to improve the budget of the subrequest owner by trying to satisfy incoming subrequests first, that is to commit the subrequests inside which one of the books of the current subrequest owner is requested. If by this process, the budget of the subrequest owner is fixed, then the current subrequest is committed, otherwise all the committed subrequests in this process are rolled back. The method continues with the next subrequest the index of which is determined in accordance with the smallest index of the satisfiable subrequests of the participants whose budget are increased when the current subrequest is committed as seen in lines 34-43 of Alg. 2.

Both FS and FSWI methods are forward traversing methods which start with an empty solution and construct a feasible solution by trying to satisfy the subrequests in the list  $S$  one by one without sacrificing feasibility. In the third proposed method, called *BackwardRollback (BR)*, the reverse approach is taken such that at first all the subrequests are committed producing most likely an infeasible solution. Then, the list of subrequests  $S$  is traversed in the reverse direction of the traversal direction of the forward methods. During the traversal, the current subrequest is checked whether it contributes to the infeasibility of the current solution. If so, then it is rolled back. It may be the case that after the current subrequest is rolled back, the owner of the book requested in the subrequest may have a budget deficit. If this is the case, then the largest index of the already committed subrequests of the book owner is found. If this index is larger than the index of the current subrequest, this index is used as the index of the next subrequest to be processed. Otherwise, the method moves to the next subrequest in the list  $S$ . Note that after  $S$  is traversed, it is guaranteed that the BR method produces a feasible solution although in the worst case it may be a zero solution. When a feasible solution is obtained, some participants may have remaining budgets to purchase books in some of their unsatisfied subrequests. In order to satisfy these subrequests, the BR method calls FSWI method as to improve the current feasible solution. The pseudocode of the BR method can be seen in Alg. 3.

The complexity analyses of the proposed heuristic algorithms are quite straightforward. The worst case time complexities of all proposed heuristics are  $O(n^2)$  where  $n = \max_k |r_k| * |R|$  and space complexities are only  $O(n)$ .

## V. EXPERIMENTAL RESULTS

In order to estimate the performances of the proposed heuristic methods under real-life market conditions, a test case generator was developed and a test suite was prepared. The test case generator uses GNU Scientific Library [12] for generating pseudo-random numbers which supports all common continuous and discrete random number distributions.

```

---

The generated test suite consists of 1600 problem instances in which the number of participants varied between 2,000 and 10,000 for simulating different market sizes. The following parameters of the case generator: the number of books that each participant put up for sale, the number of purchase requests, the number of purchase requests per participant, and the sizes of the purchase requests are configured as to be distributed with Poisson distribution with *mean values* varying between 1 and 7. The requested books in the purchase requests are uniformly selected among all the books. In order to determine the prices of the books, a statistical profile is generated according to the study of Ghose et al. [13] which is based on the sales information in the Amazon.com book marketplace. As discussed in Section II, when all the

participants have zero budget limits, the problem instances are difficult to solve. In fact, these instances would possibly have no nonzero feasible solutions at all. On the other hand, when all the participants have enough budget for all their possible purchases, the problem instances becomes quite easy, requiring polynomial time to be solved. Actually, the market instances in the real life would mostly be in between these two endpoints. Therefore, in order to determine the budget limits of the participants in the generated problem instances, five different budget limit ratios are used varying between 5% to 75%. Using these ratio values, the budget limit  $l_i$  for a participant  $t_i$  is calculated as:

$$l_i = blr_i \cdot (bl_i^{max} - bl_i^{min}) + bl_i^{min}$$

where  $blr_i$  is the budget limit ratio,  $bl_i^{min}$  the minimum budget the participant  $t_i$  needs in order to be able to purchase the cheapest book listed in her requests if all of her books are sold, and  $bl_i^{max}$  is the maximum budget she needs in order to be able to purchase all the books she wants even if none of her books are sold.

The generated test cases were solved using Gurobi mixed-integer programming (MIP) solver version 7 [14] on two 8-cores 3.10 GHz CPUs with 128 GB of memory. The solver was configured to use single thread and a time limit of 60 minutes was defined for each instance. The operating system used was 64 bit Linux. Among the generated 1600 problem instances, the MIP solver found the optimal solutions for 972 instances. For the remaining 628 instances, the solver could not find the optimal solution within the time limit, however, the MIP solver was able to find a nonzero feasible solution for these instances.

Optimally solved instances by the MIP solver were used to measure the quality of the solutions found by the three proposed heuristic methods, FS, FSWI, and BR. For each heuristic method, four different sorting criteria which are explained in Section IV are used. For representing the quality of the solutions, a *goodness* measure is defined such as:

$$\text{Goodness of a Sol.} = \frac{\text{Obj. Val of Heuristic Sol.}}{\text{Optimal Objective Value}} \cdot 100\%$$

The goodness of the solutions found by the proposed heuristic methods and the best solution found by all heuristic methods (Best of All) can be seen in Table I. According to the results, among the four sorting criteria, all three heuristics in which the subrequests are sorted in descending order according to *Weight \* Price* values find the best solutions. The results for the sorting criterion *Weight* follows the *Weight \* Price* criterion by a close margin. As seen from the results, the sorting criterion to be used is quite important causing up to 5% difference in mean goodness values.

Considering the best performing sorting criterion, that is *Weight \* Price*, FSWI method performs better compared with the FS and BR methods. Mean goodness values of the solutions found by the FSWI method is approximately 92.4%, that is within less than 8% of the optimal solutions. The

corresponding standard deviation is also small, less than 9%. The lowest goodness value obtained in the FSWI method is approximately 40%. Best solutions found by all three heuristics are also very close to the solutions found by the FSWI method indicating that the FSWI method is almost dominant to other two heuristic methods for the generated test instances. Note that the maximum goodness values for all heuristics are 100%, and therefore these value are not included in Table I for the sake of clarity.

For 628 problem instances among the generated 1600 instances, the MIP solver could only find suboptimal solutions (note that some of these solutions could in fact be optimal, however, the MIP solver might not have proven the optimality of the solutions within given time limit). For these instances, the proposed heuristics found better solutions on average compared to the solutions found by the MIP solver. The results can be seen in Table II. However, in this case, the goodness values were calculated as the ratio of the objective value of the heuristic solution to the suboptimal solution found by the MIP solver. Thus, goodness values may be higher than 100%. For these instances, the FSWI and the BR methods perform almost equal producing approximately 40% better solutions than the solutions found by the MIP solver on average, and more than 400% better solutions for some specific instances.

The running times of the heuristic methods and the MIP solver for all problem instances can be seen in Table III. All three heuristics are very fast, finding solutions less than 1 second on average whereas the MIP solver requires approximately 1500 seconds for an instance on average. The FSWI method again can be considered the best method in terms of running time compared to the other two methods. The maximum running time of the FSWI method is also very low, which is less than 10 seconds for all sorting criteria.

## VI. DISCUSSION AND CONCLUSION

In his open letter on used book sales dated April 14, 2002, Jeff Bezos, CEO of Amazon.com, wrote “. . . when a customer sells used books, it gives them a budget to buy more new books.” [15]. However, in current book markets, a participant without a budget for purchasing new books must sell her books first so as to get a revenue, after then she may be able to purchase new books. In this study, an electronic market model, the EMBook model was proposed for trading of used books as well as new ones in order to overcome this issue. In this market model, participants may simultaneously place sale and purchase requests for books allowing participants to spend the revenue to be obtained from the books they want to sell for the books they want to buy. Furthermore, a budget limiting mechanism is also provided such that for each participant, the difference between the cost of purchased books and the revenue of sold books does not exceed the declared budget limit of the participant. This mechanism provides the participants to place purchase requests without being afraid of having a budget deficit in case their books are not sold. Additionally, a participant may also be indifferent to multiple books, for instance, there may be multiple sellers of the same

book or the participant may be indifferent to the different editions of a book. For such situations, the participant can declare a set of substitutable books which is ordered according to the participant's preferences. Then, the model ensures that the participant buys at most one of the books from this set. By means of these features, the EMBook model aims to attract more participants to the book markets and to increase the markets' allocative efficiencies.

In this study, the EMBook model was defined mathematically and the winner determination problem of the EMBook model was formulated as a multi-objective linear integer program. Since this problem is NP-Hard, three polynomial-time heuristic methods were also proposed. In order to understand whether the model can be used in large-scale online electronic markets efficiently, a test suite consisting of 1600 test instances with up to 10,000 participants were prepared. These instances were solved using the state-of-the-art MIP Solver and also using the proposed heuristic methods. The MIP solver failed to solve approximately 40% of the instances optimally within one hour of execution time. For the optimally solved instances, the best heuristic method, ForwardSatisfyWithIncome, provided results as good as 92.4% on average with respect to the optimal solutions with a standard deviation of less than 9%. For the remaining instances, this heuristic method provided solutions with 40% better objective values on average compared with the solutions found by the MIP solver in one hour. The proposed heuristics, however, are quite fast requiring less than 1 second on average and less than 10 seconds maximum.

The high quality of the solutions found by the proposed heuristic methods and methods' low polynomial complexities enable them to be used efficiently in very large-scale electronic markets with tens of thousands of participants. Note that although this study focuses on secondary book markets, the model is surely applicable to the secondary markets in which other types of durable goods are exchanged.

# Distance-2 Collision-Free Broadcast Scheduling in Wireless Networks

Valentin Pollet, Vincent Boudet, Jean-Claude König  
UM/CNRS  
LIRMM - UMR 5506 - CC 477  
France  
Email: {pollet,boudet,konig}@lirmm.fr

**Abstract**—In this paper, we study the distance-2 broadcast scheduling problem in synchronous wireless networks of known topology. Two constraints are taken under consideration: the schedule must be collision-free and the nodes at distance 2 must be informed by nodes at distance 1. In general graphs, a tight bound of  $\mathcal{O}(\log(n)^2)$  slots to complete the broadcast is known,  $n$  being the number of nodes at distance 2. We improve this bound to  $\mathcal{O}(\log(n))$  in unit disk graphs, and to  $\mathcal{O}(1)$  when the neighbourhoods of the nodes are circular intervals.

## I. INTRODUCTION

WE consider the communication model proposed by [1] in which nodes communicate at synchronous slots, using only one frequency. When a node transmits at a given slot, all the nodes connected to it may receive the message. Collisions occur when a node receives several messages at the same slot. Collisions cannot be detected. When exactly one of its neighbours transmits at a given slot, a node is said to be informed.

We study the distance-2 broadcast scheduling problem (D2B) when the topology of the graph is known in advance. Given a graph and a source node, one must schedule the roles of the nodes over several slots in order to inform every node at distance 2 from the source. We assume that nodes at distance 2 from the source cannot be used to inform other nodes. We quantify the quality of a scheduling by the number of slots it uses, the less the better. The number of slots used is an intuitive measure of the time taken to complete the broadcast. This problem is motivated by the fact that knowledge at distance 2 is often assumed when designing communication protocols.

### A. Related work

This work is primarily inspired by [2], [3], dealing with D2B in general graphs. They give polynomial algorithms to schedule distance-2 broadcasts using  $\mathcal{O}(\log(n)^2)$  slots, where  $n$  is the number of nodes at distance 2 from the source. Their result provides a tight upper bound on the number of slots needed to complete broadcast since there exists a family of graphs of diameter 2 requiring a logarithmic number of slots to complete broadcast.

The global broadcast problem, in which a source must flood the whole network, has been widely studied in general graphs. See [4] for a survey.

On a theoretical point of view, solving D2B under the collision model is linked to the exact cover problem. Authors

in [5] give a polynomial algorithm to solve the weighted covering problem for sets of pseudo-disks in the plane. Their algorithm can be adapted to decide the existence of a 1-slot solution to D2B on unit disk graphs.

### B. Our results

Our work focuses on restricted classes of graph, and show that the upper bounds in those cases are strictly lower.

First, we exhibit a family of instances over unit disk graphs such that solving D2B requires exactly  $\log(n) + 1$  slots,  $n$  being the number of nodes at distance 1 from the source. We further prove that it is always possible to complete broadcast using  $\mathcal{O}(\log(n))$  slots, tightening the bound.

Then we consider a more restrictive case: when the neighbourhoods of the nodes at distance 1 are circular arcs of the nodes at distance 2. We give a simple greedy algorithm yielding solutions using at most 3 slots. This algorithm proves a constant upper bound on the number of slots needed to complete distance-2 broadcasts in these graphs.

### C. Notations

An instance of the distance-2 broadcast scheduling problem (D2B) is given by a graph  $G = (V, E)$  and a node  $x_e$  of this graph. The immediate neighbours  $X$  of  $x_e$  are called the *source nodes*. We call *target nodes* the set of nodes  $Y$  at distance 2 from  $x_e$ . This terminology is motivated by the fact that nodes from  $Y$  cannot be scheduled in the broadcast. Assuming so, solving D2B then consists in scheduling the transmission of some nodes in  $X$  such that every node in  $Y$  gets informed at some slot. A solution to D2B is a set of subsets of  $X$ ,  $\{X_1, \dots, X_k\}$ ,  $k$  being the number of slots the solution uses.

It is clear that  $X$  can be fully informed in one slot when  $x_e$  acts as the sole transmitter, the bounds we prove in the following do not count this trivial step.

## II. UNIT DISK GRAPHS

In this section,  $D_u$  denotes the unit disk centred at the origin. We can assume without loss of generality that the source node  $x_e$  is at the origin. When a disk is referred to as  $D_i$  for some label  $i$ , then  $C_i$  will be the corresponding circle *i.e.* the border of  $D_i$ .

Fig. 1. Three disks ( $D_1, D_2, D_3$ ). The gray areas (partitioning the union of the disks) are the target areas induced by these disks. Each target area contains its signature

Let us assume that the nodes lie on a plane and that each source node has a communication disk - its *source disk*. Target nodes must be covered using these disks. An instance of D2B is now a couple  $(\mathcal{D}, Y)$ ,  $\mathcal{D}$  being a set of source disks and  $Y$  a set of targets. Let  $\mathcal{D} = \{D_1, \dots, D_m\}$  be a set of labelled source disks. Given  $\mathcal{D}' \subset \mathcal{D}$ , the proper intersection of all the disks in  $\mathcal{D}'$  is  $\cap_{x \in \mathcal{D}'} x \setminus \bigcup_{y \in \mathcal{D} \setminus \mathcal{D}'} y$ . If said proper intersection is non-empty, we say that  $\mathcal{D}'$  induces a *target area*. We define the *signature* of a target area as the set containing all the labels of the disks inducing this area. In Figure 1, three disks  $D_1, D_2, D_3$  intersect each other. The gray areas are target areas. Each area has a signature. For instance the target area of signature (1, 2) is the intersection between  $D_1$  and  $D_2$  minus  $D_3$ . Note that the target areas partition the union of all the disks.

#### A. Unit disk graphs requiring a logarithmic number of slots

**Theorem II.1.** Let  $m \in \mathbb{N}$ . Let  $\mathcal{D} = (D_1, \dots, D_m)$  be a set of distinct source disks which centres lie on the same radius of the unit disk. There exists a set  $Y$  of points such that solving D2B over  $(\mathcal{D}, Y)$  requires  $1 + \lfloor \log_2(|Y|) \rfloor$  slots.

*Proof.* We can assume that  $\mathcal{D}$  is ordered by the disks' centres' distance to the origin. For all  $D_i$  in  $\mathcal{D}$ ,  $x_i$  is the centre of  $D_i$ . The *signature matrix*  $\mathcal{M}$  given in Figure 2 contains the signatures of all the non-empty target areas induced by  $\mathcal{D}$ .

Now we build an instance of D2B by placing a target node in each target area. Denote  $n$  the number of target nodes ( $n = \frac{m(m+1)}{2}$ ) and  $t_k$  the number of slots needed to inform  $k$  targets for all  $k \in \{1, \dots, n\}$ . Clearly  $t_1 = 1$ .

For some  $i$ , let us remove from  $\mathcal{M}$  all the target areas which signatures contain  $i$  (see the gray part in Figure 3). Note that the remaining areas to cover may form two disjoint instances—*residual instances*—of the problem on smaller graphs. One

(1)		
(1, 2)	(2)	
$\vdots$	$\vdots$	$\ddots$
$(1, \dots, m)$	$(2, \dots, m)$	$\dots (m)$

Fig. 2. Signature matrix  $\mathcal{M}$ . Each entry is the signature of a target area induced by  $\mathcal{D}$ . Note that an entry  $(i, j)$  corresponds to the signature  $(i, \dots, j)$ .

instance uses disks of indexes 1 to  $i - 1$  and the other uses disks of indexes  $i + 1$  to  $m$ . Note that if  $i = 1$  or  $i = m$ , there is only one residual instance.

(1)		
$\vdots$	$\ddots$	
$(1, \dots, i)$	$\dots$	$(i)$
$\vdots$	$\vdots$	$\vdots$
$(1, \dots, m)$	$\dots (i, \dots, m)$	$\dots (m)$

Fig. 3. When node  $i$  is the sole emitter at a given slot, the gray rectangle is covered. The remaining uncovered parts of the matrix are disjoint and can be processed in parallel without risking to interfere at an uncovered area.

Observe that the signature matrices of the residual instances have the same form as the original instance. Whichever  $i$  is chosen to emit at first slot, at least one of the residual matrices has size at least  $\lceil \frac{m-1}{2} \rceil$ . Since the two residual instances are disjoint, they can be processed in parallel. The following recurrence on  $t_n$  is now verified.

$$t_n \geq t_{\lceil \frac{n-1}{2} \rceil} + 1 \quad (1)$$

$$\geq 1 + \lfloor \log_2(n) \rfloor \quad (2)$$

Now let us prove that the recurrence equation can be tight. The two following properties are verified.

- 1) There exists a target area of signature  $(1, \dots, m)$ . In any solution  $(X_1, \dots, X_k)$  there is thus a  $X_i$  of cardinality 1.
- 2) Given a solution  $(X_1, \dots, X_k)$ , permuting two sets in the solution does not change it.

Taking these two facts under account, we can assume that in any solution the first slot is occupied by a single source node i.e.  $|X_1| = 1$ .

Now if we choose the central node  $i = \lceil \frac{m-1}{2} \rceil$  to transmit at each recursion step, then the solution produced is necessarily optimal. Indeed, in each residual instance the target area with the biggest signature has to be covered. By choosing the central node as sole transmitter for the first step, we ensure that said area is covered, and that the residual instances have roughly the same size. We then have  $t_n = 1 + \lfloor \log_2(n) \rfloor$ .  $\square$

#### B. A logarithmic number of slots always suffices

We call *angular region* any part of the plane delimited by two half-lines with a common extremity being the origin. An

angular region is of angle  $\alpha$  if the angle formed by the half-lines delimiting it is  $\alpha$ .

**Lemma II.1.** *Let  $\mathcal{D}$  be a set of source disks, and  $Z$  be an angular region of angle  $\frac{\pi}{2}$ . For all  $D_i, D_j$  in  $\mathcal{D}$ ,  $C_i$  and  $C_j$  intersect at most once in  $Z \setminus D_u$ .*

Fig. 4. Circles of centres A and B intersecting at points P and Q. Using the angle at center theorem on  $\gamma$  and  $\beta$ , we show the angle  $\alpha$  to be at least  $\frac{\pi}{2}$ .

*Proof.* Let  $D_1$  and  $D_2$  be two disks of centres A and B, containing the origin O. Let P and Q be the intersection points between  $C_1$  and  $C_2$ . Let C be the intersection between the line (OA) and  $D_1$ . We can assume without loss of generality that A and B lie in a half of the unit disk centred in O. We can also assume that A is closer to O than B is. Now let  $\alpha$  be the angle  $(\vec{OP}, \vec{OQ})$ ,  $\beta$  the angle  $(\vec{AQ}, \vec{AP})$  and  $\gamma$  the angle  $(\vec{CP}, \vec{CQ})$  (see Figure 4). Since  $\beta$  and  $\gamma$  intercept the same arc of  $C_1$ , the angle at center theorem states that  $\gamma = \frac{\beta}{2}$ . By construction, since the triangle OPQ is contained in the triangle CPQ, we have  $\alpha \geq \gamma$ . Then,  $\beta > \pi$  because if  $\beta = \pi$  then PQ is a diameter of both  $C_1$  and  $C_2$  meaning that these two circles are equal. We thus have  $\alpha > \frac{\pi}{2}$  and therefore  $C_1$  and  $C_2$  cannot intersect more than once in  $Z \setminus D_u$ .  $\square$

Given a set of source disks  $\mathcal{D}$  and a disk  $D \in \mathcal{D}$  labelled  $i$  we say that  $D$  induces a *proper area* if there exists a target area induced by  $\mathcal{D}$  of signature  $(i)$ . Now consider an angular region  $Z$  of angle  $\frac{\pi}{2}$ , we define  $\mathcal{D}_{|Z}$  as the set of all disks in  $\mathcal{D}$  intersecting  $Z$  non-emptily. We then remove from  $\mathcal{D}_{|Z}$  all the disks not inducing a proper area in  $Z$ . Now order the disks in  $\mathcal{D}_{|Z}$  according to the angle to the proper area they induce (see Figure 5). After this ordering  $\mathcal{D}_{|Z} = (D_1, \dots, D_m)$  if  $S_i$  and  $S_j$  are proper areas induced by  $D_i$  and  $D_j$  with  $i < j$  then  $\forall P \in S_i, \forall Q \in S_j, (\vec{OP}, \vec{OQ}) \in ]0, 2\pi[$ .

We will next assume that  $\mathcal{D}_{|Z}$  does not contain three circles intersecting in one point in  $Z$ . It is not hard to work around it, but simplifies the proof of the following lemma.

Fig. 5. Ordering disks w.r.t the proper areas in a quadrant.  $D_1$ 's proper area appears first then  $D_2$ 's then  $D_3$ 's.

**Lemma II.2.** *Let  $S$  be a target area induced by  $\mathcal{D}_{|Z}$  such that  $S \cap Z \neq \emptyset$  then the signature of  $S$  is of the form  $\sigma(S) = (i, i+1, \dots, i+p)$  for some  $i, p$ .*

*Proof.* Let us assume it is not the case, thus there is a gap in the signature of  $S$  :  $\sigma(S) = (i, \dots, k, k+j, \dots, i+p)$  with  $j > 1$ . Consider the set of source disks  $D' = \{D_k, D_{k+1}, D_{k+j}\}$  which we can renumber  $D' = \{D_1, D_2, D_3\}$  to clarify things. Now there exists an area of signature  $(1, 3)$ . Using Lemma II.1 we know that there is a unique intersection point P between  $C_1$  and  $C_2$  in  $Z$ . Let  $Z^-$  (resp.  $Z^+$ ) be the part of  $Z$  located counterclockwise before (resp. after) the line (OP). Let  $D_i^+ := D_i \cap Z^+$  and  $D_i^- := D_i \cap Z^-$  for  $i = 1, 2, 3$ . Since  $C_1$  intersects  $C_2$  only once, we know that  $D_2^- \subset D_1^-$  and  $D_1^+ \subset D_2^+$ . As a consequence, the area of signature  $(1, 3)$  cannot lie in  $Z^+$ , it has to lie in  $Z^-$ .

- 1) Assume that  $C_1$  and  $C_3$  do not intersect in  $Z^-$ , then  $D_3^- \subsetneq D_1^-$  because otherwise the proper area induced by  $D_3$  appears before the proper area induced by  $D_1$  which is absurd. Note that  $C_2$  and  $C_3$  have to intersect in  $Z^+$  because if not
  - a) either  $D_2^+ \subsetneq D_3^+$  and then  $D_2$  does not induce a proper area in  $Z$  since  $D_2^- \subsetneq D_1^-$  which is absurd;
  - b) or  $D_3^+ \subsetneq D_2^+$  and then the proper area induced by  $D_3$  appears in  $Z^-$  thus before the one induced by  $D_2$  which lies in  $Z^+$ . That is absurd as well.

Thus,  $C_2$  intersects  $C_3$  in  $Z^+$  and we know they do not intersect in  $Z^-$  using Lemma II.1. Under these assumptions  $D_3^- \subsetneq D_2^-$  because otherwise  $D_2^- \subsetneq D_3^-$  and  $P \in D_3^-$ , thus  $D_3^- \cap D_1^- \neq \emptyset$  or  $D_3^- \subsetneq D_1^-$ , in both cases it is absurd. Thus, we have  $D_3^- \subsetneq D_2^-$ , and in that case the area of signature  $(1, 3)$  cannot exist, which is absurd since we assumed it did exist.

- 2) Finally, assume that  $C_1$  and  $C_3$  do intersect in  $Z^-$ . Then  $C_3$  intersects  $C_1$  before P (because we assume that three circles never intersect in one point) and the proper area induced by  $C_3$  appears before the proper area induced by  $C_2$ , absurd again.

Both cases lead to contradictions, the area of signature (1, 3) cannot exist. The signature of  $S$  is thus of the form  $(i, i+1, \dots, i+p)$ , thus the lemma.  $\square$

**Theorem II.2.** *Let  $\mathcal{D}$  be a set of source disks, then all the target areas induced by  $\mathcal{D}$  can be covered using  $\mathcal{O}(\log_2(n))$  slots.*

*Proof.* Partition the plane in four angular sectors of angle  $\frac{\pi}{2}$   $Z_1, Z_2, Z_3, Z_4$ . First, consider  $Z_1$  then using Lemma II.2 any target area appearing in  $Z_1$  has signature of form  $(i, i+1, \dots, i+j)$  for some  $i, j$  (after removing the disks not inducing proper areas and reordering  $D|_{Z_1}$ ). We can thus build a signature matrix for  $D|_{Z_1}$  having the same form as the matrices considered in subsection II-A. Since we showed that instances with such signature matrices can be dealt with using  $\mathcal{O}(\log_2(n))$  slots, we can cover any target area appearing in  $Z_1$  using  $\mathcal{O}(\log_2(n))$  slots. We can then do the same for  $Z_2, Z_3$  and  $Z_4$  sequentially and cover any target area induced by  $\mathcal{D}$  in  $\mathcal{O}(\log_2(n))$  slots.  $\square$

### III. CIRCULAR ARC NEIGHBOURHOODS

We now suppose that the set  $Y$  of target nodes can be placed on a circle, and the neighbourhoods of  $X$  can be represented by proper arcs on that circle - that is a target node  $y$  can be reached by a source node  $x$  if  $y$  lies on the arc representing  $x$ 's neighbourhood. For instance, on Figure 6,  $x_1$  has neighbourhood  $\{y_1, y_2, y_3, y_4\}$ .

$X$  and  $Y$  can be arbitrarily ordered as follows. Pick one of the source nodes  $x$  to be the first one in the  $X$  order ( $x = x_1$ ), then number  $\{y_1, \dots, y_k\}$  its neighbours. Now number  $x_2$  the node which arc starts after  $x_1$ , and its neighbours can be numbered following  $x_1$ 's neighbours. One can do so until every node in  $X$  and every node in  $Y$  have been ordered (see Figure 6).

Fig. 6. Dots are target nodes, arcs represent source nodes

**Theorem III.1.** *3 slots are always enough to solve D2B in the circular arc neighbourhoods case.*

*Proof.* The following procedure produces a solution to D2B using at most 3 slots.

- 1) order  $X$  and  $Y$  as previously explained
- 2) let  $y$  be the first target in  $Y$  not yet covered

- 3) add to the solution the arc covering  $y$  ending the furthest possible after  $y$
- 4) go to 2 while  $Y$  is not entirely covered

Denote  $x_1, \dots, x_k$  the nodes selected during the procedure. Then  $N(x_i) \cap N(x_{i+2}) = \emptyset$  for all  $i = \{1, \dots, k-3\}$ . Indeed, if  $N(x_i) \cap N(x_{i+2}) \neq \emptyset$  then consider the target  $y$  that forced the algorithm to pick  $x_{i+1}$ , and the target  $y'$  that made it pick  $x_{i+2}$ . We know that  $y \notin N(x_i)$ , and that the arc  $x_{i+1}$  ends after the arc  $x_{i+2}$  (otherwise  $x_{i+2}$  would have been picked instead since  $N(x_i) \cap N(x_{i+2}) \neq \emptyset$ ), but then  $y'$  being the first target after  $x_{i+2}$  would be contained in  $N(x_{i+1})$  and  $x_{i+2}$  would not have been picked, that is absurd thus  $N(x_i) \cap N(x_{i+2}) = \emptyset$ .

Possibly  $N(x_{k-2}) \cap N(x_k) \neq \emptyset$ . Now, let  $X_1 = \{x_i, i < k \text{ is odd}\}$ ,  $X_2 = \{x_i, i < k \text{ is even}\}$  and  $X_3 = \{x_k\}$ .  $\{X_1, X_2, X_3\}$  is thus a broadcast using three slots.  $\square$

### IV. CONCLUSION

We studied the distance-2 broadcast problem in two specific cases. In general graphs, there is a tight  $\mathcal{O}(\log(n)^2)$  upper bound on the number of slots needed to solve the problem. We improved this bound in unit disk graphs to  $\mathcal{O}(\log(n))$ . In the case the neighbourhoods can be represented as circular intervals, we proved the bound to be even lower:  $\mathcal{O}(1)$ .

In the future we would like to extend our research to other classes of graph, or more accurate communication models. Another interesting problem is the maximal cover in a fixed number of slots.

**Abstract**—Managing a one-way vehicle sharing system means periodically moving free access vehicles from excess to deficit stations in order to avoid local shortages. We perform a lower bound analysis for the static version of the resulting operational decision problem, and derive from this analysis two heuristic algorithms whose main feature is to be vehicle oriented, which means that they focus on the way vehicles are exchanged between excess and deficit stations.

## I. INTRODUCTION

**V**EHICLE Sharing systems [13, 16] are emerging mobility systems which aim at compromising between purely individual mobility and rather rigid public transportation. Such a system is composed of a set of stations, at which free access vehicles are parked. Those vehicles can be bicycles or electric cars. There exists a special station called *Depot*, in which a set of carriers (trucks, self-platoon convoys, ...) are stored, which periodically exchange vehicles between the stations and eventually provide the system with additional vehicles. A trend is to make the system be a one-way system, which means that users are not imposed to give vehicles back at the station where they have been picking up. This feature makes the system more attractive. But a drawback is that it raises the eventuality of unbalanced situations, in the sense that some stations may become overfilled other under-filled, provoking local shortages or making users unable to give their vehicle back. In order to avoid such a situation, managers have to periodically perform a relocation process: carriers pick up vehicles from excess stations and transfer them to deficit stations. Performing this process while meeting both economic and quality of service purposes means addressing a Vehicle Sharing Relocation problem (VSR). Though practically this VSR problem has to be handled on line [13, 14], most related academic studies have been involving static (see [5, 6, 13, 15, 19]), or eventually dynamic formulations [11, 17].

Those formulations, which differ in a significant way from an author to another, have been mostly

handled through hierarchical decomposition into a carrier routing master model and a vehicle load/unload slave model, and through local search or genetic algorithms (see [6, 8, 10, 18]). Their common feature is that they are carrier oriented, in the sense that they focus on the construction of the recollection tours which are run by the carriers, and consider the routing of the vehicles inside the carriers as a kind of slave object. Such an approach may be discussed because it cannot rely on a backward link between the master carrier tour collection and the vehicle sub-problem, which would provide sensitivity information and help in driving the search for the master object. It comes that the search for the master carrier tour collection is very often performed in a somewhat blind way.

We adopt here the opposite point of view and consider that an efficient way to perform a relocation process is to route the vehicles from excess stations to deficit ones in a way which make them share, as often as possible, related carriers. So the purpose of this work is to propose and test alternative approaches to carrier oriented ones, which we shall call vehicle oriented: the vehicle routing strategy becomes the master object, which determines in turn the carrier routes.

The paper is organized as follows. First we introduce a formal VSR model, generic in the sense that it mixes different criteria: economic cost of the relocation process (number of carriers and carrier riding time), and quality of service (unavailability of the vehicles during the process). Next we perform a lower bound analysis of this VSR model. The way we obtain lower bounds leads us to the design of 2 heuristic VSR algorithm: the first one considers the way vehicles are distributed from excess stations to deficit ones as the master object and relies on a *Min Cost Assignment/Pick up and Delivery* decomposition; the second one considers the aggregated routing of the vehicles along the station network as a main object, and relies on a *lift* procedure which turns an aggregated routing of vehicles and carriers into a feasible VSR solution. We end with numerical experiments.

## II. THE VSR MODEL

### A. Instances, Feasible Solutions and Models.

#### VSR (Vehicle Sharing Relocation Problem)

**Instances:** We consider here a set  $X$  of stations, one of them being a specific station *Depot*. Any station  $x$  is provided with a coefficient  $v(x)$ , which tells us that  $v(x)$  vehicles are in *excess* at station  $x$ : if  $v(x)$  is strictly negative, then we need to bring  $-v(x)$  vehicles to station  $x$  ( $x$  is then said to be a *deficit* station); if  $v(x)$  is strictly positive, then  $x$  is an *excess* station and we need to remove  $v(x)$  from  $x$ ; if  $v(x) = 0$  then  $x$  is said to be *neutral*. We suppose that  $\sum_{x \in X} v(x) = 0$ , which means that the *Depot* station may be used to bring additional vehicles to the system, or, conversely, to remove some of them. *DIST* denotes the  $X \times X$  distance matrix:  $DIST_{x,y}$  is the distance (time required for a carrier to go from  $x$  to  $y$ ) between station  $x$  to station  $y$ . Matrix *DIST* is not required to be symmetric, but should satisfy the *Triangle* inequality. *T-Max* is the maximal *makespan* of the relocation process, which means that the total duration of this process should not exceed *T-Max*. By the same way, *COST* denotes the carrier cost matrix:  $COST_{x,y}$  is the cost which is induced for a carrier when it moves from  $x$  to  $y$ . All carriers are identical with capacity *CAP* and initially located at the *Depot* station. This defines a VSR instance  $(X, v, CAP, T-Max, DIST, COST)$ .

**VSR Feasible Tours:** A VSR tour  $\Gamma$  is a finite sequence  $\Gamma_{Route} = \{x_0 = Depot, x_1, \dots, x_{n(\Gamma)} = Depot\}$  of stations, which is called a *route*, given together with a *loading strategy*, that means with 2 sequences  $\Gamma_{Load} = \{L_0, L_1, \dots, L_{n(\Gamma)}\}$  and  $\Gamma_{Time} = \{T_0 = 0, T_1, \dots, T_{n(\Gamma)}\}$  of coefficients whose meaning is: a carrier which follows the route  $\Gamma$  loads, at time  $T_i$ ,  $L_i$  vehicles at station  $x_i$  (unloads in case  $L_i < 0$ ). The *COST*-length  $L-COST(\Gamma)$  of such a tour is the sum  $\sum_j (COST_{x_j, x_{j+1}})$  and its *DIST*-length  $L-DIST(\Gamma)$  is the sum  $\sum_j (DIST_{x_j, x_{j+1}})$ . This VSR tour  $\Gamma$  is VSR feasible if:

- For any  $i = 0, \dots, n(\Gamma)-1$ ,  $T-Max \geq T_{i+1} \geq T_i + DIST_{x_i, x_{i+1}}$ ; (E1)

- For any  $i = 0, \dots, n(\Gamma)-1$ ,  $0 \leq L_i^* = \sum_{j=0..i} L_j \leq CAP$ ; (E2)

- $\sum_{j=0..n(\Gamma)} L_j = 0$ ; (E3)

- For any  $j$  such that  $v(x_j) \geq 0$ , then  $v(x_j) \geq L_j \geq 0$ ; (E4)

- For any  $j$  such that  $v(x_j) \leq 0$ , then  $v(x_j) \leq L_j \leq 0$ . (E5)

**Explanation:** (E1): A carrier needs at least  $DIST_{x_i, x_{i+1}}$  time units in order to go from  $x_i$  to  $x_{i+1}$ ; (E2):  $L_i^*$  denotes its current load when it leaves  $x_i$ , and this loads cannot exceed the capacity *CAP*; (E3): Any carrier is empty when it starts and finishes a

tour; (E4, E5): loading (unloading) operations are respectively restricted to *excess* (*deficit*) stations, which also means that we impose a given vehicle to be moved from an *origin* station to a *destination* station by exactly one carrier (*Non Preemption* hypothesis).

Given scaling coefficients  $\alpha, \beta, \delta$ , together with a VSR instance  $(X, v, CAP, T-Max, DIST)$ , we set:

**VSR Model:** {Compute a VSR feasible tour collection  $\Gamma^* = \{\Gamma(k), k = 1..K\}$  such that:

- For any station  $x$ :  
 $\sum_k \sum_{i \text{ such that } x(k)_i = x} L(k)_i = v(x)$ . (E6)
- Minimize  $Cost(\Gamma^*) = \alpha K + \beta \sum_k L-Cost(\Gamma(k)) + \delta (\sum_k \sum_j (DIST_{x(k)_j, x(k)_{j+1}} \cdot L_j^*))$ .

**Explanation:** (E6): For any *excess* station  $x$ ,  $v(x)$  vehicles have to be picked up in  $x$ , and for any *deficit* station  $x$ ,  $-v(x)$  vehicles have to be delivered to  $x$ . Minimize:  $Cost(\Gamma^*)$  is a weighted sum of the active carrier number  $\alpha K$ , the carrier riding cost  $\sum_k L-Cost(\Gamma(k))$  and the vehicle riding time (time vehicles spend into the carriers)  $\sum_k \sum_j (DIST_{x(k)_j, x(k)_{j+1}} \cdot L_j^*)$ .

**Remark 1 about MIP VSR models and Complexity:** Modeling VSR through a MIP (*Mixed Integer Linear Program*) is possible, but difficult and inefficient. As for complexity, VSR is NP-Hard, even if we consider one carrier ( $\alpha$  very large) with capacity 1, if every quantity  $v(x)$  is equal to 1 or -1, and if  $\delta = 0$ . In such a case, solving the problem becomes equivalent to solving the *Travelling Salesman* problem on a bipartite graph (the *excess* stations on one side and the *deficit* ones on the other side), which is known to be NP-Hard. Also, we may notice that VSR contains the *Uncapacitated Swapping Problem*, which is also known to be NP-Hard (see [2]).

### B. Loading Strategy Flow Model.

Let us suppose now that we are provided with a collection  $\Gamma_{Route}^* = \{\Gamma_{Route,1}, \dots, \Gamma_{Route,K}\}$  of  $K$  carrier routes, all with length  $\leq T-Max$ . We define a network  $H(\Gamma_{Route}^*)$  as follows:

- Nodes of  $H(\Gamma_{Route}^*)$  are :
  - copies of the nodes  $x_j^k$  of  $\Gamma_{Route,1}, \dots, \Gamma_{Route,K}$ , considered as being all distinct;
  - a source  $s$  and a pit  $p$ ;
  - nodes  $Exc(x)$ ,  $x \in X$ , *excess* nodes;
  - nodes  $Def(x)$ ,  $x \in X$ , *deficit* nodes.
- Arcs  $e$  of  $H(\Gamma_{Route}^*)$  and related costs  $C_e$  are :
  - *tour-arcs*  $e = (x_j^k, x_{j+1}^k)$  of the routes  $\Gamma_{Route,k}$ , with cost  $C_e = DIST_{x_j^k, x_{j+1}^k}$ ;
  - *load-arcs*  $e = (Exc(x), x_j^k)$ ,  $x \in X$ , *x excess*, such that the image in  $X$  of  $x_j^k$  is  $x$ , with  $C_e = 0$ ;
  - *unload-arcs*  $e = (y_j^k, Def(y))$ ,  $y$  *deficit*, such that

- the image in  $X$  of  $y_j^k$  is  $y$ , with  $C_e = 0$ ;
- $\circ$  excess-arcs  $e = (s, \text{Exc}(x))$ ,  $x$  excess, with  $C_e = 0$ ;
- $\circ$  deficit-arcs  $e = (\text{Def}(y), p)$ ,  $y$  deficit, with  $C_e = 0$ .

Then we set:

- Load-VSR Model:** {Compute on the network  $H(\Gamma_{\text{Route}}^*)$  a non negative integral arc indexed flow vector  $Z$  such that:
- $\circ$  for any arc-tour  $e$ ,  $Z_e \leq \text{CAP}$ ;
  - $\circ$  for any arc  $e = (s, \text{Exc}(x))$ ,  $x$  excess,  $Z_e = v(x)$ ;
  - $\circ$  for any arc  $e = (\text{Def}(y), p)$ ,  $y$  deficit,  $Z_e = -v(y)$ ;
  - $\circ$   $C \cdot Z = \sum_e C_e \cdot Z_e$  is the smallest possible}

**Lemma 0:** Any optimal solution (if it exists) of Load-VSR provides us with an optimal loading strategy related to the route collection  $\Gamma_{\text{Route}}^*$ .

**Proof:** Any loading strategy related to the tour collection  $\Gamma$  may be turned into a feasible solution of Load-VSR whose cost is exactly the vehicle riding time:  $\sum_k \sum_i (\text{DIST}(x(k)_i, x(k)_{j+1}) \cdot L^*_i)$ . Conversely, any flow vector  $Z$  which is a feasible solution of Load-VSR can be interpreted as a loading strategy.  $\square$

We deduce the following **VSR Route Oriented reformulation:** {Compute a route collection  $\Gamma_{\text{Route}}^* = \{\Gamma_{\text{Route},1}, \dots, \Gamma_{\text{Route},K}\}$ , and a feasible solution  $Z$  of the related Load-VSR model, such that:  $\alpha \cdot K + \delta \cdot C \cdot Z + \beta \cdot \sum_k L\text{-Cost}(\Gamma_{\text{route},k})$  is the smallest possible}.

### III. VSR LOWER BOUNDS

We propose here 2 classes of VSR lower bounds: the first one relies on *Min-Cost Assignment* models which separately bound the *active carrier number*  $K$ , the *carrier riding cost*  $\sum_k L\text{-COST}(\Gamma(k))$  and the *vehicle riding time*  $\sum_k \sum_i (\text{DIST}_{x(k)_i, x(k)_{j+1}} \cdot L^*_i)$ . The second one, more complex, embraces the 3 quantities in a *same Network-Flow* model.

#### A. Min-Cost Assignment Based Lower Bounds.

We set the following ILP models:

- VMC Vehicle-Min-Cost:** {Compute integral vector  $Q = (Q_{x,y}, x \text{ excess}, y \text{ deficit stations})$  0, such that:
- $\circ$  For any excess station  $x$ ,  $\sum_{y \text{ deficit}} Q_{x,y} = v(x)$ ;
  - $\circ$  For any deficit station  $y$ ,  $\sum_{x \text{ excess}} Q_{x,y} = -v(y)$ ;
  - $\circ$  Minimize  $\sum_{x,y} \text{DIST}_{x,y} \cdot Q_{x,y}$ }

We denote by *LB-VMC* the related optimal value, which may be computed while relaxing the integrality constraint on the vector  $Q$ .

**UCMC Unit-Carrier-Min-Cost:** {Compute rational vector  $R = (R_{x,y}, x, y \in X) \geq 0$ , such that:

- $\circ$  For any excess station  $x$ ,  $\sum_{y \text{ deficit station}} R_{x,y} = v(x)$
- $\circ$  For any deficit station  $y$ ,  $\sum_{x \text{ excess station}} R_{x,y} = -v(y)$
- $\circ$   $\sum_y R_{\text{Depot},y} = \sum_y R_{y,\text{Depot}} \geq 1$
- $\circ$  For any subset  $A$ , which is not empty and does not contain Depot,  $\sum_{x \in A, y \notin A} R_{x,y} \geq 1$  (No Subtour Constraint)
- $\circ$  Minimize  $\sum_{x,y} \text{COST}_{x,y} \cdot R_{x,y}$ }

*LB-UCMC* is the related optimal value.

**CMC Carrier-Min-Cost:** {Compute rational vector  $R = (R_{x,y}, x, y \text{ stations}) \geq 0$ , such that:

- $\circ$  For any excess station  $x$ ,  $\text{CAP} \cdot \sum_y R_{x,y} = \text{CAP} \cdot \sum_y R_{y,x} \geq v(x)$
- $\circ$  For any deficit station  $y$ ,  $\text{CAP} \cdot \sum_x R_{x,y} = \text{CAP} \cdot \sum_x R_{y,x} \geq -v(y)$
- $\circ$   $\sum_y R_{\text{Depot},y} = \sum_y R_{y,\text{Depot}} \geq 1$
- $\circ$  For any subset  $A$ , which is not empty and does not contain Depot,  $\sum_{x \in A, y \notin A} R_{x,y} \geq 1$
- $\circ$  Minimize  $\sum_{x,y} \text{COST}_{x,y} \cdot R_{x,y}$ }

*LB-CMC* is the related optimal value. We denote by *LB-Time-CMC* the value of the model which derives from CMC by replacing *COST* by *DIST*.

**Theorem 1:**  $\text{LB-MC} = \alpha \cdot \lceil \text{LB-Time-CMC} / T\text{-Max} \rceil + \beta \cdot \text{LB-CMC} + \delta \cdot \text{LB-VMC}$  is a VSR lower bound.

**Proof:** We see that *VLB-A* is a lower bound for the vehicle riding time:  $\sum_k \sum_i (\text{DIST}_{x(k)_i, x(k)_{j+1}} \cdot L^*_i)$ . Also *LB-CMC* is clearly a lower bound for the carrier riding cost  $\sum_k T(k)_{n(I(k))}$ . We conclude by noticing that the number of carriers  $K$  must be at least equal to the quantity (*Carrier Riding Time* / *T-Max*).  $\square$

**Theorem 2:** A Non Preemptive VSR lower bound is given by  $\text{LB-UMC} = \alpha \cdot \lceil \text{LB-Time-UCMC} / (\text{CAP} \cdot T\text{-Max}) \rceil + \beta \cdot \text{LB-UCMC} / \text{CAP} + \delta \cdot \text{LB-VMC}$ .

**Proof:** We notice that any tour  $\gamma$  which satisfies (E1, E2, E3) may be split into *CAP tours*  $\gamma_1, \dots, \gamma_{\text{CAP}}$ , with same lengths, which globally perform the relocation process when related  $\text{CAP} = 1$ . So, if *Carrier-Ride-Time*<sub>1</sub> and *Carrier-Ride-Cost*<sub>1</sub> respectively denote the smallest possible values for the carrier riding time and the carrier riding cost related to the case when  $\text{CAP} = 1$  and  $T\text{-Max} = +\infty$ , we see that: the *Riding Time (Riding Cost)* of any VSR solution  $\Gamma$  is at least equal to *Carrier-Ride-Time*<sub>1</sub> / *CAP* (*Carrier-Ride-Cost*<sub>1</sub> / *CAP*). We deduce that  $\alpha \cdot \lceil \text{Carrier-Ride-Time}_1 / \text{CAP} \cdot T\text{-Max} \rceil + \beta \cdot \text{Carrier-Ride-Cost}_1 / \text{CAP} + \delta \cdot \text{LB-VMC}$  is a VSR lower bound. But *Carrier-Ride-*

$Time_1$  corresponds to a kind of TSP *carrier* tour starting and ending from depot, according to which the carrier alternatively moves from *excess* to *deficit* nodes. Clearly *LB-Time-UCMCA* provides us with a lower bound for the *DIST*-length of such a tour. The same reasoning holds with *Carrier-Cost-Time<sub>1</sub>*. We conclude.  $\square$

#### B. A Network Flow Based Lower Bound.

One may reinforce the above lower bounds according to the following construction. We first define a network  $G^* = (X^*, E^*)$  as follows:

- $X^* = X \cup \{s, p\}$  where nodes  $s$  and  $p$  are additional nodes *source* and *sink*;
- The restriction of  $G^*$  to  $X$  is a complete network: any related arc  $e = (x, y)$  is provided with a *carrier cost*  $CC_e = COST_{x,y} \cdot (\beta + \alpha/T\text{-Max})$  and to a *vehicle cost*  $CV_e = \delta \cdot DIST_{x,y}$ .
- There is an arc  $(s, x)$  from  $s$  to any *excess station*  $x$ , with null *carrier* and *vehicle* costs;
- There is an arc  $(y, p)$  from any *deficit station*  $y$  to  $p$ , with null *carrier* and *vehicle* costs;
- There is a *backward arc*  $(p, s)$ , with null *carrier* and *vehicle* costs.

**Figure 1:** A network  $G^*$  derived from 3 excess stations and 5 deficit stations.

Then we set:

**VSR-Flow Model:** {Compute on the network  $G^*$  two integral flow vectors  $F$  and  $f$  such that:

- For any arc  $e = ((x, y), x, y \neq s, p)$ ,  

$$f_e \leq CAP \cdot F_e; \quad (E7)$$
- For any excess (or neutral) station  $x$ ,  

$$f_{(s,x)} = v(x) \quad (E8)$$
- For any deficit deficit station  $y$ ,  

$$f_{(y,p)} = -v(y) \quad (E8-I)$$
- $\sum_y F_{Depot,y} = \sum_y F_{y,Depot} \geq 1 \quad (E9)$
- Minimize  $\sum_{arcs e} CC_e \cdot F_e + \sum_{arcs e} CV_e \cdot f_e$

We denote by *LB-Flow* the related optimal value of this program. Then we may state:

**Theorem 3:** *LB-Flow* is a VSR lower bound .

**Proof :** Any VSR feasible solution may be represented as a *tour* collection  $\Gamma^*$  (it is enough to consider the related *route* collection  $\Gamma^*_{Route}$ ) given together with a feasible solution  $Z$  of the linear program *Load-VSR*.

Clearly,  $\Gamma$  gives rise to a flow vector  $F$ . By the same way,  $Z$  may be turned into a flow vector  $f$  which satisfies (E8), and one easily checks that (E7) is satisfied by the two projections of  $\Gamma$  and  $Z$  as flow vectors  $F, f$  on the network  $G^*$ . It comes that any VSR feasible solution  $\Gamma, Z$  may be turned into a feasible solution  $(F, f)$  of *VSR-Flow*. But the cost of  $(\Gamma, Z)$  is equal to:  $\alpha \cdot K + \beta \cdot \sum_k L \cdot COST(\Gamma_k) + C \cdot Z$ , where  $C$  is the cost vector of the *Load-VSR* model. Proceeding as in the proof of Theorem 1, we see that this quantity is at least equal to:  $\alpha \cdot (\sum_k L \cdot DIST(\Gamma_k)) / T\text{-Max} + \beta \cdot \sum_k L \cdot COST(\Gamma_k) + C \cdot Z$ , which coincides with the quantity  $CC \cdot F + CV \cdot f$ . We conclude.  $\square$

**Remark 2:** The above *VSR-Flow* model does not solve our VSR problem. One may consider as example, a *station set*  $X = \{Depot, A, B, C\}$ , a *carrier flow*  $F$  which describes the *route*  $(Depot, A, B, C, A, Depot)$  followed by 1 *carrier* with capacity 1, and a *vehicle flow*  $f$  which routes 1 flow unit from *excess station*  $C$  to *deficit station*  $B$ . Then the *carrier* cannot deliver its load in  $B$  before picking it up in  $C$ .

**Remark 3:** *LB-Flow* value provides us with a better lower bound than the *LB-MC* lower bound of Theorem 3. Still, *VSR-Flow* is a complex NP-Hard model, whose rational relaxation yields a poor lower bound as soon as *CAP* is large. The *Lagrangian* relaxation of the coupling constraint (E7) yields a *Lagrangian* value  $\sup_{\lambda \in \Lambda} (\inf_h (CV + \lambda) \cdot h) + (\inf_H (CC - \lambda) \cdot H)$  where:

- Vector flow  $h$  is subject to (E8) and vector flow  $H$  is subject to (E9);
- $\Lambda = \{\lambda \text{ such that the restriction of the graph } G_{Proj} \text{ to } X \text{ does not contain any negative } (CC - \lambda)\text{-circuit}\}$ .

But, because of total unimodularity of flow constraint matrices, this value is the same as the value obtained by performing *Lagrangian* relaxation of (E7) on the rational relaxation of *VSR-Flow*. That means that the above *Lagrangian* value does not improve the standard relaxation of the integrality constraint.

## IV. VSR HEURISTICS

### A. Min-Cost Assignment Based Heuristic.

We decompose here the VSR Problem into a Master *Min-Cost Assignment* problem and a Slave *Pick&Delivery (PDP)* Problem. Let us recall that a *Pick&Delivery* instance (see [1, 3, 15]) is defined by:

- a set  $J$  of *requests*  $j = (o(j), d(j), \lambda(j))$ , where  $o(j)$ ,  $d(j)$  and  $\lambda(j)$  are respectively the origin, the destination and the load of  $j$ ;
- a maximal duration  $D\text{-Max}$  of the routes followed by the *trucks*, all with capacity  $CH$ ;
- a *Depot* node, where all *trucks* are initially

located;

- a distance matrix  $D$ , defined on the set  $N$  of all nodes  $o(j)$ ,  $d(j)$ ,  $j \in J$ , augmented with the *Depot* node.

A collection  $\rho$  of *truck routes*  $\rho(m)$ ,  $m = 1..M$  defined on the set  $N$  is a feasible *PDP* solution if:

- Every *request*  $j$  is serviced by some *truck*  $m$ :  $m$  first loads  $\lambda(j)$  in  $o(j)$  and unloads it in  $d(j)$ ;
- The load of a *truck* never exceeds capacity  $CH$ ;
- The length (for the  $D$  matrix) of any route  $\rho(m)$ ,  $m = 1..M$ , never exceeds  $D\text{-Max}$ .

The length, in the sense of the  $D$  matrix, of route  $\rho(m)$ , is denoted by  $L\text{-}D(\rho(m))$ . Then solving our *PDP* instance means computing such a feasible *route* collection  $\rho$  which minimizes a quantity:

$$A.M + B. \sum_m L\text{-}D(\rho(m)) + C. \sum_j \lambda(j).Ride(j),$$

where  $Ride(j)$  is the time spent by load  $\lambda(j)$  inside a *truck*. A *Load-Split PDP* instance is defined the same way, but loads  $\lambda(j)$  may be split it into several sub-loads, which are separately handled.

Let us come back to our *VSR* instance, and suppose that we know, for every pair of *stations*  $(x, y)$ , where  $x$  is an *excess station* and  $y$  is a *deficit station*, which quantity  $Q_{x,y}$  had to move from  $x$  to  $y$  in order to achieve the *Relocation* process. Then, we only need to solve the *Load-Split PDP* instance defined by:

- *Requests*  $j = (o(j)=x, d(j)=y, \lambda(j)=Q_{x,y})$ , taken for all pairs  $x, y$  such that  $Q_{x,y} \neq 0$ ;
- $D\text{-Max} = T\text{-Max}$ ;  $D = DIST$ ;  $CH = CAP$ ;
- $A = \alpha$ ,  $B = b$ ,  $C = \delta$ .

One easily checks that it is possible to impose assignment vector  $Q$  to be an optimal solution, for some cost vector  $U = (U_{x,y}, x \text{ Excess}, y \text{ Deficit}) \geq 0$ , of the following *MCA(U)* (*Min-Cost Assignment*) model:

**MCA(U):**{Compute integral vector  $Q = (Q_{x,y}, x \text{ excess}, y \text{ deficit stations}) \geq 0$ , such that:

- For any *excess station*  $x$ ,  $\sum_{y \text{ deficit}} Q_{x,y} = v(x)$ ;
- For any *deficit station*  $y$ ,  $\sum_{x \text{ excess}} Q_{x,y} = -v(y)$ ;
- Minimize  $\sum_{x,y} U_{x,y}.Q_{x,y}$ .

This yields the following decomposition scheme *VSR-MCA* for the handling of the *VSR* Problem:

**VSR-MCA**( $N\text{-Rep}$ : Replication Number,  $N$ : Loop Number)

For  $j = 1..N\text{-Rep}$  do

Initialize cost vector  $U = (U_{x,y}, x \text{ Excess}, y \text{ Deficit}) \geq 0$ ;

For  $j = 1..N$  do (\*Local Search Loop\*)

Derive a *PDP Assignment* vector  $Q$  through optimal resolution of *MCA(U)*;

Solve (in a heuristic way) the related *Load-Split PDP* instance;

Update cost vector  $U$ ;

Apply to the resulting *route* collection  $\Gamma_{Route}^* = \{\Gamma_{Route}(1), \dots, \Gamma_{Route}(K)\}$  the *Load-NP-VSR* model, and remove from the routes  $\Gamma_{Route}(k)$  all stations which do not correspond to any effective load/unload transaction;

Keep the best result ever obtained.

We deal with *Load-Split PDP* through a GRASP-VNS (*Variable Neighborhood Search*) process based upon *Insert/Remove* operators:

- *Insert* operator: Inserting request  $j = (o(j), d(j), \lambda(j))$  into some route  $\rho(m)$  means:
  - computing 2 insertion nodes  $x$  and  $y$  in  $\rho(m)$ , and some sub-load  $\lambda \leq \lambda(j)$ ;
  - inserting  $o(j)$  ( $d(j)$ ) between  $x$  ( $y$ ) and its successor in  $\rho(m)$ ;
  - adding  $\lambda$  to the current load of  $\rho(m)$  between  $x$  and  $y$ , and updating  $\lambda(j)$ ;
- *Remove* operator: Delete  $o(j)$  and  $d(j)$  from  $\rho(m)$  and update the load of  $m$  accordingly.

**Cost vector  $U$  initialization:** Because of Theorem 1 about *LB-MC* lower bound, we initialize  $U$  according to the *Shortest Cost/Distance Strategy*, that means by setting, for any  $x, y$ ,  $x \text{ Excess}$ ,  $y \text{ Deficit}$ ,  $U_{x,y} = DIST_{x,y} + \lambda. (COST_{x,y} + COST_{y,x})$  where  $\lambda$  is some randomly generated non negative coefficient.

**“Update cost vector  $U$ ” instruction:**

Let us denote by  $U^0$  the initial cost vector and let us consider that we are provided with a current cost vector  $U$ . We derive from  $U$  a *request* vector  $Q$ , a *request* set  $Req(U) = \{r = (x, y, Q_{x,y}) \text{ such that } Q_{x,y} \neq 0\}$  and a *VSR* feasible solution  $\Gamma^*$ , whose global cost  $Global\text{-}Cost(\Gamma^*)$  may be distributed among requests  $(x, y, Q_{x,y})$  in a natural way:

- The *carrier* cost  $\alpha + \beta.L\text{-}COST(\Gamma(k))$  related to a given *carrier*  $k$  is shared between the *requests* which are served by this *carrier*, proportionally to the value  $L\text{-}COST(\Gamma(k)_{x,y}).Q_{x,y}$ , where  $\Gamma(k)_{x,y}$  is the sub-route which is induced by the restriction  $\Gamma(k)_{x,y}$  of  $\Gamma(k)$  between  $x$  and  $y$  (in case  $Q_{x,y}$  is split into sub-loads, we deal separately with those sub-loads);
- Every *request*  $r = (x, y, Q_{x,y})$  is assigned its part  $L\text{-}DIST(\Gamma(k)_{x,y}).Q_{x,y}$  of the *vehicle riding time*. It comes that  $Global\text{-}Cost(\Gamma^*)$  may be written  $Global\text{-}Cost(\Gamma^*) = \sum_{r \in Req(U)} Partial\text{-}Cost(r, \Gamma^*)$ , where  $Partial\text{-}Cost(r, \Gamma^*)$  is the part of  $Global\text{-}Cost(\Gamma^*)$  which is charged this way to request  $r$ . Then, for every request  $r = (x,y, Q_{x,y} \neq 0)$  we set  $V_{x,y} = Partial\text{-}Cost(r, \Gamma^*) / Q_{x,y}$  and update  $U$  as follows:
  - If  $Q_{x,y} \neq 0$ ,  $U_{x,y}$  is replaced by  $(U_{x,y} + V_{x,y})/2$  else  $U_{x,y}$  is unmodified;
  - When  $U = U^0$ ,  $U$  values may be very different

from  $V$  values. So we compute the mean value  $\tau$  of the ratio  $V_{x,y}/U_{x,y}$ ,  $x,y$  such that  $Q_{x,y} \neq 0$ , and replace every value  $U_{x,y}^0$  by  $\tau \cdot U_{x,y}^0$ .

A natural question comes about the quality of the *Shortest Distance strategy*. We may state:

**Shortest Cost/Distance Theorem 4:** *If  $\alpha = \delta = 0$  (carrier riding time minimization) and  $T\text{-Max} = +\infty$ , then the Shortest Cost/Distance Strategy induces an approximation ratio of  $(1+CAP)$ . This is the best possible ratio.*

**Sketch of the Proof.** We first notice that we may, since  $T\text{-Max} = +\infty$ , deal with only one *carrier*. In order to check that there is no ratio better than  $(1+CAP)$ , we build a VSR instance as follows:

- $K = 1$ ;
- $X = \{Depot\} \cup \{o_{n,c}, d_{n,c}, n = 0..N-1, c = 1..CAP - 1\}$  where  $N$  is a large number; function  $v$  is equal to 1 for  $o_{n,c}$  stations and to  $-1$  for  $d_{n,c}$  stations.
- $X$  is the node set of a graph  $G = (X, E)$  whose arc set  $E = E_1 \cup E_2 \cup E_3 \cup E_4$  comes as follows:
  - $E_1 = \{(Depot, o_{0,1}), (o_{N-1,1}, Depot)\}$ , both arcs with length equal to  $1/2$ ;
  - $E_2 = \{(o_{n,c}, o_{n,c+1}), (d_{n,c+1}, d_{n,c}), n = 0..N-1, c = 1..CAP - 1\}$ , all arcs with length  $\varepsilon$ , where  $\varepsilon$  is a small number;
  - $E_3 = \{(o_{n,CAP}, d_{n,CAP}), n = 0..N-1\} \cup \{(d_{n,1}, o_{n+1,1}), n = 0..N-2\}$ , all arcs with length 1;
  - $E_4 = \{(o_{n,c}, d_{n+c-CAP-1,c}), n = 0..N-1, c = 1..CAP\}$  addition being performed modulo  $N$ , all arcs with length  $1 - \alpha$ , where  $\alpha$  is a small number}.

Then we see that the length of a *carrier tour* is equal to  $2n \cdot (1 + (CAP-1)\varepsilon)$ . But the vector  $Q$  which derives from the *Shortest Cost/Distance Strategy Distance* strategy is provided by  $E_4$ , and the length of a related optimal *PDP* solution is equal to  $2n \cdot (1 + (CAP-1)\varepsilon) + \sum_c ((2 - \alpha + 2(c-1)\varepsilon))$ .

In order to check that  $(1+CAP)$  provides us with an approximation ratio, we denote by  $Q^{\text{Dist}}$  some vector  $Q$  which implements the *Shortest Cost/Distance Strategy*, and prove that it is possible to derive, from any VSR solution (with only 1 *carrier*)  $\Gamma$ , another feasible solution  $\Gamma^*$  consistent with the *Shortest Cost/Distance Strategy*. We do in such a way, while using matching techniques, that  $\text{Length}(\Gamma) \leq CAP \cdot \text{Length}(\Gamma^*)$ , and we conclude.  $\square$

#### B. A Vehicle Flow Based Heuristic.

We derive from the VSR flow model the following heuristic scheme:

#### Vehicle-Flow Algorithm.

Route collection  $\Gamma_{Route^*} \leftarrow Nil$ ;

While coefficients  $v(x)$ ,  $x \in X$  are not null do

  Compute an optimal solution  $(F^*, f^*)$  of the VSR-Flow model; (I1)

  Turn  $F^*$  into an Eulerian route  $\gamma$ ; (I2)

  Split  $\gamma$  into VSR feasible sub-routes

$\gamma_1, \dots, \gamma_s$  and insert them into  $\Gamma_{Route^*}$ ; (I3)

  Apply the Load-VSR flow model with feasibility oriented objective function: “Maximize  $Z_{p,s}$ ” in order to minimize residual excesses and deficits;

  Accordingly update coefficients  $v(x)$ ,  $x \in X$ ;

Apply to the resulting collection  $\Gamma_{Route^*}$  the Load-VSR flow model and derive related tour collection  $\Gamma^*$ .

We must detail some instructions inside this algorithmic scheme:

- (I1): *Handling of the VSR-Flow model*: Since VSR-Flow is difficult to handle, we use an ILP library and impose a threshold on the CPU-Time allowed for LB-Flow computation as soon as the number of stations exceeds 30.
- (I2): *Deriving an Eulerian route from  $F^*$* : Flow vector  $F^*$  defines a collection of arcs  $(x, y)$ , each of them taken  $F^*_{(x,y)}$  times, in such a way that for any node  $x$ , there exists as many arcs which enter into  $x$  as arcs which come out  $x$ . So, every connected component  $X_j$ ,  $j = 1..s$ , of the resulting graph gives rise to some Eulerian route  $\gamma_j$ . We build  $\gamma$  by starting from *Depot*, reaching the closest  $X_j$  into some node  $x_j$ , running  $\gamma_j$  until being back to  $x_j$  and then reaching the next closest  $X_j$  and so on. As a matter of fact, since there exists several ways to perform this route construction process, we do it while simulating related loading/unloading transactions and trying to maximize them.
- (I3): *Splitting the tour  $\gamma$  into feasible sub-tours*: Since  $L\text{-DIST}(\gamma)$  may exceed  $T\text{-Max}$ , we run along  $\gamma$  (starting from *Depot*), and every time we arrive to some station  $x$  such that:
  - interrupting current sub-route  $\gamma_j$  by going from  $x$  to *Depot* maintains the feasibility of  $\gamma_j$ ,
  - going to the successor  $y$  of  $x$  according to  $\gamma$  and next to *Depot* makes  $L\text{-DIST}(\gamma_j)$  exceed  $T\text{-Max}$ ,
 then we close  $\gamma_j$  by going from  $x$  to *Depot*, and start  $\gamma_{j+1}$  by going from *Depot* to  $y$  and so on.

## V. NUMERICAL EXPERIMENTS

Our purpose is to get a comparative evaluation of both the lower bounds which were described in Section III and the two heuristic scheme described in Section IV, and at testing the influence of scaling coefficients  $\alpha$ ,  $\beta$ ,  $\delta$ .

Algorithms were implemented in C, on PC AMD Opteron 2.1GHz, while using gcc 4.1 compiler. We used the CPLEX12 library for the handling of linear models.

**Instances:** No standardized benchmarks exist for generic *VSR*. So we built instances as follows:

- The station set  $X$  is randomly generated as set of  $n + 1$  points  $x_0, x_1, \dots, x_n$ , inside the  $[0,10] \times [0,10]$  sub-square of the Euclidean 2D-space ;
- $DIST$  corresponds to the Euclidean Distance;
- $COST$  corresponds either to a multiple of either the Euclidean distance or the Sum distance  $DIST-S$ :  $COST_{(x,y),(x',y')} = |x' - x| + |y' - y|$ ;
- Each station but  $Depot = x_0$  is assigned a random  $v(x)$  value chosen between -10 and 10, in such a way that the sum of demands over all stations equal to 0;
- $T-Max$  is randomly chosen between 30 and 100.

### A. Testing the Impact of Scaling Coefficients $\alpha, \beta, \delta$ .

On a given instance  $(X, v, CAP, T-Max, DIST)$ , we fix  $\alpha = 10$ , make vary  $\beta, \delta$  with  $\beta + \delta = 1$ , and compute solutions through the *Shortest Distance Strategy*. We obtain the Pareto frontier of figure 2, with  $t_s$  denoting the *carrier riding cost* and  $t_{ind}$  the *vehicle riding time*.

**Figure 2:** Pareto frontier carrier riding cost versus vehicle riding time

**Comment:** Carrier riding cost and vehicle riding time behave like antagonistic criteria.

### B. Comparing the Lower Bounds of Section III

For several groups of 10 instances each related to a given size  $n$ , we compute the mean value of:

- $LB-Flow$ : as defined in Theorem 3;
- $LB-MC$  and  $LB-UMC$  as defined in Theorem 1 and 2.

We get the following results:

TABLE 1: LOWER BOUNDS WITH  $A=10, B=1, \Delta=0$

$n$	$LB-Flow$	$LB-MC$	$LB-UMC$
20	84.8	82.3	73.6
30	96.5	84.6	77.2
40	108.4	92.2	89.7
50	135.1	117.8	112.7
60	141.5	130.1	115.2

TABLE 2: LOWER BOUNDS WITH  $A=10, B=0, \Delta=1$

$n$	$LB-Flow$	$LB-MC$	$LB-UMC$
20	182.7	176.9	160.0
30	228.2	216.2	210.0
40	235.6	218.7	205.9
50	299.9	288.3	269.7
60	297.3	270.1	261.4

**Comment:** Experiments confirm Theory (Theorem 3). We notice the quality of the lower bound  $LB-LF$ .

### C. Testing the Heuristics of Section IV

We compute, for the same groups of 10 instances as above, the average of the following *Cost* values:

- $SD$  ( $SD(50)$ ) obtained through 1 (50) replications ( $N-Rep = 1$  and  $N-Rep = 50$ ) of *Shortest Cost/Distance Strategy* initialization of *VSR-MCA*  $\Rightarrow$   $CPU-SD$  is the related CPU time (s).
- $LS(50)$ : obtained through 50 iterations ( $N = 50, N-Rep = 1$ ) of the Local Search loop of *VSR-MCA*, after initialization through  $SD \Rightarrow$   $CPU-LS$  is the related CPU time.
- $VF$ : obtained through the *Vehicle-Flow* heuristic  $\Rightarrow$   $CPU-VF$  is the related CPU time.
- $LB$  denotes here the  $LB-Flow$  lower bound of the previous experiment. For  $n = 40$  (50, 60) we force the CPLEX computation to stop after 150 s (150 s, 500 s, 1000 s)

We get:

TABLE 3: VALUES  $SD, RSD(50)$  WITH  $A=10, B=1, \Delta=0$

$n$	$LB$	$SD$	$CPU-SD$	$SD(50)$
20	84.8	99.5	0.1	94.7
30	96.5	120.5	0.3	113.6
40	108.4	152.6	0.9	166.1
50	135.1	182.3	1.4	169.0
60	141.5	200.1	1.8	178.5

TABLE 4: VALUES PI(50), VF WITH A =10, B =1, Δ =0

n	LB	LS(50)	CPU-LS	VF	CPU-VF
20	84.8	96.3	5.2	92.3	4.7
30	96.5	112.5	12.6	108.9	9.6
40	108.4	139.7	40.4	132.0	140.1
50	135.1	164.0	61.5	161.8	549.3
60	141.5	176.7	80.2	169.3	1086.0

TABLE 5: VALUES SD, RSD(50) WITH A =10, B =0, Δ =1

n	LB	SD	CPU-SD	SD(50)
20	182.7	220.0	0.1	212.1
30	228.2	273.1	0.2	264.6
40	235.6	297.5	0.6	277.7
50	299.9	372.2	1.0	346.3
60	297.3	378.4	1.4	348.9

TABLE 6: VALUES PI(50), VF WITH A =10 ,B =0, Δ =1

n	LB	LS(50)	CPU-LS	VF	CPU-VF
20	182.7	217.6	4.1	205.6	5.8
30	228.2	270.9	8.3	255.7	10.2
40	235.6	288.7	31.6	264.6	187.1
50	299.9	364.7	50.7	335.9	561.0
60	297.3	369.8	61.8	340.8	1098.4

**Comment :** The improvement margin induced by the *VSR-MCA* local loop is not very high, especially when the focus is on the *vehicle riding time*. A consequence is that performing random diversification according to the *Randomized Shortest Cost/Distance Strategy* is most often more efficient. Both require small computational time. Conversely, the *Vehicle Flow* oriented algorithm provides better results but equires higher computation times. At the end, the gap which remains between the *LB* value and the values which are produced by our heuristics suggests that our lower bound probably misses the optimal value of our *VSR* problem by about 8 %.

## II. CONCLUSION

We mainly dealt here with a *Vehicle Sharing Relocation* problem, related to the operational management of *Vehicle Sharing* systems, and which we handled according to an approach which puts the focus on the way transported object (*vehicles*) move from *excess stations* to *deficit* ones. Still, many open problems remain, related to the design of exact algorithms, to the way allowing *carriers* to exchange *vehicles* may eventually improve the quality of the solutions, and also, if we refer to practical context, to the way algorithms which have been designed for static model may be adapted in order to fit with *on line* contexts. Future research will be carried on in order to address these issues.

**Abstract**—We describe a stochastic method using Dirichlet processes to derive mixture models that allow the numerical description of outbreaks of diseases with multiple sources. We show that existing disease models may be extended using this method and how this may be used in a practical context to support the simulated response to a mass casualty public health emergency.

**Index terms** epidemiology, stochastic processes, clustering, mixture models, Chinese restaurant process, non-parametric fitting.

## I. INTRODUCTION

MODERN epidemiological practice during the investigation of the outbreak of a disease often involves the construction of mathematical or computation models. Frequently, these models are used to answer operational questions such as forecasting where further cases are likely to occur, what the total number of casualties are likely to be, and perhaps even where the likely source of the disease may be found. To be of greatest value such estimates need to be made from a small number of cases early in the course of the outbreak so that public health officials may prioritize resources.

Many of these epidemiological models use the approach of representing the outbreak as a *probability density function* [1]–[3]. As such, samples taken from this function should produce a similar spread of cases as the real outbreak. These probability density functions are usually parametrized by a fixed and finite number of parameters *e.g.* spatio-temporal location, climatic conditions, transmission rates, *etc.* [3]. The values of these parameters are manipulated until a set is found which maximises the likelihood of the probability density function. This

optimisation process is a well known problem in mathematics and computer science with a huge literature. Major reviews may be found in [4]–[6] and also see Fletcher [7] for a partial overview and introduction of current theory and techniques.

Diseases however may not be limited to a single source or event. Examples where there may be multiple clusters within an outbreak could include:

- A legionella outbreak where multiple cooling towers or air conditioning units are responsible for the cases.
- A shipment of infected food distributed to a large number of restaurants, schools, canteens *etc.* over a region.
- A terrorist incident involving multiple covert releases of a pathogen in a short period of time.

Where there are multiple sources, the scenario can be thought of as several simultaneous, independent outbreaks in space and time. Since we do not know *a priori* how many sources there are, the process of determining the parameter values becomes substantially more difficult. The problem now requires a solution related to cluster analysis for which there are many well-known algorithms such as *k-means clustering* [8], [9], *principal component analysis* [10]–[12] and *hierarchical cluster analysis* [13] which have been applied to problems within the field of epidemiology [14]–[17].

Applying such clustering algorithms directly to a multi-outbreak situation is complicated, especially as it may not be clear many sources of exposure there are and consequently what the ‘correct’ number of clusters should be. In this paper we show how multiple solutions for the value of parameters in the base model can be considered as a *mixture model*, *i.e.* a weighted sum of several probability density functions each with different parameter values. We show how such a mixture model may be calculated by applying a *Dirichlet process* and extend a single source disease plume model using Dirichlet processes to encompass multiple sources to provide a concrete example of this method in action during a table top exercise.

## II. MIXTURE DISTRIBUTIONS

### A. Finite mixture models

In this paper we denote probability density functions by  $F$  (or  $F_*$ ) and probability mass functions by  $H$  (or  $H_*$ ).

Given a finite collection of probability density functions, a *finite mixture distribution* is the probability density function for a random variable derived by first randomly selecting one of the probability density functions and then drawing a sample from that probability density function.

Formally, let  $F_1, F_2, \dots, F_n$  be probability density functions with the same domain and  $w_1, w_2, \dots, w_n$ , be positive real numbers (weights) such that  $w_1 + w_2 + \dots + w_n = 1$ .

Then the probability density function for the derived mixture distribution is given by:

$$F(x) = \sum_{i=1}^n w_i F_i(x).$$

To sample from this distribution we first choose a distribution  $F_k$  with probability  $\mathbf{P}(k = i) = w_i$ , then we draw from  $F_k$ .

From an epidemiology perspective, we can think of each pair  $(F_i, w_i)$  as distinct clusters and the probability that a case belongs to that cluster. Here we take all the probability density functions to be the same (*e.g.* all lognormal distributions), but this is not necessary.

### B. Infinite mixture models

The mixture model can be extended in a natural way to an *infinite mixture distribution*. Infinite mixtures often have much nicer theoretical properties than finite mixtures and in the next section we describe a natural relationship between infinite mixtures and Dirichlet processes. In particular, infinite mixtures models are often used as they allow us to “*by-pass the need to determine the “correct” number of components in a finite mixture model, a task fraught with technical difficulties*” [18].

An infinite mixture distribution is defined to be:

$$F(x) = \sum_{i=1}^{\infty} w_i F_i(x),$$

note that we still require that

$$\sum_{i=1}^{\infty} w_i = 1.$$

As before, we sample from this distribution by first choosing a distribution  $F_k$  with probability  $\mathbf{P}(k = i) = w_i$ , then sampling from  $F_k$ . In practice it is computationally impossible to construct an infinite mixture model, instead we approximate them with finite mixtures for some very large  $n$ .

## III. DIRICHLET PROCESSES

### A. A formal definition of a Dirichlet process

A *stochastic process* is a distribution over a function space. Each sample path from the stochastic process is a function drawn from the distribution. *Dirichlet processes* are a class of stochastic process where the sample path is a probability

distribution with special properties. Less formally, a Dirichlet process is a distribution over distributions, and draws from a Dirichlet process are random probability mass functions.

Dirichlet processes can be thought of as an infinite dimensional generalization of the Dirichlet distribution. Recall (from [19]) that the Dirichlet distribution  $\mathbf{Dir}(\alpha)$  is a continuous multivariate probability density function parametrized by  $K$ , the number of dimensions and a vector of  $K$  positive reals  $\alpha = (\alpha_1, \dots, \alpha_K)$ , the *concentration parameters*.

Let  $F$  (the *base distribution*) be a probability density function with support  $\mathcal{S}$ , and  $\alpha$  (the *concentration parameter*) be a positive real number. We denote the Dirichlet process by  $\mathbf{DP}(F, \alpha)$ .  $F$  is the expected value of the Dirichlet process and draws from  $\mathbf{DP}(F, \alpha)$  are ‘around’  $F$  (in the same way that draws from a normal distribution are around the mean). It is impossible to describe  $\mathbf{DP}(F, \alpha)$  itself or any probability mass function  $H$  drawn from  $\mathbf{DP}(F, \alpha)$ , both would require an infinite amount of information. However there are properties of  $\mathbf{DP}(F, \alpha)$  and  $H \sim \mathbf{DP}(F, \alpha)$  that can be precisely stated.

Let  $\{S_i\}_{i=1}^n$  be a measurable finite partition of  $\mathcal{S}$  and  $H$  be a random probability mass function distributed according to  $\mathbf{DP}(F, \alpha)$  (remember that  $\mathbf{DP}(F, \alpha)$  is a ‘distribution of distributions’). Then the random vector

$$(H(A_1), \dots, H(A_K)) \quad (1)$$

is distributed according to the multivariate distribution

$$\mathbf{Dir}(\alpha F(A_1), \dots, \alpha F(A_K)). \quad (2)$$

Note that we have made no assumptions on the base probability density function  $F$ , in particular we have not assumed that it is parametrized, or even finitely parametrizable.

The concentration parameter  $\alpha$  controls the ‘discreteness’ of the distributions drawn from  $\mathbf{DP}(F, \alpha)$ . As  $\alpha \rightarrow 0$  the drawn distribution becomes more concentrated at a single value and at the limit the distribution is a Dirac delta function. As  $\alpha \rightarrow \infty$  the drawn distribution becomes ‘more continuous’, and in the limit, the distributions are continuous *i.e.* they are probability density functions. Note that for finite  $\alpha$  any distribution drawn from  $\mathbf{DP}(F, \alpha)$  will *almost surely* be a probability mass function.

We cannot draw a distribution  $H$  explicitly from  $\mathbf{DP}(F, \alpha)$ . Instead we use a method that allows us to draw a large number of observations  $X_1, X_2, \dots$  from  $H$  without ever describing  $H$  concretely.

Given  $F$  and  $\alpha$  as above, we sample  $X_1, X_2, \dots$  from  $H$  as follows:

- 1) Sample  $X_1$  from  $F$ .
- 2) For  $n > 1$ :
  - a) With probability  $\frac{\alpha}{\alpha + n - 1}$  draw  $X_n$  from  $F$ .
  - b) With probability  $\frac{n_i}{\alpha + n - 1}$  set  $X_n = X_i$ , where  $n_i$  is the number of  $X_j$ ,  $j < n$  such that  $X_j = X_i$ .

It can be shown rigorously, using *de Finetti’s theorem*, that this process is the same as drawing a probability mass function from  $\mathbf{DP}(F, \alpha)$ , then sampling  $X_1, X_2, \dots$  from  $H$  (see, for

example, Aldous [20]). This construction is often called the *Chinese restaurant process*.

#### B. From mixture models to Dirichlet processes

Our assumption was that complex multi-source disease outbreaks can be approximated by samples from *finite* mixture models, a weighted sum of finitely many parametrized distributions. Our goal is to find the parameters and the weights based on a small number of observations.

**Example** Consider a mixture model where the probability density function  $F$  is given by a sum of three 1-dimensional Gaussians with means and standard deviations  $\mu_1, \mu_2, \mu_3$  and  $\sigma_1, \sigma_2, \sigma_3$  respectively. As  $\mu_i$  are real numbers and  $\sigma_i$  are positive real numbers, the parameter space for  $F$  is  $(\mathbb{R} \times \mathbb{R}_{>0})^3$  and the probability mass function is:

$$H(x) = \begin{cases} w_1, & \text{if } x = (\mu_1, \sigma_1); \\ w_2, & \text{if } x = (\mu_2, \sigma_2); \\ w_3, & \text{if } x = (\mu_3, \sigma_3); \\ 0, & \text{otherwise.} \end{cases} \quad (3)$$

Given no information about  $F$  except for a small number of values sampled from it, we seek to recover  $H$ . However it is not possible to do this directly. In the next section we describe a method for approximating  $H$  using Dirichlet processes.

#### IV. GIBBS SAMPLING IN A MONTE CARLO MARKOV CHAIN

The approach used here is that of a modified Gibbs sampling algorithm on a Monte Carlo Markov chain (MCMC) and follows from algorithm 5 as described by Neal [18]. This method is specifically for use when we believe the unknown probability density function is a mixture model where all the components are from the same family of parameterized probability density functions.

Our hypothesis is that there exists a mixture distribution that explains the data. Since there is a bijection between mixture models and probability mass functions on the parameter space, we use Dirichlet processes to find the probability mass function corresponding to the ‘best’ mixture model.

Let  $y_1, \dots, y_n$  be our data and  $F_\theta$  a distribution parameterized by  $\theta$  and let  $G_0$  be a base distribution on the parameter space  $\Theta$ . Then our hypothesis can be restated as the data  $y_i$  are distributed identically to samples from the mixture distribution

$$F(y) = \sum_{i=1}^{\infty} w_i F_{\theta_i}(y).$$

The goal is to find the mixture, *i.e.* the pairs  $(w_i, \theta_i)$ , that best explain the data. This is equivalent to finding a probability mass function  $H$  over  $\Theta$ .

The likelihood function is defined to be  $\mathbf{F}(y_i, \theta) = F_\theta(y_i)$ . We initialize the Markov chain by randomly sampling  $n$  times from  $G_0$ , *i.e.* we draw  $n$  sets of parameters  $\{\theta_i\}_{i=1}^n$  from  $\Theta$  parameter space.

We repeatedly sample from the MCMC as follows:

- 1) For each data point  $y_i$ ,  $i = 1, \dots, n$ , update  $\theta_i$ . First generate a candidate  $\theta_i^*$  as follows:

- a) With probability  $\frac{\alpha}{\alpha+n-1}$ , use  $\theta_i^*$  from  $G_0$ .
- b) With probability  $\frac{n_i}{\alpha+n-1}$  set  $\theta_i^* = \theta_j$ , where  $i \neq j$ .

The acceptance probability is

$$\theta a(\theta_i^*, \theta_i) = \min \left\{ 1, \frac{\mathbf{F}(y_i, \theta_i^*)}{\mathbf{F}(y_i, \theta_i)} \right\}.$$

With probability  $\theta a(\theta_i^*, \theta_i)$ , set  $\theta_i$  to be equal to  $\theta_i^*$ , otherwise leave  $\theta_i$  unchanged. Repeat this step ‘several times’ (to ensure thorough mixing and thinning).

- 2) Update each distinct  $\theta_i$  by drawing a new value from  $\theta_i|y_i$ .

After sampling from the MCMC chain a large number of times, normalize to get a probability mass function  $H$  over  $\Theta$ . We then map this to a finite mixture model  $F$ . The probability mass function  $H$ , and consequently the mixture model, arising from this process is very likely to have a large number of components. This reflects the uncertainty arising from the small number of cases and the limitation of the models. The resulting probability mass function  $H$  is likely to have many thousands of components depending of the length of the chain. If the MCMC has converged we would expect the components of  $H$  to be grouped around the components of the ‘true’ mixture model where the ‘true’ mixture model is likely to consist of a small number of components, reflecting the small number of sources.

Since each state of the MCMC is an assignment of a set of parameters to each observed data point, we can take a ‘vertical slice’ through the MCMC chain. That is, we can isolate individual data points or subsets of data points and produce probability mass functions for data points of particular interest. This could also allow the additional weighting for specific data points. *e.g.* in an epidemiological context, we may be unsure about the diagnosis of some patients, while being sure about others. We could use this information to weight the more certain cases more heavily.

#### V. EXAMPLE OF USE

This optimization method was developed to extend existing disease models to respond to the challenge of multiple source disease outbreaks. To ensure greatest utility of this method in genuine emergency situations the Dirichlet process optimizer was implemented as part of a wider suite of large-scale emergency response tools constructed as part of the IMPRESS system [21]. The IMPRESS system’s components cover the range of emergency response disciplines from field triage through to strategic oversight of a broad scale biological incident. These capabilities are designed to strengthen coordination between response organizations and emergency medical services, including requests for international support.

Here the method was applied to an implementation of the Anthrax infection model presented in Legrand’s 2009 paper [3]. The model describes a covert, aerosolized release of Anthrax in a populated area. The model parameters to be optimized are: the location of the release, the time of the release, the amount of Anthrax released, and parameters related to wind speed and wind direction at the time of release.

Fig. 1. A simulated example of the plume output from SorLoc. Input case locations are marked as triangles with output plume density shaded.

The optimizer combined with the disease model forms the SorLoc (source location) module.

The SorLoc module was tested and validated in the last phase of the IMPRESS project life cycle as part of a wider Greek-Bulgarian table top exercise. The Table Top Exercise was held in Sofia, Bulgaria on 16<sup>th</sup> March 2017. The exercise was operated by Greek and Bulgarian actors drawn from public services and hospitals across the two countries.

The exercise was based on a scenario where a combination of heavy rainfall and a strong earthquake had struck Southern Bulgaria. As a result, extensive damage was caused to buildings and infrastructure along with a landslide which damaged the road beside the Struma(BG)/Strimon(GR) River causing the river to overflow and flood part of the E79 Highway. These incidents were coupled with multiple car accidents caused by rockfalls along this segment of the E79 near the Greek-Bulgarian border. This situation generated many fatalities and injuries requiring immediate response, pre-hospital medical intervention and transportation of casualties to nearby hospitals. Victims' transportation via the collapsed E79 connecting the southern part of Bulgaria with the rest of the country caused the Bulgarian authorities to request international medical assistance, activating the standard procedures via the European Emergency Response Centre (EERC) in Brussels.

In order to facilitate the SorLoc module demonstration within this exercise, a scenario for aerosol released Anthrax was run in parallel to the main exercise. An outbreak was simulated for Shoreditch, London. We presented the course of the epidemic (as home locations and time at which each person fell ill) to SorLoc at a simulated five days from the first case and ran the optimization so that predictions of further evolution of the disease, numbers and locations of affected people and the original source of the outbreak might be calculated.

An illustrative input and result from the SorLoc module may be found in Figure 1. The output is provided as the inhalational dose generated by the plume(s) on a raster grid. This allows direct and immediate interpretation of size and the scale for the outbreak. It also provides a foundation for the mitigation effort and delivery of countermeasures to the population.

## VI. CONCLUSION

Within this paper we have shown that a model which has been formulated as a probability density function and which would ordinarily be solved by standard optimization techniques may be extended to support multiple versions of the modeled process through the use of mixture models and Dirichlet processes. In addition we have explicitly shown the use of this within the field of disease modeling where it is directly applicable to existing models. We also constructed and demonstrated a production-ready implementation which was used to support a simulated response to a mass casualty, public health emergency.

# Computer Science & Systems

CS is a FedCSIS conference area aiming at integrating and creating synergy between FedCSIS events that thematically subscribe to more technical aspects of computer science and related disciplines. The CSNS area spans themes ranging from hardware issues close to the discipline of computer engineering via software issues tackled by the theory and applications of computer science and to communications issues of interest to distributed and network systems. Events that constitute CSNS are:

- CANA'17—10<sup>th</sup> Computer Aspects of Numerical Algorithms
- C&SS'17—<sup>th</sup> International Conference on Cryptography and Security Systems
- CPORA'17—2<sup>nd</sup> Workshop on Constraint Programming and Operation Research Applications
- MMAP'17—10<sup>th</sup> International Symposium on Multimedia Applications and Processing
- WAPL'17—6th Workshop on Advances in Programming Languages
- WSC'17—9th Workshop on Scalable Computing

# 10<sup>th</sup> Workshop on Computer Aspects of Numerical Algorithms

**N**UMERICAL algorithms are widely used by scientists engaged in various areas. There is a special need of highly efficient and easy-to-use scalable tools for solving large scale problems. The workshop is devoted to numerical algorithms with the particular attention to the latest scientific trends in this area and to problems related to implementation of libraries of efficient numerical algorithms. The goal of the workshop is meeting of researchers from various institutes and exchanging of their experience, and integrations of scientific centers.

## TOPICS

- Parallel numerical algorithms
- Novel data formats for dense and sparse matrices
- Libraries for numerical computations
- Numerical algorithms testing and benchmarking
- Analysis of rounding errors of numerical algorithms
- Languages, tools and environments for programming numerical algorithms
- Numerical algorithms on coprocessors (GPU, Intel Xeon Phi, etc.)
- Paradigms of programming numerical algorithms
- Contemporary computer architectures
- Heterogeneous numerical algorithms
- Applications of numerical algorithms in science and technology

**Abstract**—The aim of this paper is to investigate the impact of thread affinity on computing performance for matrix factorization on shared memory multicore systems with hierarchical memory. We consider two parallel block matrix factorizations (LU and WZ) and employ thread affinity to improve their performance. We study decomposition without pivoting and we compare differences between various affinity strategies for diagonally dominant matrices. Our results show that the choice of thread affinity has the measurable impact on the performance of the matrix factorizations.

## I. INTRODUCTION

THE ADVANCE of the shared memory multicore and manycore architectures caused a rapid development of one type of the parallelism, namely the *thread level parallelism*. This kind of parallelism relies on splitting a program into subprograms which can be executed concurrently. Each of such subprograms is performed by one or more software threads.

The *thread affinity* is a set of policies that determine how software threads are pinned to processing units [1]. The goal of the thread affinity is to bind software threads to the hardware threads in such a way that memory accesses to data shared between software threads are optimized and all the cores are equally loaded.

Determining the efficiency of the thread mapping depends on the machine and the application. There is not a single thread mapping strategy that suits all the applications. In this work, we are going to try to state rules which guide us to determine efficient thread affinity to improve the performance of matrix factorization on shared memory multithreaded machines.

Efficient parallel matrix factorizations and their implementations on different contemporary parallel machines are crucial for engineering applications and computational science. In this work, we study the LU factorization, and another form of the factorization, namely the WZ [3], [4] factorization. We assume that the factorized diagonally dominant matrix is dense, non-singular, square. For both factorizations (LU and WZ), we consider block versions which use a standard set of Basic Linear Algebra Subprograms (BLAS) [2].

The rest of this paper is organized as follows. Section II describes the methodology of the numerical experiments. Section III shows the results of numerical experiments carried

out on shared memory multicore architectures and evaluates different thread affinities for the matrix decomposition. Section IV concludes our research.

## II. ENVIRONMENT

We tested the execution time of two matrix decompositions, namely the LU factorization and the WZ factorization. We compared three implementations of these matrix decompositions, namely:

- a multithreaded implementation of the `dgetrfnpi` routine from the MKL library, which computes the complete LU factorization of a general matrix without pivoting. In our case, the matrices are square which size is  $n \times n$ . In the implementation of the `dgetrfnpi` routine the panel factorization (factorization of a block of columns) is used, as well as the level 3 BLAS routines (DTRSM and DGEMM). We denoted this LU factorization implementation by LU.
- a parallel block WZ factorization with the use of multithreaded level 3 BLAS routines (DTRSM and DGEMM), where the matrix is partitioned into  $r \times r$  tiles (denoted by TWZ( $r$ ));
- a parallel block WZ factorization with the use of level 3 BLAS routines (DTRSM and DGEMM) and the OpenMP standard (denoted by TWZ( $r$ )-OpenMP). OpenMP is used to parallelize for loops with the `dynamic` scheduler.

Experiments were carried out on Intel Xeon E5-2670 v3 (Haswell) with two 12-cores (24 cores). All applications were compiled with `icc` using the following options: `-xHost`, `-mkl`, `-openmp`, `-O3`. Here, the `-xHost` option generates instructions for the highest instruction set and processor available on the compilation host machine. The `-mkl` and `-openmp` options link the program against two libraries (MKL and OpenMP). The last one, `-O3`, orders the compiler to optimize the code automatically with the use of vectorization and parallelization (among others).

All floating point calculations were performed in the double precision. The input matrices were generated by the author. They were random matrices, with a dominant diagonal of an even size of  $1024 \times \{1, \dots, 9\}$ . Various numbers of tiles were tested, namely, each matrix was divided into  $r = 8, 16, 32, 64$  tiles for each side (for the rows and the columns). The

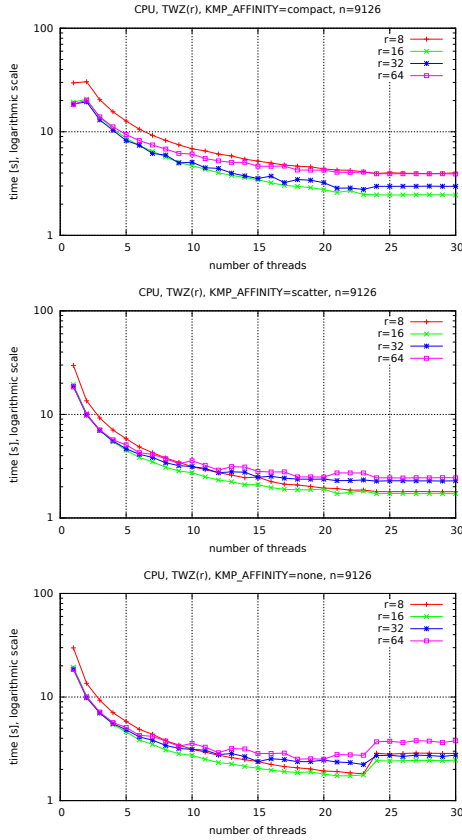

Fig. 1. Run-time in seconds of the parallel block WZ factorization algorithm for different  $r = 8, 16, 32, 64$  for a matrix of size 9216 for various numbers of threads and three values of the `KMP_AFFINITY` environment variable — `TWZ(r)` implementation.

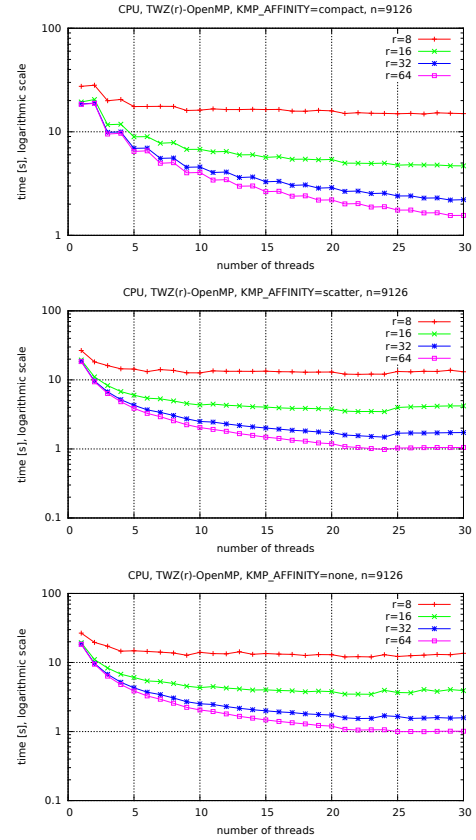

Fig. 2. Run-time in seconds of the parallel block WZ factorization algorithm for different  $r = 8, 16, 32, 64$  for a matrix of size 9216 for various numbers of threads and three values of the `KMP_AFFINITY` environment variable — `TWZ(r)-OpenMP` implementation.

performance times were measured with the use of a standard function, namely `dsecnd()` from MKL library. Another environment variable used in the tests is `KMP_AFFINITY`, which is set to one of the three values: `compact`, `scatter`, `none`. To better control assigning software threads to hardware threads, we chose the granularity as `thread`.

We studied a connection between the `KMP_AFFINITY` environment variable and the following parameters: the number of the threads — from 1 to 30, the size of the matrix:  $1024 \times \{1, \dots, 9\}$ , the number of the tiles for each side (for the rows and the columns):  $r = 8, 16, 32, 64$ .

### III. RESULTS

Figures 1 and 2 present the time (in seconds) of the block WZ factorization for 4 different numbers of tiles ( $r = 8, 16, 32, 64$ ), for different number of threads (1 – 30 threads), for a matrix of the size 9216, for three values of the `KMP_AFFINITY` environment variable — for the `TWZ(r)` and `TWZ(r)-OpenMP` implementations (respectively).

Figures 3 and 4 present the time (in seconds) of the block WZ factorization for various number of tiles ( $r = 8, 16, 32, 64$ ) for 24 threads and different sizes of matrices for all three considered values of the `KMP_AFFINITY` environment vari-

able for the `TWZ(r)` and `TWZ(r)-OpenMP` implementations (respectively).

At least one important conclusion can be seen from these results. Namely, the number of tiles influences the time of the computation. For  $r = 64$  the `TWZ(r)` implementation is the slowest but `TWZ(r)-OpenMP` is the fastest. The `TWZ(r)` implementation is the fastest for  $r = 16$ . This conclusion holds true independent of the value of the `KMP_AFFINITY` variable, the number of threads or the matrix size.

Secondly, we investigate the effect of the thread affinity on the execution time for all three implementations. Figure 5 compares all three values of the `KMP_AFFINITY` environment variable and it shows the time (in seconds) for different numbers of threads (1–30 threads) for a matrix of the size 9216 — for `TWZ(16)` (top left), `TWZ(64)-OpenMP` (top right) and the LU factorization (at the bottom).

Figure 6 compares all three values of the `KMP_AFFINITY` environment variable and it shows the time (in seconds) for different matrix sizes for 24 threads — for `TWZ(16)` (top left), `TWZ(64)-OpenMP` (top right) and the LU factorization (at the bottom). Thus, it implies that (for the considered applications) the best value of the `KMP_AFFINITY` environment variable is `scatter` which is further investigated.

Fig. 3. Run-time in seconds of the parallel block WZ factorization algorithm for different  $r = 8, 16, 32, 64$  for various sizes of matrices for 24 threads and three values of the `KMP_AFFINITY` environment variable — TWZ( $r$ ) implementation.

Finally, we analyzed the execution times of the three implementations (namely LU, TWZ(16) and TWZ(64)-OpenMP) for the `KMP_AFFINITY` environment variable set to `scatter`. Figure 7 compares the performance times (in seconds) of the TWZ(16), TWZ(64)-OpenMP and LU implementations for `scatter` and for different numbers of threads and matrix sizes.

The shortest execution time is obtained for LU. Our TWZ(64)-OpenMP implementation is a little worse. The slowest implementation is TWZ(16). To better investigate the performance time for LU and our best implementation, they were tested for larger matrices and various values of the `KMP_AFFINITY` environment variable. Table I presents the times (in seconds) of the LU and TWZ(64)-OpenMP implementations.

For `none` our implementation is faster than LU; however, for `scatter`, LU wins. This implies that LU is more sensitive for the `KMP_AFFINITY` setting.

The tests show the following facts. **The number of the threads.** To achieve the shortest execution time, it is the best to use all the physical cores (here, 24 threads), although, without hyper-threading. **The matrix size.** For small matrices, our implementations are better. It is caused by the fact that

Fig. 4. Run-time in seconds of the parallel block WZ factorization algorithm for different  $r = 8, 16, 32, 64$  for various sizes of matrices for 24 threads and three values of the `KMP_AFFINITY` environment variable — TWZ( $r$ )-OpenMP implementation.

TABLE I  
THE TIMES (IN SECONDS) OF THE LU AND TWZ(64)-OPENMP IMPLEMENTATIONS — FOR VARIOUS VALUES OF `KMP_AFFINITY`

matrix size	implementation	compact	scatter	none
12 288	TWZ(64)-OpenMP	4.06	<b>2.22</b>	2.39
	LU	3.66	<b>1.80</b>	3.50
13 312	TWZ(64)-OpenMP	5.16	2.70	<b>2.24</b>
	LU	4.53	<b>2.23</b>	4.70
14 336	TWZ(64)-OpenMP	6.59	<b>3.39</b>	3.50
	LU	5.69	<b>2.77</b>	4.30
15 360	TWZ(64)-OpenMP	8.18	<b>4.08</b>	4.24
	LU	6.96	<b>3.42</b>	6.40

MKL does not create threads for small problems. However, for the size of 9216, the shortest time is achieved by LU. All three implementations scale well in regard to the size of the matrix. **The number of the tiles.** The block size used by the MKL implementation of `dgetrf` is internally hidden in the library and unknown to us at the time of this writing. The  $r$  parameter impacts the execution time of the block WZ factorization for both implementations. **Thread Affinity.** The thread affinity had an important impact on the performance. All three implementations (both the LU factorization implementation provided by a vendor as well as the WZ factorization implemented by the author) work fastest

Fig. 6. Run-time in seconds of the parallel block WZ factorization algorithm (top left: TWZ(16); top right: TWZ(64)-OpenMP) and the LU factorization (at the bottom) for different matrix sizes for 24 threads for three values of the KMP\_AFFINITY environment variable.

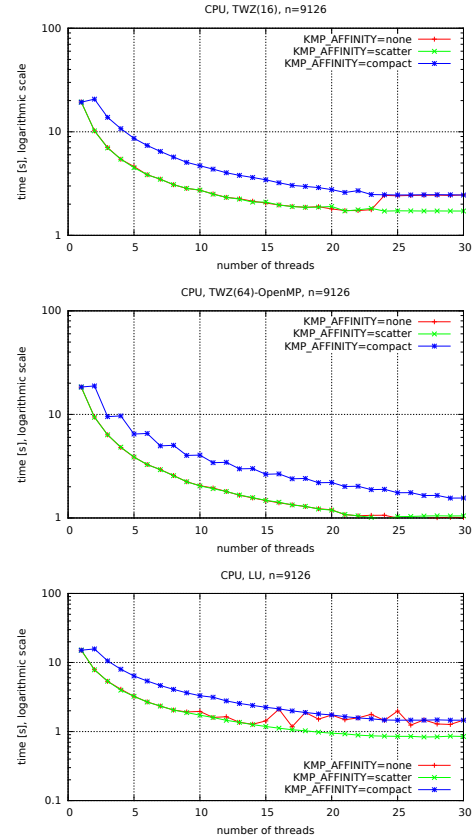

Fig. 5. Run-time in seconds of the parallel block WZ factorization algorithm (top left: TWZ(16); top right: TWZ(64)-OpenMP) and the LU factorization (at the bottom) for a matrix of the size 9216 for different numbers of threads for three values of the KMP\_AFFINITY environment variable.

Fig. 7. Run-time in seconds of TWZ(16), TWZ(64)-OpenMP and LU for KMP\_AFFINITY=scatter — for various numbers of threads and matrix sizes

for scatter, and slowest for compact — and it does not depend on the number of threads, the matrix size or the value of  $r$ .

#### IV. CONCLUSION

The paper highlights the significant impact of thread affinity on the performance of the matrix factorizations which use BLAS operations in their implementations. For the matrix factorization, the KMP\_AFFINITY environment variable should be set to scatter because this way we efficiently exploit the potential of modern shared memory multicore machines. With this setting, threads are put far from each other (as on different packages) what improves the total memory throughput and the usage of the caches.

# A Framework for Generating and Evaluating Parallelized Code

Jarosław Bylina

Maria Curie-Skłodowska University

Lublin, Poland

Email: jaroslaw.bylina@umcs.pl

**Abstract**—The work describes a flexible framework built to generate various (parallel) software versions and to benchmark them. The framework is written with the use of the Python language with some support of the gnuplot plotting program. An example of the use of this tool shows the tuning of a matrix factorization on different architectures (Intel Haswell and Intel Knights Corner) with various parameters of parallelization, vectorization, blocking etc.

## I. INTRODUCTION

THE OPTIMAL use of the contemporary hardware and software is not an easy and straightforward job. The efficiency and the accuracy of the applications depends on a lot of parameters as: places and manners of parallelization and vectorization, loops' order, block sizes, scheduling, affinity etc. The number of possible (and potentially beneficial) combinations is huge and the choice of the best set of parameters is not always obvious. So, generating different versions, testing and benchmarking them, and then tuning is very time consuming and boring, repetitive task. Thus, it is suitable for automation.

Moreover, the code tuned for one hardware often needs a very different treatment on another machine. The parameters chosen and set for one machine as the most profitable can give a very poor performance of the same code after the change of the memory, the accelerators, or, especially, the central processing unit. Now, the hardware market is full of various parallel machines, processors, and coprocessors. We have multicore architectures (like Intel Haswell — with not too many cores), as well as manycore ones (like Intel Knights Corner and other MIC models) and also very-many-core chips (like various GPU coprocessors). Some of them have hierarchical shared memory — with various sizes and numbers of levels — and vector units — of different sizes. All of them demand a different treatment to acquire the best results in terms of performance and efficiency. On top of that, they can be combined into hybrid machines — which have to be treated differently than their components.

Our framework addresses these problems. It enables developers to rapidly generate and automatically test a lot of versions of the algorithms after a little preparation. It can easily be employed on different architectures and be utilized to find the optimal set of parameters on them.

There is also a number of tools to create parallel versions of an algorithm for various hardware — like OpenMP, MPI, OpenACC, OpenCL and others. Our framework can be used

with all of them; although we tested it with the use of OpenMP for now.

The philosophy behind our framework is parametrizing and testing (and tuning) programming units — like functions or classes. The developer provides the template of the unit — with some formal parameters — and some sets of actual parameters with which the function (or class) is to be tested. The software generates all the permitted (by actual parameters) versions of the function (class) and tests them (measuring their computation speed and/or numerical accuracy).

Since our software works on the text of the source code, it is very flexible. We can, for example, enable and disable various directives and pragmas (like OpenMP pragmas or similar), change the sizes of the blocks and also the order of loops. Shortly, any textual parametrization of the investigated function/class can be utilized.

The framework itself is a Python 3 application. However, the source code in any language with separate and named units (like functions in C or functions and classes in C++) can be investigated with it. For now, there are configuration files created to study efficiency and accuracy of the units written in C and C++ and compiled with Intel C++ Compiler (icc) and GNU Compiler Collection (gcc), although it can be easily extended to other languages.

An advantage of such an approach is an automatic generation, compilation, and testing of a large number of versions of the same function/class (or functions/classes) which differ in an organized manner. The output of the software is a set of plots of the desired characteristics, which can be easily compared by the developer. However, we prepare a further facilitation — automatic ordering and selection of the generated versions on the ground of their efficiency and accuracy.

The remainder of this work is following. Section II gives some background of other similar projects. Section III describes the working of our framework. Section IV shows a working example of the testing and tuning with our software. Finally, Section V concludes the work and gives some plans for the future of the project.

## II. RELATED WORK

There is a long tradition of software automatic optimization in scientific computing and other computer applications. Thus, there are also a lot of software performing tasks similar to our framework.

One of the approaches to the optimization of the algorithms (or their building blocks) is auto-tuning. It is based on performing many efficiency tests on different versions of building blocks (like BLAS subroutines) and choosing the best for a given architecture. Some examples of the narrow libraries using this approach are ATLAS [10] and FFTW [3]. There are also languages and libraries which employ the approach of auto-tuning to general source codes and use the parameter space (similar to our framework). Their examples are Active Harmony [9], Atune-IL [7], Chapel [2].

On the other hand, we have profilers and similar tools which investigate the code and gather information about the utilization of the architecture and weak points of the implementations. Their examples are PAPI [1], Tau [8], Vampir [5], Scalasca [4], Intel VTune Amplifier [13], Intel Advisor [12].

Finally, there is ELAPS (Experimental Linear Algebra Performance Studies), an interactive multi-platform open source framework [6]. It is designed to build experiments testing dense linear algebra algorithms, functions, libraries. However, that software tests ready subroutines and their combinations and it is very convenient for standard linear algebra building blocks, but it is not very usable for other applications.

### III. THE FRAMEWORK DESCRIPTION

Figure 1 shows the workflow of the framework. The dashed arrows represent the steps not requiring the user's intervention (that is, intermediate steps) and the dashed borders represent files not demanding user's direct concern (or even user's view). However, all the work can be repeated from an arbitrary step — for example, after some changes in the configuration.

The flexibility of the framework is provided in two manners — in the preparation of input files and in choosing configuration options.

#### A. Input files

The first step the user is to make is to prepare input files. The files are source codes of tested units (functions and/or classes) with some of their text parametrized — one file per unit. Both the formal parameters and actual parameters are included in the file. The formal parameters are represented in the code as the Python format strings, that is, `%(name)s` where *name* is an arbitrary name of the parameter. The actual sets of parameter values are given as special comments in the beginning of the file. In C or C++ these must be single-line comments starting with `//`, directly after which there is a character indicating the kind of configuration command.

#### B. Configuration

There are some configuration options with which we can set other features of the tests. We have, among others:

- the language and the compiler used in tests (C/C++ on `icc/gcc` for now);
- the compiler options;
- the precision of the computations (like `float`, `double` etc.);

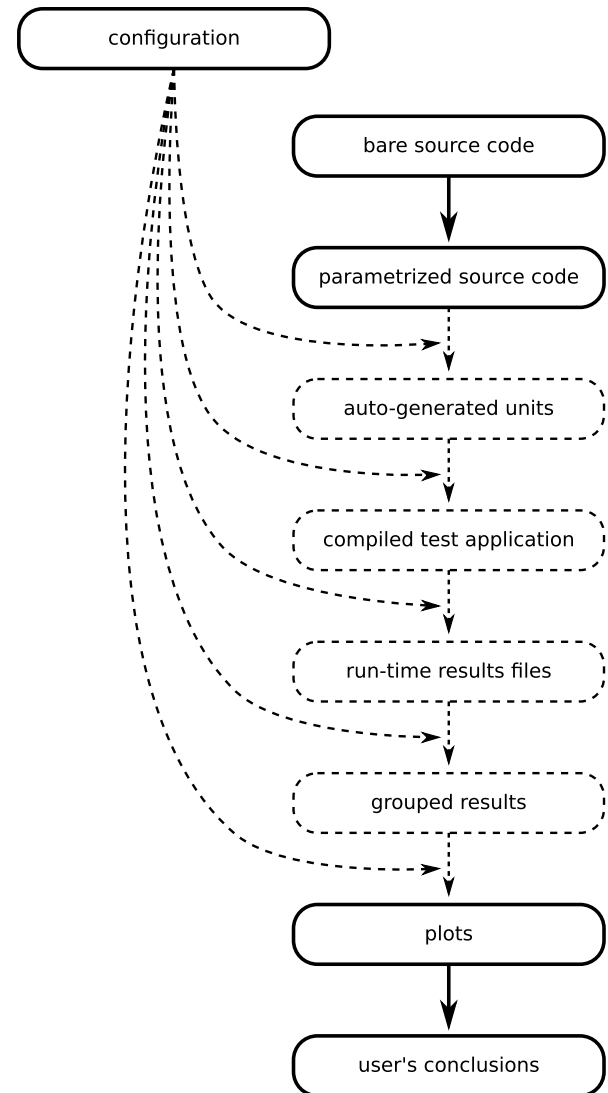

Fig. 1. The framework operation scheme (dashed lines shows the elements processed without the user's awareness)

- the investigated measure (or measures — accuracy, run time and performance for now);
- the number of repetitions of each test (the final value of the performance or accuracy is computed as a mean value from these repetitions);
- the set of the number of threads;
- the set of the problem sizes;
- various parameters of the target plots (groups of plots, ranges etc.).

### IV. A FRAMEWORK APPLICATION EXAMPLE

We show more details on the operation of the framework on an example of parallelizing a numerical problem, namely the WZ factorization [11]. Two sequential versions of this algorithm (in pseudocode) are shown in Figures 2 (the basic version) and 3 (the fission version). In both versions, the matrix

$a$  is an input-output data and the matrix  $w$  is an output data (the factors of the given matrix  $a$  of the size  $n$  are stored in matrices  $a$  and  $w$  after the end of the algorithm).

```

for(k = 0; k < n/2-1; k++) {
    p = n-k-1;
    akk = a[k][k];    akp = a[k][p];
    apk = a[p][k];    app = a[p][p];
    detinv = 1 / (apk*akp - akk*app);
    for(i = k+1; i < p; i++) {
        w[i][k] = (apk*a[i][p]
                  - app*a[i][k]) * detinv;
        w[i][p] = (akp*a[i][k]
                  - akk*a[i][p]) * detinv;
        for(j = k+1; j < p; j++)
            a[i][j] = a[i][j]
                    - w[i][k]*a[k][j]
                    - w[i][p]*a[p][j];
    }
}

```

Fig. 2. The pseudocode of the basic WZ factorization algorithm

```

for(k = 0; k < n/2-1; k++) {
    p = n-k-1;
    akk = a[k][k];    akp = a[k][p];
    apk = a[p][k];    app = a[p][p];
    detinv = 1 / (apk*akp - akk*app);
    for(i = k+1; i < p; i++) {
        w[i][k] = (apk*a[i][p]
                  - app*a[i][k]) * detinv;
        w[i][p] = (akp*a[i][k]
                  - akk*a[i][p]) * detinv;
    }
    for(i = k+1; i < p; i++)
        for(j = k+1; j < p; j++)
            a[i][j] = a[i][j]
                    - w[i][k]*a[k][j]
                    - w[i][p]*a[p][j];
}

```

Fig. 3. The pseudocode of the fission WZ factorization algorithm

We would like to use our software to parallelize the WZ factorization with the use of the OpenMP standard and to test it on two platforms, namely Intel Haswell (denoted CPU) and Intel Knights Corner (denoted MIC). To achieve that we use our framework, writing our algorithms in C, with some parameters which can help us try various variants and test them on both platforms (CPU and MIC).

The basic versions implemented with the use of our framework is presented in Figure 4, and the fission version — in Figure 5. Here, the matrices are represented in 1D vectors, stored column-wise or row-wise and accessed through the macros `INDc` and `INDr`, respectively.

We can see that both are quite straightforward implementations of pseudocodes from previous Figures — apart from first lines (special comments) and `%` signs (parameters). The meanings of the special comments are following (their order is freeform).

- `// =` gives the template of the unit (here: function) name. Each file generates a lot of functions, and functions have to possess unique names. We achieve this including parameters into the name template.
- `// ?` describes the header of the function, where a special parameter `%s` is the name of the function (generated on the basis of the previous line).
- Each `// :` describes one of the template parameters. Consecutively, we give the name of the parameter (`IND`, for example) and then its possible values, in two variations each: the first used in the function name (here: `col`, `row` — it should be short and adjusted to the function name syntax) and the second used in the function body (here: `INDc` and `INDr`, respectively; `_` means ‘space’).
- In Figure 5, we can also see `// +` which restricts the function names to strings containing the given character sequences (here, we want to test different loop orders, so we use it to disable incorrect loops, that is `ij` and `ji` allowing only `ij` and `ji`).

A lot of functions were generated, compiled and tested on CPU and MIC for various sizes of the matrix and numbers of threads. The plots for the results were also automatically created.

As we can see, we can quite freely shape our source code and test cases with the use of described above directives. We can easily investigate the influence of

- the matrix storage order,
- OpenMP scheduling,
- vectorization,
- loop order,

and many others — not presented here; however, everything which can be parametrized within the text of the function can be investigated.

## V. CONCLUSION

The aim of our work was to create a software which can support a program developer in his attempts to utilize the hardware, the compiler, and the libraries the best.

The advantage of the framework is generating a lot of versions of parallel (for example, but not only) code. These versions differ in an organized way. Moreover, they are automatically compiled and run, then some measures are taken and plots are drawn. The results in such form can be easily compared by the code developer.

Our framework can be easily used to test not only programs written with the use of OpenMP on CPU and MIC, but it can also be adapted to tests on GPU with the use of CUDA compilers, OpenCL and OpenACC — for example.

Very important — but missing for the present — feature is the next step in the automatic analysis, namely, automatic selection of the best (that is the fastest or the most accurate) sets of parameters. We are working on such a feature to be included in the future versions of the framework.

**Abstract**— The method for extracting natural vibration frequencies and modes of design models arising when the finite element method is applied to the problems of structural and solid mechanics is proposed. This approach is intended to be used on multicore SMP computers and is an alternative to the conventional block Lanczos and subspace iteration methods widely used in modern FEA software. We present the main idea of the method as well as the parallel fast block incomplete factorization approach for creating efficient preconditioning, the shift technique and other details accelerating the solution and improving the numerical stability. Real-life examples are taken from the computational practice of SCAD Soft IT company and approve the efficiency of the proposed method.

## I. INTRODUCTION

THE application of the finite element method to the problems of natural vibrations of structures results in a generalized algebraic eigenvalue problem

$$\mathbf{KV} - \mathbf{MVA} = 0, \quad (1)$$

where  $\mathbf{K}$  and  $\mathbf{M}$  are the symmetric positive definite stiffness and semidefinite mass sparse matrices,  $\mathbf{V} = \{\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_n\}$  – matrix of eigenvectors  $\mathbf{v}_i$ , located in  $\mathbf{V}$  column-by-column,  $\mathbf{A}$  is a diagonal matrix of eigenvalues  $\lambda_1, \lambda_2, \dots, \lambda_n$ ,  $\lambda_i = \omega_i^2$ ,  $\omega_i = 2\pi f_i$ ,  $i \in [1, n]$ ,  $\omega_i$  is a cyclic frequency in  $s^{-1}$  and  $f_i$  is a frequency in Hz. The dimension of the problem is  $N$  and the number of required eigenpairs is  $n \ll N$ .

For large finite element design models the problem dimension  $N$  reaches 200 000 – 6 000 000 equations and more. The required number of eigenpairs  $\{\lambda_i, \mathbf{v}_i\}$ ,  $i \in [1, n]$  depends on the type of dynamic analysis and properties of construction. Usually  $n = 20 - 100$ , but in the case of seismic analysis it can be 1 000 – 3 000 and more. Some of the constructions have a lot of local vibration modes in the lower part of the spectrum. Such modes produce very small contributions in a seismic response of the structure, but create huge difficulties for eigenvalue solvers, because a very large number of eigenpairs are required in such cases.

The block Lanczos method or block subspace iteration method is used most often in contemporary FEA software. But these powerful methods use the inverse iteration procedure on each iteration step which requires the twice

reading of the factorized stiffness matrix [10]. Most users prefer to solve these problems on laptops and desktops, which have the amount of RAM 8 – 16 GB. In the case of a large dimensionality of the problem, the amount of core memory is insufficient for storing a factorized stiffness matrix, which is stored on the disk. Therefore, when performing forward and backward substitutions at each iteration, we need to read twice from the disk the amount of data on the order of 6 – 20 or more GB. The above methods work with the speed of a slow disk, not a fast processor, and it takes many hours to solve the problem.

Therefore, it seems interesting to develop a method that would solve the problem (1) in a core memory. Our choice is based on the preconditioned conjugate gradient method (PCG). It is known that for many problems of structural mechanics, which are poorly conditioned for a number of reasons [21], the conjugate gradient method demonstrates unacceptably slow convergence. In order to correct the situation, it is necessary to create efficient preconditioning [2], [3], [5], [6], [8], [9], [13] – [15], [19], [20], [22]. Our experience shows that a stable convergence of the eigenvalue problem (1) is much more difficult to obtain than when solving a system of linear algebraic equations

$$\mathbf{Kx} = \mathbf{b}, \quad (2)$$

where  $\mathbf{x}$  and  $\mathbf{b}$  are respectively the unknown vector and the right-hand part vector. Therefore, the successful solution of the problem (1) usually requires more effective preconditioning than when solving the problem (2). In addition, in order to obtain the stable convergence in the presence of multiple and close eigenvalues, it is required to introduce the shift into preconditioning

$$(\mathbf{B} - \sigma \mathbf{M}) \mathbf{z}_i^k = \mathbf{r}_i^k, \quad (3)$$

where  $\mathbf{B}$  is a preconditioning operator without shift,  $\sigma$  is a shift,  $\mathbf{z}_i^k$  – residual vector for a preconditioned problem and  $k$  is an iteration step number. The preconditioned algebraic eigenvalue problem is formulated as

$$\mathbf{B}_\sigma^{-1}(\mathbf{KV} - \mathbf{MVA}) = 0, \quad (4)$$

This work was supported by IT company SCAD Soft (www.scadsoft.com)

where  $\mathbf{B}_\sigma = \mathbf{B} - \sigma\mathbf{M}$ . The residual vector of an initial problem (1) is:

$$\mathbf{r}_i^k = \lambda_i^k \mathbf{M} \mathbf{x}_i^k - \mathbf{K} \mathbf{x}_i^k. \quad (5)$$

Here subscript  $i$  denotes a mode number and  $\mathbf{x}_i^k$ ,  $\lambda_i^k$  are the approximations of the  $i$ -th eigenmode and eigenvalue on iteration step  $k$ .

The article [5] presents PCG method with element-by-element aggregation multilevel preconditioning [6] and shift technique. This method does not use multithreading, it was implemented in SCAD software in 2004 and enables to extract a relatively small number of eigenpairs (5 – 30). A parallel version of PCG method has been proposed in [9], but acceleration with the increasing number of threads was poor.

The local block PCG method (LOBPCG – [17], [18], [25]) uses the following approximation:

$$\begin{cases} \mathbf{x}_i^{k+1} = \sum_{j=1}^m \alpha_j^k \mathbf{z}_j^k + \sum_{j=1}^m \tau_j^k \mathbf{x}_j^k + \sum_{j=1}^m \gamma_j^k \mathbf{p}_j^k \\ \mathbf{p}_i^{k+1} = \sum_{j=1}^m \alpha_j^k \mathbf{z}_j^k + \sum_{j=1}^m \gamma_j^k \mathbf{p}_j^k \end{cases}, \quad i \in [1, m] \quad (6)$$

where  $\mathbf{p}_j^k$  is a conjugate direction vector and  $m$  is a dimension of the block. The dimension of the block  $m \geq n$  and is constant until all required eigenpairs are extracted. For the problems of structural mechanics, we found that as soon as the first eigenpair begins to converge, the method loses the computational stability (see section IV, A), because for a converged eigenpair the residual vector  $\mathbf{r}_i^k$  in (5) tends to zero, vector  $\mathbf{z}_i^k$  tends to zero too (3) and a zero column appears in the projection matrix  $\mathbf{Q}_k = \{\mathbf{Z}_k, \mathbf{X}_k, \mathbf{P}_k\}$ , where  $\mathbf{Z}_k = \{\mathbf{z}_1, \mathbf{z}_2, \dots, \mathbf{z}_m\}^k$ ,  $\mathbf{X}_k = \{\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_m\}^k$  and  $\mathbf{P}_k = \{\mathbf{p}_1, \mathbf{p}_2, \dots, \mathbf{p}_m\}^k$ .

To ensure the computational stability of the method, we keep a constant dimension of the block  $m < n$ , and as soon as some vectors in the block converge, we immediately remove them, store them as the final results and replace them with the new start vectors. In addition, when the columns in the projection matrix  $\mathbf{Q}_k$  become almost linearly dependent, we orthogonalize all the vectors in the block using the modified Gram-Schmidt method.

This article is a continuation of [10], and we focus our attention on a block parallel sparse Cholesky incomplete factorization method used for a fast creation of efficient preconditioning, shift technique, allowing to improve the computational stability of PCG method and other important moments of the proposed approach.

## II. BLOCK SUBSPACE PROJECTION PRECONDITIONED CONJUGATE METHOD

The details of our approach have been presented in [10], therefore here we briefly mention their general stages.

### A. Initialization

To ensure a load balance between threads, we accept that dimension of block  $m$  is multiple to the number of threads  $np$ :  $m \% np = 0$ . Usually, we accept  $m \in [16, 64]$ . There are no strict recommendations, and the value of  $m$  depends on the number of required eigenpairs and peculiarities of the problem. We prepare the block of linearly independent start vectors  $\mathbf{X}_0$ , set  $\mathbf{P}_0 = 0$  and start the iteration process  $k = 0, 1, \dots$ , until all required eigenpairs are extracted.

### B. Computing of residual vectors

On the  $k$  iteration step we obtain the residual vectors using (5) and replacing the subscript  $i$  by  $j \in [1, m]$ . The approximations of eigenvalues are computed applying the Rayleigh quotient

$$\lambda_j^k = \left( (\mathbf{x}_j^k)^T \mathbf{K} \mathbf{x}_j^k \right) / \left( (\mathbf{x}_j^k)^T \mathbf{M} \mathbf{x}_j^k \right). \quad (7)$$

Using (3) ( $i \rightarrow j$ ), we receive the block of vectors  $\mathbf{Z}_k$ . The procedures (5), (7) and (3) are produced in a parallel region because for each mode  $j \in [1, m]$  we can run all computations separately.

The check of convergence is performed. If  $\|\mathbf{r}_j^k\|_2 / \lambda_i^k < tol$ , where  $tol$  is a required tolerance, convergence is achieved, all approximations of eigenpairs in the block,  $\{\lambda_j^k, \mathbf{x}_j^k\}$ , satisfying this condition, are stored as the final results. The new start linearly independent vectors  $\mathbf{x}_j^k$  are generated and put instead of the converged vectors. The orthogonalization of these vectors against all converged eigenvectors is performed. The conjugate direction vectors, corresponding to new start vectors, are accepted as  $\mathbf{p}_j^k = 0$ . The evaluation of approximations of eigenvalues (7) for the new start vectors, residual vectors  $\mathbf{r}_j^k$  (5) and vectors  $\mathbf{z}_j^k$  (3) are produced in a parallel region because it often turns out that several vectors are converged. The new vectors  $\mathbf{z}_j^k$ ,  $\mathbf{x}_j^k$  and  $\mathbf{p}_j^k$  are located on positions of converged and removed vectors in blocks  $\mathbf{Z}_k$ ,  $\mathbf{X}_k$  and  $\mathbf{P}_k$ .

### C. Projection of mass and stiffness matrices on the subspace

The reduced matrix  $\mathbf{m} = \mathbf{Q}_k^T \mathbf{M} \mathbf{Q}_k$  is prepared in a parallel region. The developed algorithm bypasses zero columns  $\mathbf{p}_j^k$  in the projection matrix  $\mathbf{Q}_k$ , if any appeared at the previous step B. If Cholesky factorization of matrix  $\mathbf{m}$  is successful, we evaluate the reduced matrix  $\mathbf{k} = \mathbf{Q}_k^T \mathbf{K} \mathbf{Q}_k$  in a parallel region. Otherwise, the total reorthogonalization of columns in the projection matrix  $\mathbf{Q}_k$  is applied to ensure the linear independence of basis vectors. In comparison with the previous version [10] we have parallelized this algorithm (section V). After reorthogonalization procedure, we recalculate the matrix  $\mathbf{m}$  and prepare the matrix  $\mathbf{k}$  in a parallel region. After this, we solve the reduced eigenproblem

$$\mathbf{k} \mathbf{q} - \mathbf{m} \mathbf{q} \mu = 0, \quad (8)$$

where  $\mathbf{q}$  is a matrix of eigenvectors located column by column, and  $\boldsymbol{\mu}$  is a diagonal matrix of eigenvalues. The LAPACK procedures from Intel Math Kernel Library (Intel MKL) [26] are applied. We omit a subscript  $k$  denoting the iteration number.

#### D. Evaluation of basis vectors at the next iteration step

After solving (8), the eigenvectors in matrix  $\mathbf{q}$  have been sorted in the ascending order of eigenvalues. Then, we compute:

$$\mathbf{X}_{k+1} = \mathbf{Q}_k \bar{\mathbf{q}}, \quad \mathbf{P}_{k+1} = \mathbf{Z}_k \mathbf{q}_z + \mathbf{P}_k \mathbf{q}_p, \quad (9)$$

where  $\bar{\mathbf{q}}$  – the first  $m$  eigenvectors from  $\mathbf{q}$ ,  $\mathbf{q}_z$  and  $\mathbf{q}_p$  – the blocks of subvectors from  $\bar{\mathbf{q}}$ , related to residual vectors and conjugate direction vectors respectively.

#### E. Orthogonalization of basis vectors against all converged eigenpairs.

We perform the orthogonalization of columns in subblocks  $\mathbf{X}$  and  $\mathbf{P}$  against all converged modes in a parallel region.

### III. THE BLOCK PARALLEL INCOMPLETE CHOLESKY FACTORIZATION

We found that a stable solution of the partial algebraic generalized eigenvalue problem (1) by the PCG method requires a more efficient preconditioned technique than the solution of the linear algebraic equations with the same stiffness matrix  $\mathbf{K}$ . It means that in the case of the incomplete Cholesky factorization approach we must accept a much smaller drop parameter  $\psi$  than when we solve the linear equations. In the last case, we apply the incomplete Cholesky factorization using a sparse matrix technique [8]. However, it turned out that in order to solve many large-scale real-time problems of natural vibrations, the drop parameter  $\psi$  must be so small that the time of incomplete factorization by this method becomes unacceptably large. Therefore, there was an urgent need to develop a left-looking two-level incomplete Cholesky solver “by value” for multi-core SMP computers.

First of all, we prepare a nodal adjacency graph and perform its reordering with the help of the METIS or MMD reordering method [16]. Then, we assemble a stiffness matrix, the lower triangular part of which is packed in a compressed column format (CCF). It is source information for the solver.

#### A. Analysis stage

Taking the nonzero structure of the stiffness matrix from CCF, we prepare an equation adjacency graph and produce a symbolic factorization procedure [4] to create a nonzero structure of the completely factorized matrix, which is accepted as an initial nonzero structure for the incomplete factorization.

Then, we create an elimination tree and reorder the sequence of elimination in accordance with moving along the elimination tree from the leaves to the root. Such reordering does not change the amount of fill-in, but puts the columns of the matrix, processed consequently, in the close memory addresses and slightly improves the work with the caches of processors. The symbolic factorization procedure runs again to correct the nonzero structure of the factorized matrix for a changed sequence of elimination and CCF for source matrix is repacked.

After this, we combine the neighbor vertexes of the elimination tree in supernodes, where it is possible [12], and create a structure of levels for the supernodal elimination tree. It is well-known that the supernodal elimination tree is poorly balanced to ensure a load balance between processors. In order to balance the supernodal elimination tree, we apply the algorithm 1 (Figure 1).

Fig. 1 Balancing of supernodal elimination tree

#### Algorithm 1. The task scheduling for the first parallelization level.

```

level = 1;
root ← str_lev(level); put vertexes of level to root
L0 ← root; put root to L0
while(1)
{
    sum_weights ← 0;
    ∀v ∈ L0: weight_v ← get_weight_subtree(v);
    Find: max_weight = max{weight_v} and v_max_weight;
    L0 ← (L0 \ v_max_weight);
    L0 ← all descendants of v_max_weight;
    sort{L0};
    ∀v ∈ L0:
        sum_weights[ip_min] ← get_weight_subtree(v);
        stack[ip_min] ← v;
    if((max{sum_weights} - min{sum_weights})/

```

```

    max{ sum_weights } < tol1) break;
}

```

Here we denote: *str\_lev* is a structure of levels for supernodal elimination tree and *str\_lev(level)* returns all vertexes belonging to *level*; *get\_weight\_subtree(v)* returns the sum of weights for vertexes of all subtrees, outgoing from vertex *v*; weight of vertex is equal to the number of columns in the given supernode, *L0* – “level zero”, *sort{L0}* is a sorting of all vertexes belonging to *L0* in the descending order of their weights. All vertexes of supernodal elimination tree, placed above *L0*, create a second level of parallelization. Remaining vertexes constitute the first level. Parameter *ip\_min* means the thread number which comprises a minimum sum of weights of all supernodes, mapped onto this thread.

Algorithm 1 searches for a set of *L0* until an imbalance of weights for vertices of the first level is less than the required tolerance *tol<sub>1</sub>*. The general operations include finding a vertex with the maximum weight of subtrees among all vertexes of *L0* ( $\forall v \in L0: weight_v \leftarrow get\_weight\_subtree(v)$ ; Find:  $max\_weight = \max\{weight_v\}$  and  $v_{max\_weight}$ ), removing this vertex from *L0* ( $L0 \leftarrow (L0 \setminus v_{max\_weight})$ ) and adding all descendants of removed vertex to *L0* ( $L0 \leftarrow \text{all descendants of } v_{max\_weight}$ ) (see Figure 1). A similar algorithm but with cyclic mapping onto threads has been used in [1]. We found that sorting vertexes in *L0* in the descending order of weights and mapping of the current vertex from *L0* to the thread which has a minimum sum of weights, results in a better load balance than cyclic mapping [11], [12].

After algorithm 1 is finished, we add the vertexes of all subtrees to vertexes of *L0*, belonging to *stack[ip]*, where  $ip \in [0, np-1]$  and *ip* is a current thread number. So, we obtained the set of parallel tasks in *stack[ip]*,  $ip \in [0, np-1]$  for the first level of parallelism. Each vertex, added to any *stack[ip]*,  $ip \in [0, np-1]$ , is marked.

Then, we run Algorithm 2 to prepare the parallel tasks for the second level of parallelism.

Algorithm 2. The task scheduling for the second parallelization level.

```

sum_weights ← 0; L1 ← 0;
while(until all vertexes are marked)
{
    loop ∀v ∈ L0: → vnext;
    if(vnext is unmarked)
    {
        marks vnext;
        L1 ← vnext;
        weightv ← weight(vnext)
        queue[ip_min] ← vnext;
    }
}

```

```

    sum_weights[ip_min] += weightv;
}
end of loop
L0 ← 0; L0 ← L1; L1 ← 0;
}

```

Loop *while* runs until all vertexes of supernodal elimination tree are marked as added to the parallel tasks. For each vertex belonging to *L0* (**loop**  $\forall v \in L0$ ), we obtain its parent vertex *v<sub>next</sub>*. If *v<sub>next</sub>* is marked, pass to the next vertex of *L0*. Otherwise, we mark *v<sub>next</sub>*, add it to the set *L1*, map onto thread *ip\_min* ( $queue[ip\_min] \leftarrow v_{next}$ ), which has a minimum sum of weights of mapped vertexes, and add the weight of *v<sub>next</sub>* to  $sum\_weights[ip\_min] += weight_v$ . After **loop**  $\forall v \in L0$  is finished, we reset *L0* and *L1* to the next iteration.

The parallel tasks of the second level of parallelism are presented by queues *queue[ip]*,  $ip \in [0, np-1]$ . After Algorithms 1 and 2 have been run, all vertexes of the supernodal elimination tree must be marked.

### B. Numerical factorization stage

Algorithm 3 presents the numerical factorization stage.

Algorithm 3. The two-level left-looking numerical factorization.

```

parallel region
{
    //the first level of parallelization
    while(stack[ip] is not empty)
    {
        jb ← stack[ip] (stack[ip]jb)
        alloc_block(jb);
        aggreg_block(jb);
        if(!update_block(jb))
        { push_front: stack[ip] ← jb; continue; }
        factor_block(jb);
    }

    //the second level of parallelization
    while(queue[ip] is not empty)
    {
        jb ← queue[ip] (queue[ip]jb)
        alloc_block(jb);
        aggreg_block(jb);
        if(!update_block(jb))
        { push_back: queue[ip] ← jb; continue; }
        factor_block(jb);
    }
}

```

In a parallel region of the first parallelization level, we run the loops **while** until the *stack[ip]*, corresponding to the

thread  $ip \in [0, np-1]$ , is empty. On each iteration, we extract from  $stack[ip]$  the last element  $jb$  (the number of block-column in the matrix, corresponding to the supernode in the supernodal elimination tree), and remove it from  $stack[ip]$  ( $stack[ip] \setminus jb$ ).

Then, we allocate memory for sparse block-column  $jb$ , calling the procedure  $alloc\_block(jb)$ , assemble a block-column  $jb$  ( $aggreg\_block(jb)$ ) and update it by columns placed at left ( $update\_block(jb)$ ).

The procedure  $alloc\_block(jb)$  prepares the list of global equation numbers for non-zero rows of block-column  $jb$ . The nonzero rows of the block-column  $jb$  of the initial stiffness matrix as well as the fill-in that appeared at the previous steps of the incomplete factorization take part in the creation of this list. Then we apply the parallel dynamic allocation of memory, using a separate heap for each thread and the Thread Local Storage technique [24].

The  $aggreg\_block(jb)$  procedure puts the elements of the initial stiffness matrix stored in CCF to the non-zero structure of block-column  $jb$ .

The  $update\_block(jb)$  procedure in the critical section extracts from  $List[jb]$  the block-column number  $kb$ ,  $kb \in List[jb]$ , placed at left from the block-column  $jb$  and updating it, removes  $kb$  from  $List[jb]$  and checks, whether the block-column  $kb$  is currently factorized. If yes, the update of block-column  $jb$  is performed using the  $dgemm$  procedure from Intel MKL (see Figure 2):

Fig. 2 An update of the block-column  $jb$  by block-column  $kb$ , placed at left. The black areas correspond to the updated elements of the block-column  $jb$ .

$$\mathbf{A}_{ib,jb} = \mathbf{A}_{ib,jb} - \mathbf{L}_{ib,kb} \cdot \mathbf{L}_{jb,kb}^T, \quad (10)$$

where  $ib$  belongs to the non-zero structure of the block-column  $jb$ .

Otherwise (the block-column  $kb$  is not currently factorized) the number  $kb$  puts to the end of  $List[jb]$ , and the

next element of  $List[jb]$  is extracted. When all the block-columns from the  $List[jb]$  have participated in the correction of the block-column  $jb$  and  $List[jb]$  is empty, the procedure  $update\_block(jb)$  returns *true*. Otherwise, the  $update\_block(jb)$  returns *false*, and the given block-column  $jb$  is pushed in  $stack[ip]$  and we have to wait until the remaining threads factorize all the block-columns from  $List[jb]$ . Such a technique is similar to [23].

The  $factor\_block(jb)$  procedure produces a Cholesky factorization of the diagonal block using the  $dpotrf$  procedure from Intel MKL [26]:

$$\mathbf{A}_{jb,jb} = \mathbf{L}_{jb,jb} \cdot \mathbf{L}_{jb,jb}^T, \quad (11)$$

and updates the off-diagonal part of the block-column  $jb$ , applying the  $dtrsm$  procedure from Intel MKL [26]:

$$\mathbf{L}_{jb,jb} \cdot \mathbf{L}_{ib,jb} = \mathbf{A}_{ib,jb} \rightarrow \mathbf{L}_{ib,jb}, \quad (12)$$

where a lower triangular matrix  $\mathbf{L}_{jb,jb}$  has been obtained in (11) and  $ib$  belongs to the nonzero structure of the block-column  $jb$ .

After this, we run the  $drop\_proc(jb)$  procedure, presented by algorithm 4.

Algorithm 4. The drop procedure.

```

do iloc = 0, M - 1
{
    djj = ∑ Hij, j ∈ [Ns, Ne]
    si = ∑ Hij2
    dii = Bii
    if(si < ψN djj dii)
    {
        reject_list ← iloc; s ← 0;
        for(j = Ns; j ≤ Ne; ++j)
        {
            Hjj += |Hij|√(Hjj/dii);
            s += |Hij|√(Hjj/dii)
        }
        critical section
        diag_add[i] = s;
        end critical section
    }
}
    
```

Here  $M$  is the number of non-zero rows in the block-column  $jb$ ,  $iloc$  – the current local row number in block,  $N_s$  – the global number of the first column in the block,  $N_e$  – the global number of the last column in the block,  $d_{jj}$  is a sum of diagonal elements in the block-column  $jb$ ,  $s_i$  is a sum of elements in the  $i$ -th row ( $i$  belongs to the nonzero structure of the block-column  $jb$ ),  $H_{ij}$  is an element of the factorized matrix,  $i$  and  $j$  are the global subscripts,  $B_{ii} = H_{ii}$ , if the block-column comprising an element  $H_{ii}$  has been already factorized, and  $B_{ii} = A_{ii}$  – an element of the initial

matrix otherwise. If the sum of squares of elements in the row  $i$  is less than  $\psi^N d_{ij} d_{ii}$ , we put  $i$  number to *reject\_list*, and correct the diagonal elements to ensure the positive definiteness of the lower triangular part of the incomplete factorization  $\mathbf{H}$ . The value  $s$  corrects the diagonal element  $D_{ii}$ , which at the current time is not factorized. Such a correction is accumulated in the array *diag\_add* and will be used later. Several threads can produce this correction simultaneously, therefore we use a critical section.

After loop **do** is over, we remove from the nonzero structure of the block-column  $jb$  the entire rows, stored in *reject\_list*, compress the block-column  $jb$  and reallocate the memory in order to free up the amount of memory occupied by the rejected rows of the block-column.

When *stack[ip]* is empty (see Algorithm 3), the thread  $ip$  begins to run the second loop **while** from the second level of parallelization. The nearest element of *queue[ip]* is extracted and removed from the queue. If *update\_block(jb)* returns a *false*,  $jb$  is pushed at the end of *queue[ip]* and will be processing later.

After the numeric factorization is finished, we start the post-factorization drop procedure, which is similar to the one, presented in Algorithm 4. The post-drop procedure uses a post-drop parameter  $\psi_1$  instead of the drop parameter  $\psi$  ( $0 \leq \psi \leq \psi_1 < 1$ ) and does not produce the correction of the diagonal entries. This approach allows us to maintain a low level of error accumulation if the value of the parameter  $\psi$  is small because every rejection in the incomplete factorization process leads to the accumulation of errors [8]. And only after the factorization is completed, secondary dropping is performed to reduce the amount of data in the preconditioning and accelerate the procedure (3) without considerable degradation of the quality of preconditioning. In addition, if  $\psi = 0$  and  $\psi_1 > 0$ , the proposed method produces the complete Cholesky factorization and then makes a post-factorization dropping. For large poorly conditioned problems, the application of this approach can be very efficient if the capacity of the core memory allows the allocation of the completely factorized matrix.

#### IV. SHIFT TECHNIQUE

It is widely known ([5], [7], [9] and others) that the application of a properly selected shift accelerates the convergence of methods based on the iteration by the inverse matrix. In the PCG method, based on minimizing of Rayleigh quotient, we introduce a shift into preconditioning – see (3), (4). We do not evaluate  $\mathbf{B}_\sigma$  directly and use the iterative procedure [5], [9] when solving the system of linear equations (3). Let us assume that  $\hat{\mathbf{z}}_i^k$  is an approximation of the exact vector  $\mathbf{z}_i^k$  and  $\mathbf{q}$  is a small correction:

$$\hat{\mathbf{z}}_i^k = \mathbf{z}_i^k + \mathbf{q}. \quad (13)$$

Then, after substituting (13) in (3) we obtain:

$$\mathbf{B}\mathbf{q} = \sigma \mathbf{M}\hat{\mathbf{z}}_i^k + \underbrace{\mathbf{r}_i^k - \mathbf{B}\hat{\mathbf{z}}_i^k + \sigma \mathbf{M}\mathbf{q}}_{\text{is dropped comparing with the first term}}. \quad (14)$$

Due to the assumption that  $\mathbf{q}$  is a *small* correction, we neglect  $\sigma \mathbf{M}\mathbf{q}$  in comparison with other terms and accept  $\mathbf{B}\hat{\mathbf{z}}_i^k \approx \mathbf{r}_i^k$ . In addition, the iterative procedure for the solution of (3) is:

Algorithm 5. Iterative solution of (3)

```

 $\mathbf{B}\hat{\mathbf{z}}_i^k = \mathbf{r}_i^k \rightarrow \hat{\mathbf{z}}_i^k$ 
do  $s = 1, 2, \dots, S$ 
     $\mathbf{B}\mathbf{q} = \sigma \mathbf{M}\hat{\mathbf{z}}_i^k \rightarrow \mathbf{q}$ 
     $\hat{\mathbf{z}}_i^k = \hat{\mathbf{z}}_i^k + \mathbf{q}$ 
end do

```

Usually, 1 – 2 iterations are required. We start the natural vibration problem analysis with  $\sigma = 0$ . The shift value is corrected at the iteration step  $k$ , where the convergence of at least one eigenpair is achieved, and new starting vectors are added to the block, or when five iterations are performed, on which no eigenpair has converged. The new value of shift is taken as a current approximation of the eigenvalue  $\lambda_{i\_shift}^k$ , where  $i\_shift = (m - 1)/4 + 1$  and  $m$  is the dimension of the block.

#### V. THE ALGORITHM OF TOTAL REORTHOGONALIZATION

When the Cholesky factorization of the reduced mass matrix  $\mathbf{m}$  has failed (section II,C), we perform the total reorthogonalization (Algorithm 6) of the columns in the matrix  $\mathbf{Q}_k$ .

Algorithm 6. The parallel reorthogonalization of the columns of the matrix  $\mathbf{Q}_k$

Parallel loop for  $i = 1, 3m$

```

{
     $\mathbf{q}_i = \mathbf{q}_i / \sqrt{(\mathbf{q}_i^T \mathbf{M} \mathbf{q}_i)}$ 
}

```

do  $i = 2, 3m$

$\mathbf{w} \leftarrow \mathbf{M}\mathbf{q}_i$

Parallel loop for  $j = 1, i - 1$

```

{
     $\beta_{ij} = \mathbf{q}_j^T \cdot \mathbf{w}$ 
}

```

Parallel loop for  $l = 1, N$ , schedule (static, chunk)

```

{
  do j = 1, i - 1
     $q_i^l \leftarrow q_i^l - \beta_{ij} q_j^l$ 
  end do
}

 $q_i \leftarrow q_i / \sqrt{q_i^T M q_i}$ 
end do

```

In the first parallel loop, we perform the normalization of all columns in the matrix  $Q_k$ . Then, we apply the modified Gram-Schmidt orthogonalization method (loop **do**  $i = 2, 3m$ ). The second parallel loop (*Parallel loop for*  $j = 1, i - 1$ ) calculates  $\beta_{ij} = q_j^T M q_i$ . Here it is very important to ensure the coherence in caches of different processors, and we make a padding of the array for  $\beta_{ij}$  to exceed the dimension of the cache line – 64B. The third parallel loop (*Parallel loop for*  $l = 1, N$ ) covers all elements of vectors  $q_i$  and  $q_j$ . It is very important to ensure the coherence in caches too, and we accept a chunk size as the 16 words of double. The inner loop **do** covers the number of vectors  $j$ . Finally, each corrected vector  $q_i$  should be normalized.

We underline that it is very important to ensure the coherence in caches of different processors because otherwise, we obtain a drastic degradation of performance at least on the AMD Opteron 6276 processor, not protected at the hardware level. The second column in Table III demonstrates the efficiency of the proposed parallel algorithm.

## VI. NUMERICAL RESULTS

Let us consider examples taken from the collection of SCAD Soft (<http://www.scadsoft.com>) — IT Company, developer of the SCAD FEA software, one of the most popular softwares used in the CIS countries for structural analysis and design, certified according to the regional standards.

We use the computer A with 16-core processor AMD Opteron 6276, 2.3/3.2 GHz, 64 GB DDR3 RAM, OS Windows Server 2008 R2 Enterprise SP1, 64 bit, and computer B with 4-core processor Intel® Core™ i5 – 2500 CPU 3.30 GHz, 24 GB DDR3 RAM, OS Windows 7, 64 bit.

Computer A is a workstation and computer B – usual desktop.

### A. Problem 1

The uniform beam (Figure 3) is considered.

Fig. 3 The clamped beam

We accept:  $a = 2$  m,  $E = 200\,000$  MPa,  $\rho = 7\,600$  kg/m<sup>3</sup>,  $A = 0.001$  m<sup>2</sup>,  $I = 0.0001$  m<sup>4</sup>, where  $E$  is the Young's modulus,  $\rho$  – the material density,  $A$  – the cross-sectional area and  $I$  – the moment of inertia. Three eigenpairs are extracted ( $n = 3$ ). The dimension of the problem  $N = 24$  and the dimension of the block  $m = 3$ . The preconditioning parameters: reordering method is MMD (multiple minimum degree),  $\psi = 10^{-16}$ ,  $\psi_1 = 10^{-13}$ ,  $tol = 10^{-6}$  (section II.B). Figure 4 presents the comparison of convergence for both: the LOBPCG method [17], [18] and the proposed block subspace projection PCG (BSPPCG) method. The minimal error for the iterated approximations of eigenvectors in the block is depicted on the vertical axis.

Fig. 4 The convergence of the LOBPCG and BSPPCG methods

The proposed BSPPCG method performs the control of the linear independence of the basis vectors in the subspace projection matrix  $Q_k$ , decomposing the reduced mass matrix  $m$  by the Cholesky method (section II.C). If the Cholesky factorization of the  $m$  matrix has failed, the total reorthogonalization of columns in the projection matrix  $Q_k$  ensures the linear independence of the basis vectors. As soon as the first eigenpair begins to converge, the residual vector  $r_i^k$  corresponding to this pair tends to zero, since for an exact solution this vector must be strictly zero. The vector of the conjugate direction  $p_i^k$  behaves similarly since at the stationary point of the Rayleigh functional the gradient vector is also zero and its direction is not defined. Hence it follows that the convergence of eigenpairs leads to a linear dependence between the columns of the projection matrix  $Q_k$ . Therefore, we remove the converged eigenvectors from the block, replacing them with the new start vectors, and restore the linear independence of the columns of the matrix  $Q_k$ , if necessary. As a result, we obtain a fast and stable convergence for the BSPPCG method, and the given example demonstrates it.

### B. Problem 2

The design model of the multi-storey building, resting on the soil, is shown in Figure 5. The number of equations is 2 989 476. Solid finite elements simulating the soil

behavior contribute a relatively dense part in the sparse stiffness matrix. The size of the completely factorized stiffness matrix using the METIS reordering [16] is 36.53 GB. Therefore, this problem is very hard for a direct solution. We accept the required number of eigenpairs  $n = 100$ , the dimension of the block  $m = 32$ . Parameters of preconditioning are as follows: METIS reordering,  $\psi = 10^{-50}$ ,  $\psi_1 = 10^{-13}$ . The required tolerance is  $tol = 10^{-3}$ .

We compare the performance and speed up with an increase of the number of threads of the proposed incomplete block Cholesky solver with PARDISO from Intel MKL 11.3 accepting a complete factorization mode ( $\psi = \psi_1 = 0$ ) because in this mode the incomplete solver processes the maximum amount of data.

Fig. 5 Multi-storey building, based on a prism of soil

Moreover, for a lot of large poorly conditioned problems of structural and solid mechanics, we must take the parameter  $\psi$  as very small. Therefore, the mode of incomplete solver in such a case will be close to the complete factorization, which allows us on the scheduling of load on the processors based on the non-zero structure of the completely factorized matrix. If the problem admits a relatively large value of the dropping parameter  $\psi$ , the duration of the incomplete factorization considerably decreases and ceases to be critical in comparison with other stages of the solution of the problem, and we apply in such a situation the non-block version of the incomplete Cholesky solver [8], which results in better properties of preconditioning than the block Cholesky method due to dropping of single elements in columns instead of the rejection of the entire rows in the block-columns.

The Table I presents a comparison of the complete factorization time and speed up, when the number of

threads increases, for the proposed block Cholesky solver and PARDISO from Intel MKL 11.3. As it turned out, on computer A with AMD Opteron processor the PARDISO solver limits the number of threads to eight. The solver proposed by us demonstrates a steady acceleration of up to 15 threads, and only when the number of threads is equal to the number of processor cores, there is a slight decrease in performance. As a result, we achieve on 15 threads a slightly shorter total factorization time than PARDISO. In general, both solvers show close results, and this fact allows to conclude, that the developed incomplete block Cholesky solver can be used successfully for the solution of real-life large problems.

TABLE I  
COMPARISON OF THE COMPLETE FACTORIZATION TIME AND SPEED UP.  
PROBLEM 2, COMPUTER A.

Nos of threads	Duration of the block Cholesky, factorization s	Duration of the PARDISO, factorization, s	Block Cholesky, $Sp = T_1/T_p$	PARDISO, $Sp = T_1/T_p$
1	10 211	8 282	1	1
2	5 448	6 539	1.87	1.27
4	3 151	3 114	3.24	2.66
8	1 984	1 898	5.15	4.36
12	1 713	—	5.96	—
14	1 635	—	6.25	—

16	1 704	—	6.00	—

The sums of weights for each thread for both: first and second parallelization levels (see section III.4) are presented in Table II. We take a parameter  $tol_1 = 0.05$ .

Even on 16 threads, the proposed scheduling algorithms 1 and 2 ensure an acceptable balance of computational load between threads.

The duration of factorization using a conventional incomplete Cholesky solver [8] on eight threads (in such case this method demonstrates the best performance) is 42 638 s, and we believe that such a long time is unacceptable.

Table III presents the duration of the main stages of BSPPCG method. We use the following abbreviation: *Reort. time* – time of the total reorthogonalization when the columns of matrix  $\mathbf{Q}_k$  become almost linearly dependent; *Orth. against conv. modes* – orthogonalization of columns in the subblocks  $\mathbf{X}$  and  $\mathbf{P}$  against all converged modes (see section II.E); *Evaluation of residuals* – see section II.B; *Subsp. project.* – evaluation of the subspace projection matrices  $\mathbf{m}$  and  $\mathbf{k}$  (section II.C); *Prolong.* – prolongation procedure (section II.D). All these stages are parallelized.

Table IV shows the comparison of computing time required for the extraction of 100 eigenpairs for different methods. The BSPPCG method runs in the core memory, requires 35.3 GB RAM and produces 61 iterations and 17 total reorthogonalization when  $\psi = 10^{-50}$ ,  $\psi_1 = 10^{-13}$ . When

we assign  $\psi = 10^{-8}$ ,  $\psi_1 = 10^{-8}$ , the amount of required RAM is 16.4 GB, the ability of preconditioning of accelerating of the convergence is worse than in the previous case, and 142 iterations and 50 total reorthogonalization is required.

TABLE II  
THE DISTRIBUTION OF COMPUTATIONAL WORK AMONG THREADS.  
PROBLEM 2, COMPUTER A.

Thread number	First level of parallelization	Second level of parallelization
1	81 957 982	200 429 150

The block Lanczos method with the spectral transformations (SBLANC, [7]) runs in two modes. When the entire amount of the core memory is accessible (100 % RAM), solver PARFES [11], [12] – one from the fastest sparse direct solvers for multicore computers on today – works in a core mode, and the lower triangular factorized matrix  $L$ , having the size 36.53 GB, is located in RAM. Therefore, the forward and back substitutions, performed at each step of the Lanczos method, run extremely fast. In this case, we obtain practically the same durations for both methods.

When we allow using only 50% of RAM for the Lanczos method, PARFES runs in the out of core mode (OOC), and the matrix  $L$  is written block-by-block on disk. The forward and back substitutions run very slowly, and the solution time for the Lanczos method increases more than two times.

TABLE IV  
COMPARISON OF COMPUTATION TIME FOR DIFFERENT METHODS.  
PROBLEM 2, COMPUTER A.

Method	Total time, s
BSPPCG (core mode, $\psi = 10^{-50}$ , $\psi_1 = 10^{-13}$ )	14 552
BSPPCG (core mode, $\psi = 10^{-8}$ , $\psi_1 = 10^{-8}$ )	16 334
SBLANC (100% RAM)	14 096
SBLANC (50% RAM)	34 660

### C. Problem 3.

Figure 6 presents the design model of the multi-storey building, having quite a different topology and construction than the previous problem.

Fig. 6 Multi-storey building, having three towers

The dimension of the problem is  $N = 4\,262\,958$  equations, number of required eigenpairs –  $n = 100$ , dimension of the block  $m = 32$ . The parameters of preconditioning are:  $\psi = 0$ ,  $\psi_1 = 10^{-13}$ ,  $tol = 10^{-3}$ . We use a usual desktop – computer B.

This problem is very hard for stable convergence due to the presence of a large number of almost multiple frequencies, produced by similar towers, resting on the same stylobate, and we were forced to apply a shift technique. Table V shows that the given approach proved to be stable when the shift correction procedure (algorithm 5) performs at least two iterations.

As a result, we obtain about the same time of solving the problem by both methods: BSPPCG and SBLANC, but BSPPCG method works in RAM, and when Lanczos method is applied, PARFES uses the out of core (OOC) mode.

TABLE V  
COMPARISON OF COMPUTATION TIME FOR DIFFERENT METHODS.  
PROBLEM 3, COMPUTER B.

Method	Number of shift's corrections, $S$	Number of iterations	Number of total reorthogonalization	Total time, s
BSPPCG	0	Lock of convergence after 42 eigenpairs are converged		
BSPPCG	1	Lock of convergence after 53 eigenpairs are converged		
BSPPCG	2	70	19	16 901
SBLANC	—	—	—	16 568

## VII. CONCLUSION

The proposed BSPPCG method can compete with the block Lanczos method widely used in FEA software on shared memory multi-core computers. The presented approach, based on the PCG method, uses the block incomplete Cholesky factorization approach which allows to keep a very small value of the rejection parameter  $\psi$  and produces a lower triangular matrix  $\mathbf{H}$ ,  $\mathbf{B} = \mathbf{H}\mathbf{H}^T$ , which possesses a high ability to accelerate the convergence. The use of the iteration technique in a block of fixed dimension, the shift technique and the parallel algorithm for the total reorthogonalization, when a linear dependence between the columns of the projection matrix  $\mathbf{Q}_k$  was detected, ensure the high computational stability of the proposed approach.

**Abstract**—Recursive Filters (RFs) are a well-known way to approximate the Gaussian convolution and, due to their computational efficiency, are intensively used in several technical and scientific fields. The accuracy of the RFs can be improved by means of the repeated application of the filter, which gives rise to the so-called  $K$ -iterated Gaussian recursive filter. In this work we propose a parallel algorithm for the implementation of the  $K$ -iterated first-order Gaussian RF for multicore architectures. This algorithm is based on a domain decomposition with overlapping strategy. The presented implementation is tailored for multicore architectures and makes use of the Pthreads library. We will show through extensive numerical tests that our parallel implementation is very efficient for large one-dimensional signals and guarantees the same accuracy level of the sequential  $K$ -iterated first-order Gaussian RF.

## I. INTRODUCTION

NOWADAYS, the recursive filters (RFs) have become a useful computational tool in several fields. For example, Gaussian RFs are usually involved in image processing [1], [2], in data assimilation for solving three-dimensional variational analysis schemes [3], [4] and in advanced signal processing such as other class of RFs has been recently constructed specifically for the electrocardiogram (ECG) denoising [6], [7], [8]. The idea of a recursive filter is to provide a more efficient approximation either to a given filter operator, or to the convolution with the impulse response of the filter. Gaussian RFs are basically designed to approximate Gaussian-based convolutions and can be built in many ways (see [9] and the references therein). It is well-known that Gaussian RFs, when applied to signals with support in a finite domain, generate distortions and artifacts, mostly localized at the boundaries. This issue is known as *edge effect* and heuristic and theoretical tools, namely *boundary conditions*, have been proposed in literature to remove it [9], [10]. These tools can be used even in the more general case in which a Gaussian RF is repeatedly applied, i.e. the so-called  $K$ -iterated Gaussian RFs [3] where  $K$  denotes the number of filter iterations. In this paper, we consider  $K$ -iterated first-order Gaussian recursive filters. The analysis of such filters has been recently provided in terms of accuracy [3], [5].

Although Gaussian RFs have low computational complexity, they may become inapplicable in practice when the size of the input signal is very large, so that there is the need of their parallel implementation. A thorough survey on parallel

implementations of RFs is in [11]. The aim of our work is to introduce a new parallel algorithm for the  $K$ -iterated first-order Gaussian RF for 1D signals, based on a suitable domain decomposition with overlapping. Our approach is specifically designed for multicore architectures and is based on the Pthreads library. The paper is organized as follows. In Section II we briefly recall some mathematical preliminaries about the  $K$ -iterated first-order Gaussian RFs. Section III deals with the structure of the parallel algorithm and the underlying domain decomposition strategy. In Section IV we give some details about the implementation of the parallel algorithm in a multicore environment. Moreover, we discuss results of numerical tests that show that our parallel algorithm reaches the same accuracy of the sequential one, and we provide evidence of the gain obtained by the parallel implementation in terms of performance. Finally conclusions and future work are drawn in Section V.

## II. PRELIMINARIES

In the following we recall some preliminaries, notations and results presented in [5], [9]. We limit our description to the arguments needed for the understanding of the parallel approach proposed in next section. We first introduce the  $K$ -iterated  $n$ -order Gaussian RFs and in particular exhibit a sequential algorithm for the first-order case. Let:

$$s^{(0)} = \{s_j^{(0)}\}_{j \in \mathbb{Z}} = (\dots, s_{-2}^{(0)}, s_{-1}^{(0)}, s_0^{(0)}, s_1^{(0)}, s_2^{(0)}, \dots)$$

be an input signal.  $s^{(0)}$  can be thought of as a complex function defined on the set of integers, that is an element of the set of sequences of complex numbers  $\mathbb{C}^{\mathbb{Z}}$ . Let  $g$  denote the Gaussian function with zero mean and standard deviation  $\sigma$ :

$$g(t) = \frac{1}{\sigma\sqrt{2\pi}} \exp\left(-\frac{t^2}{2\sigma^2}\right). \quad (1)$$

Let  $\delta = \{\delta_j\}_{j \in \mathbb{Z}}$  be the *unit-sample*:

$$\delta_j = \begin{cases} 1 & \text{if } j = 0 \\ 0 & \text{if } j \neq 0 \end{cases} \quad (2)$$

The Gaussian filter is a filter whose response to the unit-sample (i.e. the impulse response) is the restriction of the Gaussian

function  $g$  on  $\mathbf{Z}$ . Since the Gaussian filter is linear and time-invariant, its response  $s^{(g)}$  to the input  $s^{(0)}$  can be simply expressed by the discrete Gaussian convolution:

$$s_j^{(g)} = (g * s^{(0)})_j = \sum_{t \in \mathbf{Z}} g_{j-t} s_t^{(0)}, \quad \forall j \in \mathbf{Z}, \quad (3)$$

where  $g_t \equiv g(t)$ . Gaussian RFs and  $K$ -iterated Gaussian RFs are efficient tools for approximating the entries  $s_j^{(g)}$  of  $s^{(g)}$ . A  $K$ -iterated  $n$ -order Gaussian RF filter generates an output signal  $s^{(K)}$ , the so-called  $K$ -iterate approximation of  $s^{(g)}$ , whose entries solve the  $2K$  recurrence relations:

$$p_j^{(k)} = \beta s_j^{(k-1)} + \sum_{t=1}^n \alpha_t p_{j-t}^{(k)}, \quad \forall j \in \mathbf{Z}, \quad k = 1, 2, \dots, K, \quad (4)$$

$$s_j^{(k)} = \beta p_j^{(k)} + \sum_{t=1}^n \alpha_t s_{j+t}^{(k)}, \quad \forall j \in \mathbf{Z}, \quad k = 1, 2, \dots, K. \quad (5)$$

For  $K = 1$ , the filter merely becomes an  $n$ -order Gaussian RF filter. As  $K \rightarrow \infty$  the filter converges to the Gaussian filter[20]. Relations (4) and (5) are conveniently referred to as the advancing and backing filters, respectively. The values  $\alpha_t$  and  $\beta$  are called *smoothing coefficients* and verify:

$$\beta = 1 - \sum_{t=1}^n \alpha_t.$$

In a general setting they depend on  $\sigma$ ,  $n$  and  $K$ . In the following we consider only the first-order Gaussian RF, so that relations (4) and (5) take the simplified form [9]

$$p_j^{(k)} = \beta s_j^{(k-1)} + \alpha p_{j-1}^{(k)}, \quad \forall j \in \mathbf{Z}, \quad (6)$$

$$s_j^{(k)} = \beta p_j^{(k)} + \alpha s_{j+1}^{(k)}, \quad \forall j \in \mathbf{Z}. \quad (7)$$

Now, the smoothing coefficients are:

$$\alpha = 1 + E_\sigma - \sqrt{E_\sigma(E_\sigma + 2)}, \quad (8)$$

$$\beta = \sqrt{E_\sigma(E_\sigma + 2)} - E_\sigma, \quad (9)$$

with  $E_\sigma = K\sigma^{-2}$ . If we consider an input signal  $s^{(0)}$  with support in the grid  $\{0, 1, 2, \dots, N-1\}$  then, in order to implement such a Gaussian RF as an algorithm, the index  $j$  must be treated in increasing order in the advancing filter (from 0 to  $N-1$ ) and in decreasing order in the backing filter (from  $N-1$  to 0) [9]. Such a scheme requires to set values  $p_0^{(k)}$  and  $s_{N-1}^{(k)}$  for priming the advancing and backing filters, respectively. A common choice is to set these values at zero or introduce the so-called *boundary conditions* that simulate the effect of the neglected filter equations in the algorithm. For first-order filters, the boundary conditions are [9]:

$$p_0^{(k)} = \frac{1}{1 + \alpha} s_0^{(k-1)}, \quad s_{N-1}^{(k)} = \frac{1}{1 + \alpha} p_{N-1}^{(k)}.$$

Both approaches suffer from a well-known edge effect, that is a large perturbation on the boundary entries of the finite output signal. As shown in [9], provided that the input support is in  $[0, N-1]$ , this effect can be mitigated with a

suitable *extending-resizing* strategy that allows an effective implementation of the  $K$ -iterated first-order Gaussian RF. This idea consists in three steps:

- (i) *extending* the given input signal  $s^{(0)}$ , with support in  $\{0, 1, 2, \dots, N-1\}$ , by adding artificial zero entries at the left and right boundaries. More specifically, we introduce the extended signal:

$$s^{(0),m} = (0, \dots, 0, s_0^{(0)}, \dots, s_{N-1}^{(0)}, 0, \dots, 0), \quad (10)$$

which is obtained by inserting  $m$  zeros before  $s_0^{(0)}$  and  $m$  zeros after  $s_{N-1}^{(0)}$ ;

- (ii) applying the  $K$ -iterated first-order Gaussian RF to  $s^{(0),m}$ , in order to obtain  $s^{(K),m}$ ;
- (iii) *resizing* the signal  $s^{(K),m}$ , by removing its first and last  $m$  entries, so that the (approximated) output signal  $s^{(K)}$  is recovered.

The underlying idea of this scheme is to shift the edge effects on the artificially added entries. Step (i)-(iii) are shown in Figure 1.

Fig. 1. *extending-resizing* strategy

**Algorithm 1** implements this strategy, while **Algorithm 2** is a  $K$ -iterated first-order Gaussian RF straight implementation.

---

**Algorithm 1** Extending-resizing strategy for the  $K$ -iterated first-order recursive filter

---

**Input:**  $s^{(0)}$ ,  $\sigma$ ,  $m$ ,  $K$

**Output:**  $s^{(K)}$

- 1: extend  $s^{(0)}$  to  $s^{(0),m}$  as described in step (i)
  - 2: apply **Algorithm 2** to  $s^{(0),m}$  with parameters  $\sigma$ ,  $K$  as described in step (ii), to obtain  $s^{(K),m}$
  - 3: resize  $s^{(K),m}$  as described in step (iii), to obtain  $s^{(K)}$
- 

### III. THE PARALLEL ALGORITHM

In this section we describe the strategy underlying our parallel algorithm for a  $K$ -iterated first-order Gaussian RF and highlight the main feature of our parallel software for multicore environment. A multicore processor is a single computing component with two or more independent actual processing units, called "cores" (see Figure 2). The instructions are ordinary CPU instructions (such as add, move data, and branch), but the multiple cores can run multiple instructions

**Algorithm 2**  $K$ -iterated first-order RF with boundary conditions

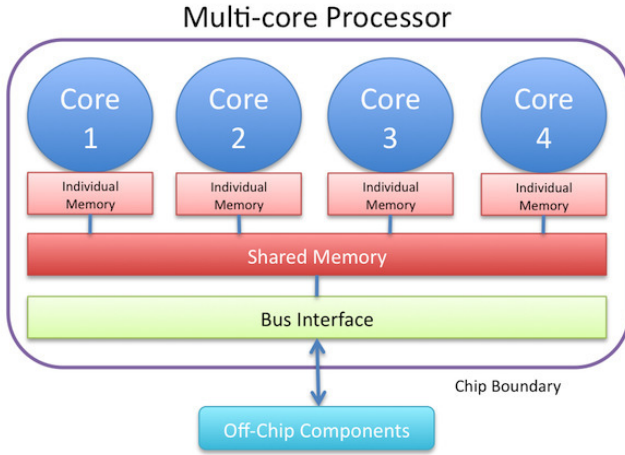

Fig. 2. Multicore architecture scheme.

concurrently, the so-called concurrent threads, increasing the overall efficiency.

Multicore processors are widely used across many application domains, including general-purpose, embedded, network, digital signal processing (DSP), and graphics (GPU).

Possible gains in efficiency are limited by the fraction of the software that can run in parallel simultaneously on multiple cores. In the best case, the so-called embarrassingly parallel problems, one can reach a speedup factor close to the number of cores, or even more, if problems' data are decomposed so that they fit within each core cache, thus avoiding the use of the slower main memory.

To implement the algorithm in this environment, our starting idea is to divide in local blocks the original signal and to apply the strategy shown in previous section to each block. Finally, after collecting local outputs, the output signal is recovered. This is a typical domain decomposition approach in which the

starting signal  $s^{(0)}$  is first partitioned in  $t$  signal blocks, with  $t$  number of threads:

$$s_0^{(0)}, s_1^{(0)}, \dots, s_{t-1}^{(0)}. \quad (11)$$

More in particular, denoting by  $d = \lfloor \frac{N}{t} \rfloor$ ,  $r = \text{mod}(N, t)$ , the  $j$ -th block ( $j = 1, \dots, t$ ) has components:

$$(s_j^{(0)})_i = \begin{cases} s_{jd+j+i}^{(0)}, & i = 0, \dots, d \quad \text{if } j < r \\ s_{jd+r+i}^{(0)}, & i = 0, \dots, d-1 \quad \text{if } j \geq r \end{cases} \quad (12)$$

We highlight that such a domain decomposition strategy relies in a sort of new method in which the output pieces are an approximation of the Gaussian convolution of the local inputs. In other words, the global output, i.e. the approximation of the Gaussian convolution of the global input, is obtained by collecting approximated local Gaussian convolutions of the local inputs that neglect the farthest entries.

A naive choice would be to apply the *extending-resizing* strategy to each block  $s_j^{(0)}$ , so that each thread extends (with  $2m$  zeros) its local input, computes the local output by means of **Algorithm 2**, and resizes the local output. Finally the global signal output can be restored by gathering all resized outputs. However this strategy suffers a serious drawback, that is a low accuracy in the output entries close to the cut points of the domain decomposition. This can be explained observing that each thread uses as extended local input a block with support in  $[m+1, m+d+1]$  (or  $[m+1, m+d]$ ) instead of the input entries of  $s^{(0)}$ . This can be seen as a perturbation in the local input signal boundary entries which causes a significant distortion in the output entries. In order to overcome the above drawback we devised a more appropriate *extending-resizing* strategy that, for extending the local inputs, uses the known entries of the signal input instead of zero values.

(i') *domain decomposition with overlapping*. The starting signal  $s^{(0)}$  is partitioned in  $t$  input blocks  $s_j^{(0)}$  as in (11), (12), and each block is assigned to a thread. Each thread *extends* its block by adding  $m$  actual input entries at the left boundary and  $m$  actual input entries at the right boundary. When not available these entries are set at zero. Formally, the extended input signal components are:

$$(s_j^{(0),m})_i = \begin{cases} s_{jd+j+i-m}^{(0)}, & i = 0, \dots, d+2m \quad \text{if } j < r \\ s_{jd+r+i-m}^{(0)}, & i = 0, \dots, d+2m-1 \quad \text{if } j \geq r \end{cases}$$

where conventionally  $s_l^{(0)} = 0$  for  $l < 0$  and  $l \geq N$ , so that zeros are considered only when the input entries do not exist. This kind of decomposition is illustrated in Figure 3;

- (ii') each thread  $j$  applies the  $K$ -iterated first-order Gaussian RF to  $s_j^{(0),m}$ , in order to obtain  $s_j^{(K),m}$ ;
- (iii') *resizing with collecting*. Each thread  $j$  *resizes* the signal  $s_j^{(K),m}$ , by removing its first and last  $m$  entries and generates the local output  $s_j^{(K)}$ . Finally, the local outputs are collected in the global output signal.

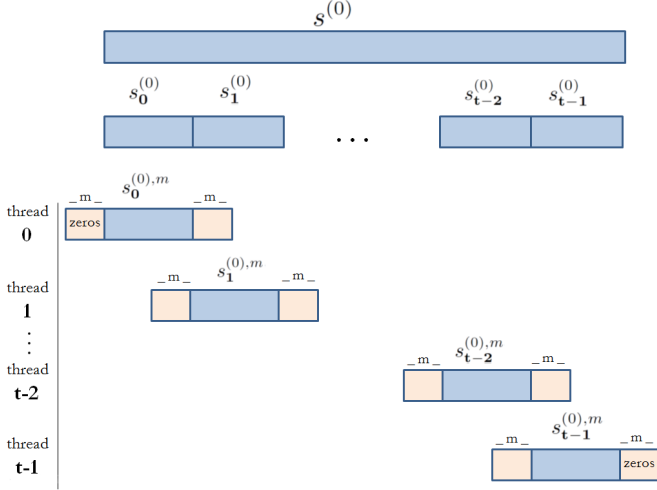

Fig. 3. Domain decomposition with overlapping scheme.

We observe that steps (i')-(iii') can be carried out by all threads in a fully-parallel way. In other words, our strategy can be considered embarrassingly parallel and can be summarized in **Algorithm 3**.

**Algorithm 3** Parallel  $K$ -iterated first-order Gaussian recursive filter based on domain decomposition with overlapping

**Input:**  $s^{(0)}$ ,  $\sigma$ ,  $m$ ,  $K$ ,  $t$

**Output:**  $s^{(K)}$

- 1: FOR ALL THREAD  $j$
- 2: save in the private memory of thread the extended input signal  $s_j^{(0),m}$  as described in step (i') (domain decomposition with overlapping)
- 3: apply **Algorithm 2** to  $s_j^{(0),m}$  with parameters  $\sigma$ ,  $K$  as described in step (ii'), to obtain  $s_j^{(K),m}$
- 4: resize  $s_j^{(K),m}$  to recover  $s_j^{(K)}$  and copy it in the shared memory in order to obtain the global output  $s^{(K)}$  as described in step (iii')
- 5: ENDFOR ALL THREAD  $j$

#### IV. IMPLEMENTATION DETAILS AND NUMERICAL TESTS

Our parallel algorithm is developed and tested on a CPU Intel Core i7 (2.8GHz), with 8 cores, 8GB of RAM memory, 4GB GDDR5 of memory size and 173 GB/s of memory bandwidth. In order to take full advantage of the capabilities provided by a multicore processor, a standardized interface is needed for programming the threads. For UNIX systems, this interface has been specified by the IEEE POSIX 1003.1c standard. Implementations adhering to this standard are referred to as POSIX threads, or Pthreads<sup>1</sup>. The Pthreads library is a set of C language programming types and procedures for managing the synchronization and concurrency in a shared memory environment. Most hardware vendors offer Pthreads in addition to their proprietary API's.

#### A. Accuracy

Here we are interested in comparing, in terms of provided accuracy, the sequential implementation (**Algorithm 1**) and the parallel implementation (**Algorithm 3**) of the  $K$ -iterated first-order Gaussian RF. The accuracy is measured by the 2-norm  $\|s^{(g)} - s^{(K)}\|_2$ , where  $s^{(g)}$  is the output of the standard Gaussian convolution, and  $s^{(K)}$  is either the output of **Algorithm 1** or the output of **Algorithm 3** depending on the context.

In Table I we report the results obtained applying **Algorithm 1** to the random input signal used in [9], for several values of  $K$  and  $m$  with fixed  $\sigma$  and  $N$ . Following [9] we notice that the larger  $m$  the better the accuracy, but the choice  $m = 2\sigma$  guarantees a good trade-off between accuracy and size of the extended signal ( $N + 2m$ ). In Table II-IV we report the results obtained applying **Algorithm 3** to same input signal of Table I, with  $t = 2, 4, 8$  threads, respectively. We observe that, regardless of the number of threads, the parallel algorithm can obtain the same accuracy level of **Algorithm 1** with a slightly larger value of  $m$  ( $m = 4\sigma$ ).

#### B. Performance analysis

Here we are interested in the performance of the parallel algorithm (**Algorithm 3**). The performance are measured in

8	2.0e-03	8.3e-03	8.0e-02

terms of execution time. In Table V we report the execution times applying this algorithm to random input signals of increasing size ( $N = 2000$ ,  $N = 20\,000$ ,  $N = 200\,000$ ) and varying the number of threads. The values of the other parameters are fixed as follows:  $\sigma = 4$ ,  $m = 4\sigma$  and  $K = 100$ . Table V shows that execution times decrease as the number of threads grows. In particular, an appreciable gain in time, expressed in percentage, reached with 8 threads and  $N = 200\,000$ , is:

$$\frac{0.24 - 0.08}{0.24} \cdot 100\% = 66.7\%.$$

## V. CONCLUSIONS

In this work, we have presented a new parallel algorithm for the approximation of the one-dimensional Gaussian convolution, based on  $K$ -iterated Gaussian recursive filters. The algorithm has been implemented on a multicore architecture. We also provided preliminary results that show the accuracy and the efficiency of our algorithm. This is a first step towards the development of algorithms and softwares, for HPC many core environments, for an efficient computation of multidimensional Gaussian convolutions that appear across several technical and scientific fields as data assimilation [12], reputation systems [13], [14], classical [15], [16] and multidimensional interpolation [17], [18], [19], image processing and data mining.

**Abstract**—The presented study analyses 563 representative benchmark sparse matrices with respect to their partitioning into uniformly-sized blocks. The aim is to minimize memory footprints of matrices. Different block sizes and different ways of storing blocks in memory are considered and statistically evaluated. Memory footprints of partitioned matrices are additionally compared with lower bounds and the CSR storage format. The average measured memory savings against CSR in case of single and double precision are 42.3 and 28.7 percents, respectively. The corresponding worst-case savings are 25.5 and 17.1 percents. Moreover, memory footprints of partitioned matrices were in average 5 times closer to their lower bounds than CSR. Based on the obtained results, we provide generic suggestions for efficient partitioning and storage of sparse matrices in a computer memory.

## I. INTRODUCTION

The way how sparse matrices are stored in a computer memory may have a significant impact on the required memory space, i.e., on the matrix memory footprints. Reduction of matrix memory footprints may positively influence related computations and executions of corresponding programs. For example:

- Lower matrix memory footprints yield faster processing of matrices by I/O subsystems, e.g., when checkpointing-restart resilience methods are applied within high performance computing (HPC) applications [1], [2].
- Lower matrix memory footprints may increase the efficiency and performance of sparse matrix computations if these are bounded by memory bandwidth. This is, e.g., often the case of sparse matrix vector multiplication (SpMV)<sup>1</sup>.
- Lower matrix memory footprints allow larger matrices to fit in the available amount of memory, which, therefore, allows to solve computational problems to higher extent or with higher accuracy.

This work was supported by the Czech Science Foundation under grant no. 16-16772S and by Czech Technical University in Prague under grant SGS17/215/OHK3/3T/18.

<sup>1</sup>Memory bandwidth is not the only bound for SpMV performance; there are others as well [3]. However, in cases where the memory bandwidth is the main bottleneck, by reducing memory footprints of matrices one can reduce the overall timings of SpMV applications such as iterative solvers.

One way of reducing memory footprints of sparse matrices is their partitioning into blocks (which also promotes spatial locality during computations). Much has been written about block processing of sparse matrices, frequently in the context of memory-bounded character of SpMV [4]–[26]. In this article, we address the problem of minimizing memory footprints of sparse matrices by their partitioning into uniformly-sized blocks. Its solution raises two essential questions: How to choose a suitable block size? And, how to store resulting nonzero blocks in a computer memory? These questions form a multi-dimensional optimization problem that needs to be solved prior to the partitioning itself. We refer to both these problems—optimization and partitioning—as *(block) preprocessing*.

The above introduced optimization problem raises another question: How to specify the optimization space, i.e., the space of tested configurations? Intuitively, the larger the optimization space is, the lower matrix memory footprint can be found, however, at a price of longer preprocessing runtime. To amortize block processing of a sparse matrix, the optimization space thus need to be chosen wisely in a form of a trade-off: we want it to be small enough to ensure its fast exploration but also large enough to contain the optimal or nearly-optimal configuration generally for any sparse matrix.

We present a study that analyses memory footprints of 563 representative sparse matrices from the University of Florida Sparse Matrix Collection (UFSMC) [27] with respect to their partitioning into uniformly sized blocks. These matrices arose from a large variety of applications of multiple problem types and thus have highly diverse structural and numerical properties. Our goal is to minimize memory footprints of matrices and we consider an optimization space that consists of different block sizes and different ways of storing blocks in memory. Based on the obtained results, we finally provide suggestions for both efficient and effective block preprocessing of sparse matrices in general.

## II. METHODOLOGY

In Section I, we referred to the *matrix memory footprint* as to the amount of memory space required to store a given

matrix in a computer memory. More precisely, we can define it as a number of bits (or bytes) which is needed to store the values of nonzero elements of a given matrix together with the information about their structure, i.e., their row and column positions.

#### A. Sparse Matrix Storage Formats

The ways how sparse matrices are stored in a computer memory are generally called *sparse matrix storage formats*; we call them *formats* only if the context is clear. Matrix memory footprint is thus a function of a given matrix and format (memory footprints for the same matrix but distinct formats may differ considerably).

In case of partitioned sparse matrices, their nonzero blocks represent individual submatrices that can be treated separately. In practice, well-proven formats used for nonzero blocks of sparse matrices are:

- The *coordinate* (COO) format, which stores values of block nonzero elements together with their row and column indices [7], [17], [21].
- The *compressed sparse row* (CSR) format, which stores values and column indices of lexicographically ordered block nonzero elements together with the information about which values / column indices belongs to which block row [17], [19]–[21].
- The *bitmap* format, which stores values of block nonzero elements in some prescribed order and encodes their row and column indices in a bit array [8], [15], [17].
- The *dense* format, which stores values of both nonzero and zero block elements in a dense array (row and column indices of nonzero elements are thus effectively determined by positions of their values within this array) [13], [14], [17], [28].

#### B. Blocking Storage Schemes

Considering these formats, we have 6 options how to store nonzero blocks of a sparse matrix in memory:

- 1) store all the blocks in the COO format,
- 2) store all the blocks in the CSR format,
- 3) store all the blocks in the bitmap format,
- 4) store all the blocks in the dense format,
- 5) store *all the blocks* in a format that minimizes the memory footprint of a given matrix (we refer to this option as *min-fixed*),
- 6) store *each block* in a format that minimizes the contribution of this block to the memory footprint of a given matrix (we refer to this option as *adaptive*).

We call these options *blocking storage schemes*, or shortly *schemes* only. Since the first 4 schemes prescribe a fixed format for all the blocks, we call them *fixed-format schemes*.

For the min-fixed and adaptive schemes, we consider formats for nonzero blocks to be chosen from COO, CSR, bitmap, and dense. In case of the min-fixed scheme, the matrix memory footprint thus contains 2 additional bits for storing the information about the format used for all the nonzero blocks. In case of the adaptive scheme, the matrix memory footprint

contains 2 additional bits for each nonzero block to store the information about its format.

#### C. Block Sizes

To evaluate memory footprints of a given matrix for different schemes and some particular tested block size, we need information about numbers of nonzero elements of all nonzero blocks [17]. In the end, this information must be obtained for each distinct block size from the optimization space, which represents the most demanding part of the whole optimization process [29]. The block preprocessing runtime is thus approximately proportional to the number of distinct tested block sizes. Consequently, the lower is their count, the higher are the chances that the partitioning will be profitable at all.

Generally, there is  $O(m \times n)$  ways how to choose a block size for an  $m \times n$  matrix, but for fast block preprocessing, we need to consider only few of them.<sup>2</sup> One possible approach is to consider only block sizes

$$2^k \times 2^\ell, \quad \text{where } 1 \leq k \leq K \quad \text{and} \quad 1 \leq \ell \leq L, \quad (1)$$

which reduces the number of tested block sizes to  $K \times L$ . Such a choice, among others, results in substantially faster preprocessing in general [29]. Within the presented study, we consider block sizes (1) and set  $K = L = 8$ . The choice of these upper bounds stemmed from our auxiliary experiments which showed that space-optimal block sizes have mostly less than 64 rows/columns. Taking into account block sizes with up to 256 rows/columns should cover even the remaining corner cases.

#### D. Optimization Space

In the summary, our optimization space is initially defined by  $\mathcal{S}_6 \times \mathcal{B}_{64}$ , where  $\mathcal{S}_6$  denotes a set of selected blocking storage schemes:

$$\mathcal{S}_6 = \{\text{COO, CSR, bitmap, dense, min-fixed, adaptive}\}$$

and  $\mathcal{B}_{64}$  denotes a set of selected block sizes:

$$\mathcal{B}_{64} = \{2^k \times 2^\ell : 1 \leq k, \ell \leq 8\}.$$

#### E. Additional Considerations

When measuring matrix memory footprints, we need to decide how to represent information about nonzero blocks and how to represent indices. In the presented study, we assume that:

- 1) nonzero blocks are stored in memory in the lexicographical order;
- 2) block column index for each nonzero block is stored explicitly;
- 3) the number of nonzero blocks for each block row is stored;

<sup>2</sup>In addition to multiplication and Cartesian product, we also use the multiplication sign “ $\times$ ” to specify matrix/block sizes. In such cases,  $m \times n$  does not denote multiplication, but a matrix/block size of height  $m$  and width  $n$  (i.e., having  $m$  rows and  $n$  columns).

- 4) a minimum possible number of bits, i.e.,  $\lceil \log_2 n \rceil$  bits, is used to store an index related to  $n$  entities (such an approach is in the literature sometimes referred to as *index compression*).

#### F. Benchmark Matrices

Sparse matrices are often divided into two main categories—*high performance computing (HPC) matrices* and *graph matrices*. Efficient processing of graph matrices is generally governed by special rules that are different from those being effective for HPC matrices [9], [30], [31] (e.g., higher matrix memory footprints in some cases lead to higher performance of computations and graph matrices are also typically not suitable for simple block processing mainly due to emergence of hypersparse blocks [8], [9]). Within this work, we focused mainly (but not exclusively) on HPC matrices. Namely, we considered all real matrices from the UFSMC that contained more than  $10^5$  nonzero elements and had a unique structure of nonzero elements. This way, we obtained 563 sparse matrices arising from different application problems (see Table I) and thus having different structural (and numerical) properties; we denote these matrices by  $A_1, \dots, A_{563}$ . Of these matrices, 281 were square symmetric and the remaining 282 were either rectangular or square unsymmetric.

#### G. Matrix Memory Footprint

For symmetric matrices, we always assume storage only of their single triangular parts in memory, which is a common practice. Referring to the *number of nonzero elements* of a matrix, we thus generally need to distinguish between the number of *all* nonzero elements and the number of elements that are assumed to be *stored* in a computer memory. While

measuring memory footprints of sparse matrices, we take into account the latter one.

According to the text above, a matrix memory footprint for a sparse matrix  $A_k$  partitioned into uniformly-sized blocks is a function of the following parameters:

- 1) sparse matrix  $A_k$ ,
- 2) block storage scheme  $s \in \mathcal{S}_6$ ,
- 3) block size  $h \times w \in \mathcal{B}_{64}$ ,
- 4) number of bits  $b$  required to store a value of a single matrix nonzero element.

We denote this function by  $\text{MMF}_{\boxplus}(A_k, s, w \times h, b)$ . We further assume storing values of matrix nonzero elements in either single or double precision IEEE floating-point format [32], which implies  $b = 32$  or  $b = 64$ , respectively, in case of real matrices. We refer to such a floating-point precision as *precision* only.

We say that a matrix memory footprint for a given matrix  $A$  and a given precision determined by  $b$  is *optimal* (with respect to our work) if it equals

$$\min\{\text{MMF}_{\boxplus}(A, s, h \times w, b) : s \in \mathcal{S}_6, h \times w \in \mathcal{B}_{64}\}.$$

We call the corresponding blocking storage scheme and block size optimal as well.

Let  $\mathcal{S} \subseteq \mathcal{S}_6$  and  $\mathcal{B} \subseteq \mathcal{B}_{64}$ .  $\mathcal{S} \times \mathcal{B}$  thus define a subspace of the optimization space  $\mathcal{S}_6 \times \mathcal{B}_{64}$ . Let

$$\Delta_{\mathcal{S}, \mathcal{B}}^b(k) = \left( \frac{\min\{\text{MMF}_{\boxplus}(A_k, s, h \times w, b) : s \in \mathcal{S}, h \times w \in \mathcal{B}\}}{\min\{\text{MMF}_{\boxplus}(A_k, s, h \times w, b) : s \in \mathcal{S}_6, h \times w \in \mathcal{B}_{64}\}} - 1 \right) \times 100.$$

This function expresses of how much percent is the minimal memory footprint of  $A_k$  from  $\mathcal{S} \times \mathcal{B}$  higher (worse) than its optimal memory footprint. To assess the subspace  $\mathcal{S} \times \mathcal{B}$ , we define the following parametrized set

$$\mathcal{U}_{\mathcal{S}, \mathcal{B}}^b = \{\Delta_{\mathcal{S}, \mathcal{B}}^b(k) : 1 \leq k \leq 563\}.$$

The minimum, mean (average;  $\mu$ ), and maximum of  $\mathcal{U}_{\mathcal{S}, \mathcal{B}}^b$  then reflect the best, average, and worst cases, respectively, for  $\mathcal{S} \times \mathcal{B}$  across the tested matrices.

If  $\mathcal{S}$  or  $\mathcal{B}$  consists of a single element only, we omit the curly braces in the subscript of  $\mathcal{U}$  for the sake of readability; e.g., we write  $\mathcal{U}_{s, \mathcal{B}_{64}}^b$  and  $\mathcal{U}_{\mathcal{S}_6, h \times w}^b$  instead of  $\mathcal{U}_{\{s\}, \mathcal{B}_{64}}^b$  and  $\mathcal{U}_{\mathcal{S}_6, \{h \times w\}}^b$ .

### III. RESULTS AND DISCUSSION

#### A. Blocking Storage Schemes

First, we assessed blocking storage schemes. Table II shows for how many tested matrices were individual schemes optimal. The adaptive scheme clearly dominates this evaluation metric; it was optimal for 464 tested matrices, which corresponds to 82.4 % of their total count. Note that the min-fixed scheme was never optimal; this is due to the necessity to store additional information about the format used for blocks (if

Fig. 1: Numbers of tested matrices for which are block sizes optimal, measured for double precision; block size  $8 \times 8$  was optimal for 257 matrices.

TABLE II: Counts of tested matrices for which are blocking storage schemes optimal; the numbers are the same for both single and double precision.

Scheme	Matrices
COO	58
CSR	0
bitmap	36
dense	5
min-fixed	0
adaptive	464

we ignored the additional 2 bits required by this scheme, it would be optimal for  $58 + 36 + 5 = 99$  matrices). However, the numbers in Table II reflect only best cases, i.e., matrices that were most suitable for particular schemes. To find out how much were particular schemes better than the others in average and for their worst-case (most unsuitable) matrices, we need complete statistics of  $\mathcal{U}_{s, \mathcal{B}_{64}}^b$ ; these are presented in Table III and lead to the following observations:

- No fixed-format scheme minimized matrix memory footprints in comparison with the others. Bitmap was the best in average, however, it was inferior to both COO and CSR in worst cases.
- Dense provided extremely high matrix memory footprints in average and worst cases. Due to the explicit storage of zero elements, this scheme is suitable only for kinds of matrices that contain highly dense blocks; obviously, there were only few such matrices in our tested suite (recall that the dense scheme was optimal for 5 matrices according to Table II).
- The lowest memory footprints were provided by the min-fixed and adaptive schemes; their numbers are considerably lower in comparison with the fixed-format schemes.

### B. Block Sizes

Similarly as blocking storage schemes, we assessed block sizes. Fig. 1 shows for how many tested matrices were individual block sizes optimal in case of double precision

measurements; for single precision, the results differed only for 2 matrices. We may observe that some block sizes were especially favourable. The  $8 \times 8$  block size was optimal for 257 matrices, which corresponds to 45.6 % of their total count. Together with  $4 \times 4$  and  $16 \times 16$ , these 3 block sizes were optimal for 65.2 % of tested matrices. However, again, the numbers from Fig. 1 reflect only best cases. To find out how much were particular block sizes better than the others in average and for their worst-cases matrices, we present the average and maximum values of  $\mathcal{U}_{S_6, h \times w}^b$  in Table IV and Table V for single and double precision, respectively. According to these results, some blocks sizes—especially  $8 \times 8$ —provided alone average matrix memory footprints close to their optimal values. However, there was not a single block size that would yield the same outcome for all the tested matrices; the maxima were for all the block sizes relatively high.

Let us remind that one of our goals is a possible reduction of the number of block sizes in the optimization test space. The question thus is whether there is some subset  $\mathcal{B} \subset \mathcal{B}_{64}$  that would, at the same time:

- 1) significantly reduce the number of block sizes ( $|\mathcal{B}|$ ),
- 2) provide matrix memory footprints close to their optimal values for most of the tested matrices (average of  $\mathcal{U}_{S_6, B}^b$  close to zero),
- 3) provide low matrix memory footprints for all the tested matrices (low maximum of  $\mathcal{U}_{S_6, B}^b$ ).

Natural candidates for such a subset would be the first  $n$  block sizes from Table IV and Table V; let us denote them by  $\mathcal{C}_n^{64}$  and  $\mathcal{C}_n^{32}$ , respectively. Fig. 2 evaluates these subsets as a function of  $n$ . We may notice that

$$\begin{aligned} \mathcal{C}_9^{64} &= \mathcal{C}_9^{32} = \{h \times w : h, w \in \{4, 8, 16\}\}, \\ \mathcal{C}_{16}^{64} &= \mathcal{C}_{16}^{32} = \{h \times w : h, w \in \{4, 8, 16, 32\}\}; \end{aligned}$$

seemingly, block sizes from these subsets are especially suitable for sparse matrices in general.

Despite that, neither these first 9 nor 16 block sizes reduced the maximal matrix memory footprints too much according to

TABLE III: Minimum, average and maximum values of  $\mathcal{U}_{s, \mathcal{B}_{64}}^b$  (in percents).

6	$16 \times 16$	1.40	13.16	16	$32 \times 32$	2.82	14.18	26	$64 \times 8$	3.57	15.30
7	$4 \times 4$	1.63	12.34	17	$8 \times 64$	3.05	12.62	...	...	...	...
8	$4 \times 16$	1.66	9.96	18	$2 \times 8$	3.11	12.08	62	$256 \times 2$	7.88	21.59
9	$16 \times 4$	1.79	12.32	19	$8 \times 2$	3.14	14.02	63	$256 \times 128$	7.92	19.56
10	$8 \times 32$	1.99	11.97	20	$16 \times 64$	3.19	14.00	64	$256 \times 256$	7.93	18.96

Fig. 2. However, we may observe that there are some block sizes where these maxima significantly dropped. Based on the analysis of the statistics of  $\mathcal{U}_{S_6, \mathcal{C}_n^b}^b$ , we propose the following *reduced sets of block sizes*:

$$\begin{aligned}\mathcal{B}_8 &= \{2^k \times 2^k : 1 \leq k \leq 8\}, \\ \mathcal{B}_{14} &= \mathcal{B}_8 \cup \{2^k \times 2^\ell : 2 \leq k, \ell \leq 4\}, \\ \mathcal{B}_{20} &= \mathcal{B}_8 \cup \{2^k \times 2^\ell : 2 \leq k, \ell \leq 5\}.\end{aligned}$$

$\mathcal{B}_8$  thus consists of all square block sizes from  $\mathcal{B}_{64}$ .  $\mathcal{B}_{14}$  and  $\mathcal{B}_{20}$  equal  $\mathcal{B}_8$  plus rectangular block sizes from  $\mathcal{C}_9^{32}$  ( $\mathcal{C}_9^{64}$ ) and  $\mathcal{C}_{16}^{32}$  ( $\mathcal{C}_{16}^{64}$ ), respectively.

### C. Optimization Subspace

Table III revealed that to minimize memory footprints of (all) the tested matrices, we had to use either the min-fixed or the adaptive blocking storage scheme. To reduce the block preprocessing overhead, we now proposed several reduced sets of block sizes. Let us now assess these options together. We measured the statistics of  $\mathcal{U}_{s, \mathcal{B}_j}^b$  for all the combinations of  $s \in \{\text{min-fixed}, \text{adaptive}\}$  and  $j \in \{64, 20, 14, 8\}$ ; the results are presented in Table VI. The average matrix memory footprints

were in all cases close to their optimal values. Moreover, the reduced sets  $\mathcal{B}_j$  required much less block sizes than  $\mathcal{C}_n^b$  to achieve the same maxima. For instance:

- 1)  $\mathcal{B}_{14}$  in combination with the min-fixed scheme required only 14 block sizes to achieve the same maxima as  $\mathcal{C}_{43}^b$  in combination with all the schemes. This would effectively reduce the number of block sizes in the optimization space by a factor of about 3, which would proportionally reduce the preprocessing overhead in practice.
- 2)  $\mathcal{B}_{20}$  in combination with the adaptive scheme required only 20 block sizes to achieve the same maxima  $\mathcal{C}_{50}^b$  in combination with all the schemes. This would effectively reduce the number of block sizes by a factor of 2.5.

### D. Memory Savings Against CSR32

Likely the most widely-used storage format for sparse matrices in practice is CSR, which is supported by vast majority of software tools and libraries that work with sparse matrices. To distinguish between CSR used for blocks of partitioned matrices and CSR used for whole (not-partitioned) matrices, we call the latter CSR32, since it is typically implemented with 32-bit indices. Researchers frequently demonstrate the

Fig. 2: Average and maximum values  $\mathcal{U}_{S_6, C_n}^b$  (in percents) as a function of  $n$ .

TABLE VI: Average and maximum values of  $\mathcal{U}_{s, B_j}^b$  (in percents) for  $j \in \{64, 20, 14, 8\}$ .

(a) Single precision ( $b = 32$ )

Block sizes	$s = \text{min-fixed}$		$s = \text{adaptive}$	
	Average	Maximum	Average	Maximum
$B_{64}$	1.19	5.41	0.10	2.24
$B_{20}$	1.32	6.23	0.22	4.21
$B_{14}$	1.35	6.89	0.28	6.81
$B_8$	1.51	10.06	0.51	11.07

(b) Double precision ( $b = 64$ )

Block sizes	$s = \text{min-fixed}$		$s = \text{adaptive}$	
	Average	Maximum	Average	Maximum
$B_{64}$	0.64	2.94	0.05	1.30
$B_{20}$	0.71	3.52	0.12	2.37
$B_{14}$	0.73	3.77	0.16	3.83
$B_8$	0.81	5.34	0.28	5.88

superiority of their algorithms and data structures (formats) by comparison with CSR32, which have become de facto an etalon in sparse-matrix research.

Comparison of memory footprints of sparse matrices partitioned into blocks and the same matrices stored in CSR32 allows us to assess our blocking approach. Let  $\text{MMF}_{\text{CSR32}}(A, b)$  denote a memory footprint of a matrix  $A$  stored in memory in CSR32 with respect to a precision given by  $b$ . The function

$$\Lambda^b(k) = (1 - \min\{\text{MMF}_{\boxplus}(A_k, s, h \times w, b) : s \in \mathcal{S}_6, h \times w \in \mathcal{B}_{64}\} / \text{MMF}_{\text{CSR32}}(A_k, b)) \times 100$$

then expresses how much memory in percents we would save if we stored the tested matrix  $A_k$  in its optimal blocking configuration instead of in CSR32. We measured these memory savings for all the tested matrices and processed them statistically; the results are presented by Table VII. The obtained numbers arguments strongly in favour of partitioning of sparse matrices in general. Even in worst cases, our

TABLE VII: Statistics of  $\Lambda^b(k)$ , i.e., memory savings of optimal blocking configurations against CSR32 in percents, across the tested matrices.

Statistics	Single precision	Double precision
Minimum	25.46	17.08
Average	42.29	28.67
Maximum	50.21	35.86

blocking approach reduced the memory footprints of matrices of 25.46 % and 17.08 % for single and double precision, respectively. In average, the savings were 42.29 % and 28.67 %, which significantly reduces the amount of data that needs to be transferred between memory and processors during computations.

#### E. Memory Footprints Compared with Lower Bounds

Section III-D showed how much memory space we would save if we stored sparse matrices in optimal blocking configurations instead of in CSR32. The last object of our concern within this study was of how much are the memory footprints

of the tested matrices higher than their potential minima, i.e., their lower bounds.

We further do not consider compression of the values of matrix nonzero elements, since it is generally worth applying only for special kinds of matrices where nonzero elements contain few unique numbers. To store  $nnz$  nonzero elements of a matrix  $A$  in memory with respect to a precision given by  $b$ , we thus need  $nnz \times b$  bits to store their values and some additional space to store the information about their structure. The lower bound for the latter for any particular structure of nonzero elements is 1 bit, since it is sufficient for distinguishing whether or not a matrix has that particular structure. For instance, we can use this bit to indicate whether a matrix is tridiagonal. If it is, the bit would be set and we can store the values of nonzero elements in a dense array; their row and column indices can then be derived from the positions of values in this array. Such an approach can be generally applied for any particular structure of matrix nonzero elements.

In practice, we would likely store in memory also some additional information about a matrix, such as its dimensions or its number of nonzero elements. However, for large matrices such as those from our tested suite, this additional data require a negligible amount of memory, therefore we define a lower bound for a matrix memory footprint simply as  $MMF_{lb}(A, b) = nnz \times b$ .

Let

$$\Gamma_{\boxplus}^b(k) = \left( \min \{ MMF_{\boxplus}(A_k, s, h \times w, b) : s \in \mathcal{S}_6, h \times w \in \mathcal{B}_{64} \} / MMF_{lb}(A_k, b) - 1 \right) \times 100$$

and

$$\Gamma_{CSR32}^b(k) = \left( \frac{MMF_{CSR32}(A_k, b)}{MMF_{lb}(A_k, b)} - 1 \right) \times 100.$$

$\Gamma_{\boxplus}^b(k)$  thus expresses of how much percents is the memory footprint of  $A_k$  stored in an optimal blocking way higher than its lower bound. For comparison purposes, we define also a corresponding metric for the CSR32 format denoted by  $\Gamma_{CSR32}^b(k)$ .

The measured statistics of  $\Gamma_{\boxplus}^b(k)$  and  $\Gamma_{CSR32}^b(k)$  for the tested matrices are shown in Table VIII. Memory footprints of partitioned sparse matrices were obviously much closer to the lower bounds than memory footprints of matrices stored in CSR32; namely, 5 times closer in average and 2 times in worst cases. Moreover, in best cases, partitioned matrices almost reached their lower-bound memory footprints. For instance, in double precision, 7, 26, and 120 matrices out of 563 provided memory footprints up to 1, 2, and 5 percents above their lower bounds, respectively.

#### IV. CONCLUSIONS

Within this study, we analyzed memory footprints of 563 representative sparse matrices with respect to their partitioning into uniformly sized blocks. We considered different block sizes and different ways of storing blocks in a computer memory. The obtained results led us to the following conclusions:

TABLE VIII: Statistics of  $\Gamma_{\boxplus}^b(k)$  and  $\Gamma_{CSR32}^b(k)$  (in percents) for the tested matrices.

Statistics	Single precision		Double precision	
	Blk.-opt.	CSR32	Blk.-opt.	CSR32
Minimum	0.63	100.02	0.31	50.01
Average	21.85	111.03	10.93	55.51
Maximum	71.31	152.39	35.66	76.19

- 1) Partitioning of sparse matrices substantially reduces memory footprints of sparse matrices when compared to the most-commonly used storage format CSR32. The average observed memory savings in case of single and double precision were 42.3 and 28.7 percents of memory space, respectively. The corresponding worst-case savings were 25.5 and 17.1 percents.
- 2) Partitioning of sparse matrices provides memory footprints much closer to their lower bounds than CSR32. In average, the measured memory footprints for optimal blocking configurations were of only 21.9 and 10.9 percents higher than the lower bounds, while the corresponding memory footprints for CSR32 were higher of 111.0 and 55.5 percents. Moreover, the memory footprints of matrices most suitable for block processing approach the lower bounds; the amount of memory required for storing information about the structure of nonzero elements of such matrices is relatively negligible.
- 3) For minimization of memory footprints of partitioned sparse matrices in general, we cannot consider only a single format for storing blocks. Instead, we need to choose a format according to the structure of matrix nonzero elements either for all its blocks collectively (min-fixed scheme) or for each block separately (adaptive scheme). The latter approach mostly yields lower memory footprints.
- 4) For minimization of memory footprints of partitioned sparse matrices in general, we cannot consider only a single block size. However, we can substantially reduce the set of block sizes in the optimization space and still obtain memory footprints close to their optima. In average, the measured memory footprints for the proposed reduced sets of block sizes  $\mathcal{B}_{20}$ ,  $\mathcal{B}_{14}$ , and  $\mathcal{B}_8$  and the min-fixed/adaptive schemes were at most of only 1.51 percents higher than the optimal values. Even considering square blocks only is thus generally sufficient for minimization of memory footprints of sparse matrices. However, there exist matrices for which the corresponding metrics are significantly higher and are inversely proportional to the number of tested block sizes. One should thus be aware of whether or not his/her matrices fall into this category and if yes, he/she might consider using larger sets of block sizes.

Our findings are encouraging since they show that memory footprints of partitioned sparse matrices can be substantially

reduced even when a relatively small block preprocessing optimization space is considered. Whether or not will such a reduction pay off in practice depends first of all on the objective one wants to achieve. A big challenge is to improve the performance of memory-bounded sparse matrix operations due to the reduction of memory footprints of matrices. Within our future work, we plan to face this problem at least partially—we will focus on the development of scalable efficient block preprocessing and SpMV algorithms for the min-fixed and adaptive blocking storage schemes, and we will evaluate them experimentally on mainstream HPC architectures.

**Abstract**—A challenging task in numerical programming modern computer systems is to effectively exploit the parallelism available in the architecture and manage the CPU caches to increase performance. Loop nest tiling allows for both coarsening parallel code and improving code locality. In this paper, we explore a new way to generate tiled code and derive the free schedule of tiles by means of the transitive closure of loop nest dependence graphs. Multi-threaded code executes tiles as soon as their operands are available. To design the approach, loop dependences are presented in the form of tuple relations. Discussed techniques are implemented in the source-to-source TRACO compiler. Experimental study, carried out on multi-core architectures, demonstrates the considerable speed-up of tiled numerical codes generated by the presented approach.

## I. INTRODUCTION

ON MODERN architectures, the cost of moving data from main memory can be higher than the cost of computation. This disparity between communication and computation prompts that designing algorithms for better locality and parallelism exploiting even with simple memory models is a challenging task. Loop nest tiling allows for both coarsening parallel code and improving its locality that leads to increasing parallel code performance.

Widely known tiling techniques use the polyhedral model and affine transformations of program loop nests [1], [2], [3], [4], [5]. State-of-the-art automatic parallelizers, such as PLuTo [1], have provided empirical confirmation of the success of polyhedral-based optimization.

Techniques based on the polyhedral model and affine transformations include the following three steps: i) program analysis aimed at translating high level codes with data dependence analysis to their polyhedral representation, ii) program transformation with the aim of improving program locality and/or parallelization, iii) code generation [1].

To implement the second step of the approach mentioned above, PLuTo and similar optimizing compilers apply the affine transformation framework (ATF), which has demonstrated considerable achievement in obtaining high performance parallel codes. However, this framework is not able to parallelize some classes of serial code.

Wonnacott and Strout outlined limitations of tiling transformations that have been released in tools like PLuTo [6]. Techniques involve pipelined execution of tiles, which prevents full concurrency from the start and do not allow full scaling.

Nevertheless, there are known some attempts to enhance the power of ATF. In paper [7], tiling for dynamic scheduling is discussed. Wonnacott et al. [8] introduce the definition of mostly-tileable loop nests for which classic tiling is prevented by an asymptotically insignificant number of iterations.

Our research is concerned with alternative approaches that allow us to tile bands of non-permutable loops [9] and find parallelism when affine solutions miss it. These algorithms are implemented in the source-to-source compiler, TRACO<sup>1</sup>.

TRACO realizes all the three steps of the approach mentioned above. However, the tool does not find and use any affine function in the second step to transform the loop nest. TRACO is based on the idea of the Iteration Space Slicing Framework introduced by Pugh and Rosser [10] and applies the transitive closure of a program dependence graph to extract independent subspaces in the original loop nest iteration space.

In paper [11], we proposed a technique to find the tile free schedule<sup>2</sup> adopting parallelization based on the power  $k$  of relation  $R$ ,  $R^k$ . Unfortunately, when relation  $R^k$  cannot be calculated exactly, the value of  $k$  in the  $R^k$  constraints is usually unbounded and valid code generation is impossible. It is worth to mention that computing exact  $R^k$  guarantees computing exact  $R^+$ , but not vice versa [12].

In this paper, we show how this limitation can be overcome by means of applying positive transitive closure,  $R^+$ , and transitive closure,  $R^*$ , (instead of the power  $k$  of relation  $R$ ,  $R^k$ ) to form the free schedule of valid tiles. The proposed approach generates parallel tiled code even when producing a band of fully permutable loops with ATF is not possible. We present the performance of eight real-life parallel tiled numerical programs generated by TRACO and executed on modern multi-core processors and co-processors.

## II. BACKGROUND

The polyhedral model is a mathematical formalism for analyzing and transforming program loop nests whose all bounds and all conditions are affine expressions in the loop iterators and symbolic constants called parameters [13]. Loop transformations based on transitive closure [9], [10], [14] are mainly focused on representation and manipulation of sets and relations. A set contains integer tuples that satisfy some

<sup>1</sup>traco.sourceforge.net

<sup>2</sup>tiles are executed as soon as it is possible (their operands are available)

Presburger formula built from affine constraints, conjunctions (and,  $\wedge$ ), disjunctions (or,  $\vee$ ), projections (exists,  $\exists$ ) and negations (not,  $\neg$ ). Relations are defined in a similar way, except that the single space is replaced by a pair of spaces separated by the arrow sign “ $\rightarrow$ ”, see paper [12].

The considered approach uses an exact dependence analysis [15] which returns dependences in the form of relations. The pairs of input and output spaces represent loop statement instances corresponding to data dependence sources and destinations, respectively.

Basic operations on sets and relations include intersection ( $\cap$ ), union ( $\cup$ ), difference ( $-$ ), composition ( $\circ$ ), domain ( $\text{dom}$ ), range ( $\text{ran}$ ), relation application ( $R(S)$ ). Manual [12] describes the operations in detail.

In the sequential loop nest, the iteration  $i$  executes before  $j$  if  $i$  is *lexicographically less* than  $j$ , denoted as

$$i \prec j, \text{ i.e., } i_1 < j_1 \vee \exists k \geq 1 : i_k < j_k \wedge i_t = j_t, \text{ for } t < k.$$

The positive transitive closure of a lexicographically forward relation  $R$ ,  $R^+$ , is defined as follows [16]:

$$R^+ = \{e \rightarrow e' : e \rightarrow e' \in R \vee \exists e'' \text{ s.t. } e \rightarrow e'' \in R \wedge e'' \rightarrow e' \in R^+\}.$$

It describes which vertices  $e'$  in a dependence graph (represented by relation  $R$ ) are connected directly or transitively with vertex  $e$ . Transitive closure,  $R^*$ , additionally includes the identity relation,  $I = \{e \rightarrow e\}$ .

An *ultimate dependence source* is a source that is not the destination of another dependence. Set,  $UDS$ , comprising all ultimate dependence sources, can be found as  $\text{domain}(R) - \text{range}(R)$ , where  $R$  represents all loop nest dependences.

Let  $IS$  be a polytope representing the loop nest iteration space while the tuple  $(IS, E)$  represents a dependence graph, where  $E$  is the set of edges defining dependences. The function  $t : IS \rightarrow \mathbb{Z}$ , which assigns time execution to each loop nest statement instance, is called a valid schedule if it preserves all data dependences:  $(\forall x, x' : x, x' \in IS \wedge (x, x') \in T : t(x) < t(x'))$  [17]. The schedule that maps every  $x \in IS$  onto the first possible time allowed by the dependences is called the free schedule.

### III. FREE SCHEDULING ALGORITHM

We use the technique, presented in paper [14], to extract fine-grained parallelism based on the free schedule which represents unique time partitions; statement instances within a time partition are independent. Let us remind the idea of that approach. First, we calculate relation,  $R'$ , by inserting variables  $k$  and  $k+1$  into the first position of the input and output tuples of relation  $R$  which is the union of all dependence relations. Variable  $k$  defines execution time for each partition including a set of independent statement instances. Next, we find the transitive closure of relation  $R'$ ,  $R'^*$ , and form the following relation

$$FS = \{[X] \rightarrow [k, Y] : X \in UDS(R) \wedge (k, Y) \in \text{Range}((R')^* \setminus \{[0, X]\}) \wedge \neg(\exists k' > k \text{ s.t. } (k', Y) \in \text{Range}((R')^* \setminus \{[0, X]\}))\},$$

where  $(R')^* \setminus \{[0, X]\}$  defines the domain of relation  $R'^*$  restricted to the set including only ultimate dependences

sources (the first time partition); the constraint  $\neg(\exists k' > k \text{ s.t. } (k', Y) \in \text{Range}((R')^* \setminus \{[0, X]\}))$  guarantees that partition  $k$  includes only those statement instances whose operands are available, and each statement instance belongs to only one time partition [14].

The first element of the tuple of the set  $\text{Range}(FS)$  points out the time of partition execution. Parallel code that visits each element of the set  $\text{Range}(FS)$  in lexicographical order can be obtained by applying any well-known code generator, for example, [18], [19]. The outermost sequential loop of such code scans the values of variable  $k$  (representing the time of partition execution) while inner parallel loops scan independent instances of partition  $k$ .

### IV. THE LOOP NEST TILING ALGORITHM

To improve code locality, we apply loop tiling. In paper [9], we demonstrated how to generate valid tiled code using the transitive closure of dependence graphs. That approach envisages forming the following sets:

- $TILE(\mathbf{II}, \mathbf{B})$  includes iterations belonging to a parametric tile:  $TILE(\mathbf{II}, \mathbf{B}) = \{[I] \mid \mathbf{B}^* \mathbf{II} + \mathbf{LB} \leq \mathbf{I} \leq \min(\mathbf{B}^*(\mathbf{II} + 1) + \mathbf{LB} - 1, \mathbf{UB}) \wedge \mathbf{II} \geq 0\}$ , where vectors  $\mathbf{LB}$  and  $\mathbf{UB}$  include the lower and upper loop index bounds of the loop nest, respectively; matrix  $\mathbf{B}$  defines the size of original tiles; elements of vector  $\mathbf{I}$  represent the statement instances contained in the tile whose identifier is  $\mathbf{II}$ ;  $\mathbf{1}$  is the vector whose all elements have value 1,<sup>3</sup>
- $TILE\_LT(GT)$  are the unions of all the tiles whose identifiers are lexicographically less (greater) than that of  $TILE(\mathbf{II}, \mathbf{B})$ :  $TILE\_LT(GT) = \{[I] \mid \exists \mathbf{II}' \text{ s.t. } \mathbf{II}' \prec (\succ) \mathbf{II} \wedge \mathbf{II} \geq 0 \wedge \mathbf{B}^* \mathbf{II}' + \mathbf{LB} \leq \mathbf{UB} \wedge \mathbf{II}' \geq 0 \text{ and } \mathbf{B}^* \mathbf{II}' + \mathbf{LB} \leq \mathbf{UB} \wedge \mathbf{I} \text{ in } TILE(\mathbf{II}', \mathbf{B})\}$ ,<sup>4</sup>
- $II\_SET = \{[\mathbf{II}] \mid \mathbf{II} \geq 0 \wedge \mathbf{B}^* \mathbf{II} + \mathbf{LB} \leq \mathbf{UB}\}$  represents all tile identifiers,
- $TILE\_ITR = TILE - R^+(TILE\_GT)$  does not include any invalid dependence target, i.e., it does not include any dependence target whose source is within set  $TILE\_GT$ ,
- $TVLD\_LT = (R^+(TILE\_ITR) \cap TILE\_LT) - R^+(TILE\_GT)$  includes all the statement instances that i) belong to the tiles whose identifiers are lexicographically less than that of set  $TILE\_ITR$ , ii) are the targets of the dependences whose sources are contained in set  $TILE\_ITR$ , and iii) are not any target of a dependence whose source belong to set  $TILE\_GT$ ,
- $TILE\_VLD = TILE\_ITR \cup TVLD\_LT$  defines target tiles,
- $TILE\_VLD\_EXT$  is built by means of inserting i) into the first positions of the tuple of set  $TILE\_VLD$  elements of vector  $\mathbf{II}$ :  $ii_1, ii_2, \dots, ii_d$ ; ii) into the constraints of set  $TILE\_VLD$  the constraints defining tile identifiers  $\mathbf{II} \geq 0$  and  $\mathbf{B}^* \mathbf{II} + \mathbf{LB} \leq \mathbf{UB}$ . This set represents valid target tiles. To scan their elements in lexicographic order, we

<sup>3</sup>The notation  $x \geq (\leq) y$  where  $x, y$  are two vectors in  $\mathbb{Z}^n$  corresponds to the component-wise inequality, that is,  $x \geq (\leq) y \iff x_i \geq (\leq) y_i, i=1,2,\dots,n$ .

<sup>4</sup>“ $\prec$ ” and “ $\succ$ ” denote the lexicographical relation operators for two vectors,

can apply any code generator, for example, CLooG [18] or the isl AST generator [19].

## V. THE FREE SCHEDULE OF TARGET TILES

The approach, presented in this paper, combines the approaches presented in the two previous sections. We generate valid tiles and next apply the free schedule for those tiles. For this purpose, relation,  $R\_TILE$ , is computed which describes dependences among generated tiles but ignores dependences within each tile as follows

$R\_TILE := \{[II] \rightarrow [JJ]: \exists I, J \text{ s.t. } J \in R(I) \wedge (II, I) \in TILE\_VLD\_EXT(II) \wedge (JJ, J) \in TILE\_VLD\_EXT(JJ)\}$ , where  $II, JJ$  are the vectors representing tile identifiers; vectors  $I, J$  comprise the statement instances belonging to the tiles whose identifiers are  $II, JJ$ , respectively.

Next, we calculate relation,  $R\_TILE'$ , by inserting variables  $k$  and  $k+1$  into the first position of the input and output tuples of relation  $R\_TILE$ , respectively. In the following steps, we calculate the transitive closure of this relation and form set,  $UDS\_TILE$ , including the tile identifiers which are not dependence destinations.

We use sets  $R\_TILE'$  and  $UDS\_TILE$  to calculate relation,  $FS$ . Then, we form the free schedule for generated target tiles. Finally, we generate code scanning statement instances within the set  $Range(FS)$  in lexicographical order.

Algorithm 1 presents the discussed above approach in details. The proof of its correctness is presented in papers [9], [14].

## VI. EXPERIMENTAL STUDY

To evaluate the performance of tiled code generated by means of Algorithm 1, we have considered the following eight numerical polyhedral programs<sup>5</sup>:

- *floyd* - Floyd-Warshalls all-pairs shortest-paths from PolyBench/C<sup>6</sup>,
- *trmm* - Triangular matrix-multiply from PolyBench/C,
- *k23* - 2-D implicit hydrodynamics fragment from Livermore Loops<sup>7</sup>,
- *wz* - WZ factorization: dense, square, non-structured matrix factorization algorithm [20],
- *edge\_detect* - 2D-convolution routine to expose edge information from the UTDSP Benchmark suite<sup>8</sup>,
- *trisolv* - Triangular solver from PolyBench/C,
- *corcol*, *covcol* - Correlation and Covariance Computations, data-mining programs from PolyBench/C.

The programs *floyd*, *wz*, and *k23* cannot be parallelized by the algorithm based on the power  $k$  of relations  $R, R^k$  [11] because ISL returns only an approximation of  $R^k$ , where  $k$  is unbounded that prevents code generation – the number of time partitions is unbounded. Whereas, the transitive closure

### Algorithm 1: Parallel tiled code generation

**Input:** A loop nest and its all dependences represented with relation  $R$ ; diagonal matrix  $B$ , defining the size of rectangular original tiles.

**Output:** Code generated according to the free schedule of target tiles: tiles for each time partition are enumerated in parallel whereas statement instances in each tile are scanned serially.

**Method:**

- 1) Calculate sets  $II\_SET$ ,  $TILE\_VLD$ , and  $TILE\_VLD\_EXT$  according to the loop nest tiling algorithm [9].
- 2) Form relation  $R\_TILE$  and transform it into relation  $R\_TILE'$  as follows  
 $R\_TILE' := \{[k, II] \rightarrow [k+1, JJ]: \exists I, J \text{ s.t. } (II, I) \in TILE\_VLD\_EXT(II) \wedge (JJ, J) \in TILE\_VLD\_EXT(JJ) \wedge J \in R(I) \text{ AND } k \geq 0\}$ ,  
 where  $II, JJ$  are the vectors representing tile identifiers.
- 3) Calculate set,  $UDS\_TILE$ , as follows  
 $UDS\_TILE := II\_SET - \text{range}(R\_TILE)$ .
- 4) Form the following relation  
 $FS = \{[X] \rightarrow [k, Y] : X \in UDS\_TILE \wedge (k, Y) \in \text{Range}(R\_TILE')^* \setminus \{[0, X]\} \wedge \neg(\exists k' > k \text{ s.t. } (k', Y) \in \text{Range}(R\_TILE')^+ \setminus \{[0, X]\})\}$ ,  
 where the first element of the second tuple is a parameter  $k$  defining time under the free schedule while the next elements (represented with  $Y$ ) identify tiles.
- 5) Calculate the set  $\text{Range}(FS)$  and extend this set by inserting in its last tuple positions the elements of the tuple of set  $TILE\_VLD$ , returned by step 1, and insert the constraints of set  $TILE\_VLD$  into the constraints of set  $\text{Range}(FS)$ .
- 6) Apply to the set, returned by step 5, CLooG [18] or the isl code generator [19], and postprocess the code to a compilable form of the following structure:

```
seqfor // enumerating time partitions
parfor // enumerating tile identifiers
  // for a given time partition
  seqfor // enumerating statement instances within
    // the tiles whose identifiers are
    // defined by the previous parfor loop
```

Fig. 1. Speed-up of tiled programs executed on Intel Xeon E5-2695

<sup>5</sup>Source and target codes of the examined programs are available in the repository <https://sourceforge.net/p/traco/code/HEAD/tree/>

<sup>6</sup><http://web.cse.ohio-state.edu/~pouchet/software/polybench/>

<sup>7</sup><http://www.netlib.org/benchmark/livermore>

<sup>8</sup><http://www.eecg.toronto.edu/~corinna/DSP/infrastructure/UTDSP.html>

Fig. 2. Speed-up of tiled programs executed on Intel Xeon Phi 7120P

of  $R\_TILE'$  can be calculated exactly for those programs as well as for the rest of the examined loop nests.

To carry out experiments, we have used a computer with the following features: Intel Xeon CPU E5-2695 v2, 2.40GHz, 12 cores, 24 Threads, 30 MB Cache, 16 GB RAM. We examined parallel code performance using also a coprocessor Intel Xeon Phi 7120P (16GB, 1.238 GHz, 61 cores, 30.5 MB Cache). Programs were compiled with the Intel C Compiler (icc 15.0.2) and optimized at the  $-O3$  level.

Figures 1 and 2 depict the speed-up of the programs executed on Xeon E5-2695 v2 and Xeon Phi 7120P cores, respectively. The speedup,  $S=T(1)/T(P)$ , is defined as the ratio of the time of an original program execution to that of the corresponding parallel tiled one on  $P$  processors. The baseline  $S=1$  presents the speed-up equal to 1.

Analyzing the results, we may conclude that for the studied programs, performance improvement is achieved by means of the presented algorithm. For some programs due to considerable increasing program locality super-linear speed-up is observed.

## VII. CONCLUSION

In this paper, we presented a novel approach based on the transitive closure of dependence graphs to form tiles and their free schedule. The algorithm was implemented in the open source TRACO compiler. Experiments demonstrated that the speed up of examined parallel numerical codes generated by the approach can be achieved on shared memory machines with multi-core processors. The usage of the free schedule of tiles instead of that of loop nest statement instances improves memory utilization and allows us to adjust the parallelism grain-size to match the inter-processor communication capabilities of the target architecture.

In future, we plan to study parametric tiling based on transitive closure aimed at generating more flexible code for affine loop nests in numerical programs.

**Abstract**—This work presents a new parallel non-speculative implementation of the Unordered Reverse Cuthill-McKee algorithm. Reordering quality (bandwidth reduction) and reordering performance (CPU time) are evaluated in comparison with a serial implementation of the algorithm made available by the state-of-the-art mathematical software library HSL. The bandwidth reductions reached by our parallel RCM were more than 90% for several large matrices out of the ones tested, and the time reordering improvement was up to 57.82%. Speedups higher than 3.0X were achieved with the parallel RCM. The underlying parallelism was supported by the OpenMP framework and three strategies for reducing idle threads were incorporated into the algorithm.

## I. INTRODUCTION

COMPUTATION involving sparse matrices have been of widespread use since the 1950s, and its application includes electrical networks and power distribution, structural engineering, reactor diffusion, and, in general, solutions to partial differential equations [1]. The typical way to solve such equations is to discretize them, i.e., to approximate them by equations that involve a finite number of unknowns. The linear systems that arise from these discretizations are of the type  $Ax = b$ , in which  $A$  is a large and sparse matrix, that is, it has very few nonzero entries.

In order to simplify the solution of this type of system, the bandwidth minimization plays an efficient role. This preprocessing method consists of finding a permutation of rows and columns of a matrix which ensures that nonzero elements are located in as narrow a band as possible along the main diagonal. The sparsity of the matrix is not changed by permutations. In this way, let  $A$  be a structurally symmetric matrix, i. e., if  $a_{ij} \neq 0$  then  $a_{ji} \neq 0$ , but not necessarily  $a_{ij} = a_{ji}$ , whose diagonal elements are all non-zero. The bandwidth of  $A$  denoted by  $\beta(A)$  is defined as the greatest distance from the first nonzero element to the diagonal, considering all rows of the matrix [1]. More formally, for the  $i^{th}$  row of  $A$ ,  $i = 1, 2, \dots, n$ , let  $f_i(A) = \min\{j \mid a_{ij} \neq 0\}$ , and  $b_i(A) = i - f_i(A)$ . So,  $\beta(A) = \max_{i=2,3,\dots,n} \{b_i(A)\}$ .

Since Papadimitrou [2] proved that the bandwidth minimization problem is NP-complete, several heuristic algorithms have been presented in the literature aiming to find good

quality solutions as fast as possible. An important class of these algorithms treats a matrix bandwidth reduction under the perspective of a graph labeling problem. In this way, reordering a sparse matrix is considered a problem of labeling the vertices of the corresponding graph in such way that closest labels are assigned to most linked vertices.

The Reverse Cuthill-McKee (RCM) is a traditional heuristic for the bandwidth reduction problem. It was originally presented by [3], and a performance modification for it was proposed by [4] posteriorly. The approach based on looking into a corresponding graph structure is also explored by several other algorithms. Some of the most often referred for the bandwidth minimization problem are Sloan [5] and GPS [6]. They are also able to provide quality solutions in an efficient way.

Classically, algorithms like the aforementioned implement the matrix reordering in a serial way. Nevertheless, the advances toward the massive use of multi-core processors on scientific computation has leveraged significant performance improvements related to the solution of sparse matrices problems. In this context, in 2014 [7] described the first parallelization of the RCM algorithm, which was based on the speculative parallel model. In this parallelism model, a runtime system detects dependence violations between concurrent computations and rolls back conflicting computations as needed [8]. As the RCM is organized around a graph, which is implemented as a pointer-based data structure, it is considered as an irregular algorithm [9]. Algorithms of this type exhibit a complex pattern of parallelism which must be found and exploited at runtime [10]. To explore this kind of parallelism and to reduce the programming burden, [7] use the Galois system [11] which gives support to the speculative parallelism.

Making use of another parallel model, this paper proposes a non-speculative OpenMP-based implementation of the Unordered Parallel RCM algorithm presented by Karantasis et al. [7]. This implementation strategy was considered once the non-speculative parallel model is the traditional manner to speedup every type of algorithm, and the OpenMP [12] framework for parallelism is widely used in industry as well as in academia. To reach an efficient non-speculative parallelization

of the RCM, three optimizations for reducing idle threads were incorporated into the implemented algorithm. The performance evaluation of the Unordered RCM algorithm was against the HSL [13], a state-of-the-art mathematical software library that contains a collection of Fortran codes for large-scale scientific computations.

The outline of the paper is as follow. In the next section, an efficient sparse matrix storage format is described. Section III is dedicated to detailing an auxiliary parallel algorithm implemented for pseudo-peripheral nodes finding. The Unordered Parallel RCM algorithm is presented in the subsequent section, as well as the optimizations proposed by this work. In Section V, all tests and achieved results are described. Conclusions and future works are addressed in Section VI.

## II. OPTIMIZED STORAGE FORMAT

In many scientific computations, the manipulation of sparse matrices is considered the crux of the design. Generally, the nonzero elements in a sparse matrix constitute a very small percentage of data. This irregular nature of sparse matrix problems has led to the development of a variety of compressed storage formats. The Compressed Sparse Row (CSR) used in this work is an important sparse matrix storage method which has been widely applied in most sources [1]. Storing a given matrix  $A$  with a CSR scheme requires three one-dimensional arrays AA, JA and IA of length  $nnz$ ,  $nnz$ , and  $n+1$  respectively, where  $n$  is the number of rows and  $nnz$  is the total number of nonzero elements in the matrix  $A$  [14]. The content of each array is as follow. Figure 1 illustrates this technique.

- **Array AA:** contains the nonzero elements of  $A$  stored row-by-row.
- **Array JA:** contains the column indexes in the matrix  $A$  which correspond to the nonzero elements in the array AA.
- **Vector IA:** contains  $n+1$  pointers which delimit the rows of nonzero elements in the array AA. The last position of the vector stores the number of nonzero elements of the matrix plus one.

$$A = \begin{bmatrix} 1 & 1 & 5 & 0 & 0 \\ 3 & 4 & 0 & 0 & 0 \\ 6 & 0 & 7 & 8 & 9 \\ 0 & 0 & 3 & 6 & 0 \\ 0 & 0 & 2 & 0 & 5 \end{bmatrix}$$

AA	1	1	5	3	4	6	7	8	9	3	6	2	5
JA	1	2	3	1	2	1	3	4	5	3	4	3	5
IA	1	4	6	10	12	14							

Fig. 1: Example of a matrix  $A$  represented in CSR format.

## III. PARALLEL PSEUDO-PERIPHERAL NODE FINDING

Empirical data show that the quality of reordering algorithms are highly influenced by the nodes chosen as the source for Breadth-First Search (BFS) and RCM algorithms [15]. Often, a heuristic is used for this purpose. Thus, considering  $d(x, y)$  the distance between vertices  $x$  and  $y$  in a graph  $G$ , i.e., the length of the shortest path between  $x$  and  $y$ , the graph diameter is defined as  $\delta(G) = \max\{d(x, y) | x, y \in \text{vertices of } G\}$ . Then, ideally, one of two nodes in a pair  $(x, y)$  that achieves the diameter, denoted as peripheral nodes, can be used as a starting point. However, these nodes are expensive to determine. Instead, a pseudo-peripheral node, which has approximately the greatest distance from each other in the graph, is picked up as source node for constructing the level set structure<sup>1</sup> of these algorithms.

Moreover, the nodes choice strategy employed in order to select ones to be expanded at each search level also impacts significantly on the reordering quality. In this work, the pseudo-peripheral node finding heuristic described by [16] was implemented for the RCM algorithm. The pseudo-code is presented in Algorithm 1.

---

### Algorithm 1 Parallel Pseudo-Diameter Algorithm

---

**Input:** Graph  $g$ , ShrinkingStrategy strategy, float CHUNK

**Output:** Node start, Node end

```

1: BFS forwardBFS, reverseBFS;
2: GraphDiameter diameter;
3: diameter.start = graph.vertexOfMinimunDegree();
4: diameter.end = -1; {
5: forwardBFS = Parallel_BFS(g, diameter.start, CHUNK);
6: int localDiameter = forwardBFS.height();
7: List candSet = forwardBFS.verticesAt(localDiameter);
8: candSet = strategy.shrink(candSet);
9: int minWidth = MAX_INT;
10: foreach (Node candidate : candSet) {
11:     reverseBFS = Parallel_BFS(g, candidate, CHUNK);
12:     if (reverseBFS.width < minWidth) {
13:         if (reverseBFS.height > localDiameter) {
14:             diameter.start = candidate;
15:             diameter.end = -1;
16:             break;
17:         }
18:         minWidth = reverseBFS.width;
19:         diameter.end = candidate;
20:     } } }
21:
22: } while (diameter.end == -1);
23: if (forwardBFS.width > reverseBFS.width)
24:     return (diameter.end, diameter.start);
25: return (diameter.start, diameter.end);

```

---

<sup>1</sup>A level set structure of a graph is defined recursively as the set of all unmarked neighbors of all nodes of a previous level set. Initially, a level set consists of one node.

The pseudo-diameter computation uses two BFS engines (line 1). The *forwardBFS* always uses the current start vertex as root. The *reverseBFS* variable uses candidates for the end vertex as root. Initially, the start node is chosen to be any vertex of smallest degree (line 3) and the end node is unknown (line 4). Next, the algorithm enters the main outer loop which does not exit until a suitable end node has been determined and all candidates have been exhausted. For each iteration of the outer loop, a forward breadth-first search (line 6) is performed, the current diameter is set as the height of the level structure, and the list of all vertices that are in the farthest level set (*candSet*) is gotten (line 8).

According to [16], the most important optimization incorporated by this algorithm is the shrinking strategy (line 9). Instead of performing a reverse breadth-first search on all vertices that are farthest away from the start vertex, it is much faster to only try a selected subset. For this work, the heuristic of choosing a single vertex of each degree was adopted [17].

Therefore, after applying a shrinking strategy, the list of candidate nodes is processed. For each candidate for end vertex in candidate list (line 11), a reverse breadth-first search is done. As the aim is to find out the candidate whose reverse breadth-first search has the minimum width, so a local variable *minWidth* is initialized to an arbitrarily large number (line 10). If it is found a candidate that has a narrower level structure than the forward breadth-first search, then this candidate vertex is promoted to the new start vertex (line 15) and the algorithm is restarted. The *break* in line 17 affects only the inner loop (lines 11-21) and jumps to the line 36. Since *diameter.end* is still undetermined, the outer loop (lines 5-21) starts a new iteration. If the reverse breadth-first search is narrower than the most narrow reverse breadth-first search so far (line 18), then a new minimum width has been found (line 19), and the candidate is chosen as the end vertex (line 20).

It is important to observe that the main computation to calculate the pseudo-diameter is performing multiple BFS (lines 5 and 11). In this work, the Unordered Parallel BFS (Algorithm 2) presented in the next section is used as a way to parallelize this essential step of the pseudo-peripheral node finding algorithm. The other steps of this algorithm are executed sequentially.

#### IV. UNORDERED PARALLEL RCM ALGORITHM

The serial Cuthill-McKee algorithm [3] is based on a BFS strategy, in which the graph is traversed by level sets. As soon as a level set is traversed, its nodes are marked and numbered. The neighbors of each of these nodes are then inspected. Each time, a neighbor of a visited vertex that is not numbered is encountered, it is added to a list and labeled as the next element of the next level set. The order in which each level itself is traversed gives rise to different orderings or permutations of rows and columns. In the Cuthill-McKee ordering, the nodes adjacent to a visited node are always traversed from the lowest to the highest degree [1]. However, in 1971, the Reverse Cuthill-McKee algorithm was presented

by [4]. It was empirically observed that reversing the Cuthill-McKee ordering yields a better permutation scheme for matrix reordering problems.

The Unordered Parallel RCM proposed by [7] is based on the construction of a level structure, and an RCM-valid permutation is built after a complete level structure is computed. The four major algorithms steps are presented and detailed in the next sections.

##### A. Unordered Breadth-First Search (Step 1)

Algorithm 2 presents the non-speculative Unordered BFS including three proposed optimizations. The key aspect of the approach in which the algorithm is based on relates the level of a node with a local minimum in the graph. In fact, excepting the root, the level value of a node corresponds to the highest level among neighbors added of one [18]. Thus, the level computation for a node  $n$  may be described as a fixpoint system<sup>2</sup>:

$$\begin{cases} \textbf{Initialization:} \\ \text{level}(\text{root}) = 0; \quad \text{level}(k) = \infty, \quad \forall k \text{ other than } \text{root}; \\ \textbf{Fixed Point Iteration:} \\ \text{level}(n) = \min(\text{level}(m) + 1), \quad \forall m \in \text{neighbors of } n. \end{cases}$$

In order to explore this feature, an unordered worklist (*wl*) structure must be maintained by the algorithm. A structure of this type makes possible any node to be picked up. Thereafter, the algorithm is able to process several nodes in parallel. As the iteration over the main worklist (*wl*) do not have a strict order, it may happen that a node is temporarily assigned a level that is higher than the final value. However, the level will monotonically decrease until it reaches the correct value (a fixed point). This step of repeatedly taking a closest known vertex  $u$  and testing if  $\text{level}[v] \leq \text{level}[u] + 1$  for all of its  $v$  neighbors (lines 19-25), is called node relaxation, which relaxes constraints on the shortest path between two nodes. Particularly, the absence of order in the node iteration and the fact that nodes can be relaxed many times characterize a chaotic relaxation [20].

Fig. 2: Fixed Point Iteration Example.

Figure 2 describes an example of the chaotic relaxation process executed by speculative BFS. At the step (i), the root  $r$

<sup>2</sup>A fixed point iteration  $x^{(k+1)} := f(x^{(k)})$  yields a decreasing (increasing) monotonic sequence which converges to a fixed point  $x^*$  such that  $f(f(\dots f(x^*) \dots)) = f^n(x^*) = x^*$  [19].

**Algorithm 2** Parallel Unordered BFS Algorithm**Input:** Graph G, Node root, float CHUNK

```

1: Worklist wl =  $\emptyset$ ;
2: ENQUEUE(wl, root);
3: parallel while (wl  $\neq \emptyset \vee$  hasUnreachedNodes) {
4:   // Shifting head
5:   atomic {
6:     localHead = wl.head;
7:     localTail = wl.tail;
8:     sizeChunk = CHUNK * (localTail - localHead);
9:     wl.head += sizeChunk;
10:  }
11:  // Work Chunking
12:  Worklist localwl;
13:  while (localwl.size() < sizeChunk) {
14:    Node v = wl.dequeueAtPosition(localHead++);
15:    ENQUEUE(localwl, v);
16:  }
17:  // Fixed Point Iteration
18:  Workset relaxedwl;
19:  foreach (Node n: localwl) {
20:    int level = n.getLevel() + 1;
21:    foreach (Node v: G.neighbors(n)) {
22:      if (level < v.getLevel()) {
23:        atomic v.setLevel(level);
24:        ENQUEUE(relaxedwl, v);
25:      } } }
26:  // Relaxing nodes
27:  foreach (Node m: relaxedwl)
28:    atomic ENQUEUE(wl, m);
29: }

```

has been processed (colored black) and nodes  $a$  and  $b$  in gray are actives in the global list. In the intermediate step (ii), node  $b$  has randomly been selected from the global list. After the activation of node  $c$  by  $b$ , it has been picked up from the global list instead of the another possible active node  $a$ . Because of this unordered choice, the node  $d$  has become active and its level has temporarily been set as three. In the last step (iii), the last active node  $a$  has been selected from the global list and it has updated the level of its neighbor  $d$  with the correct value.

In this work, two optimizations suggested by Hassaan, Burtscher, and Pingali [18] (Work chunking and Wasted work reduction) and a new proposed one (Shifted head) were applied in the implemented Unordered BFS algorithm. Each implemented optimization is detailed below.

- 1) **Work chunking** (lines 12-16). To reduce the overhead of accessing the main worklist, it was adopted the strategy of making each thread able to remove a chunk of active elements from the worklist instead of just one element. In this way, a newly created worklist is cached locally by each thread, and after the entire local chunk is processed (fixed point iteration), a set of new activated

(relaxed) nodes is generated. This newest worklist is discharged into the main worklist by the respective thread. With this optimization, each synchronization is executed by a chunk of nodes rather than node by node.

- 2) **Wasted work reduction** (lines 14 and 28). It was implemented a strategy to reduce the time wasted by each waiting thread (idle threads) in which all threads remove active elements from one end of the worklist and add to the other. The concurrent access of each worklist end is managed by two distinct access lock. Naturally, this approach relaxes the strict order in which the worklist is processed. However, to ensure this strict order increases the access time of the worklist beyond the benefit of reducing the amount of wasted work.
- 3) **Shifted head** (lines 5-10). Aiming the reduction of the lock time spent by each thread, it was implemented an optimization in which the worklist head is shifted to the first position after the chunk size of the current thread. After this shifting, the access lock to the worklist head is released, and the thread starts the dequeue operation itself. Concomitantly, another different thread grabs the access lock and carries out a subsequent head shifting.

Such modifications led to the non-speculative parallel version of BFS algorithm (Algorithm 2). The parallelism begins at line 3 where threads are triggered. The shifted head optimization is carried out by the first atomic section of the algorithm (lines 5 to 10). Every time a thread reaches this region, it stores locally the current memory position of the head (*localHead*) and the tail (*localTail*) of the global main worklist *wl*. In turn, the global head is shifted *sizeChunk* positions. The next two stages of the algorithm, work chunking (lines 12-15) and fixed point iteration (lines 18-25), are executed concurrently by each thread. In fact, the cached locally worklist (*localwl*) makes possible the independent nodes processing in each scope of thread. In the second synchronization point of the algorithm (lines 27-28) there is no any dependence with the first one (shifting head). Because of this, the algorithm is able to reduce the idle time of threads.

Fig. 3: Multithreading FIFO queue.

Figure 3 describes an iteration of the implemented parallel BFS. At the execution point presented by the figure, a thread  $th_0$  has executed a shifting head and is carrying out the dequeue operation of all its corresponding nodes (red positions

$v_1, v_2, v_3$ ). At this moment, the access lock of the main worklist head has already released by  $th_0$  and, furthermore has already grabbed by  $th_1$ . Concomitantly, a thread  $th_2$  is executing the respective enqueueing of the nodes processed by it. It is important to notice that all three threads are performing their corresponding operations in a completely parallel way. The synchronization happens just when  $th_1$  must wait the shifting head executed by  $th_0$ .

### B. Counting Nodes by Level (Step 2)

Computing the number of nodes per level of a graph in a parallel way can be separated in three stages as described by the Algorithm 3 originally presented by [7].

---

#### Algorithm 3 Parallel Counting Nodes by Level Algorithm

---

**Input:** Graph G

**Output:** Array counts, int max\_level

```

1: foreach (Node n : G) {
2:   local_count[th_id][n.level]++;
3:   local_max[th_id] = max(local_max[th_id], n.level);
4: }
5: foreach (int id : threads) {
6:   max_level = max(max_level, local_max[id]);
7: }
8: foreach (int l : [0:max_level]) {
9:   foreach (int id : threads) {
10:    counts[l] += local_count[id][l];
11:   }
12: return [counts, max_level]

```

---

Fig. 4: Example of parallel counting nodes by level.

In the initial stage, all nodes of the graph are divided among the set of threads. Each thread counts locally how many nodes, from its respective subset of nodes, belong to each level. Moreover, a local maximum level is determined by each thread (lines 1-4). In the subsequent stage (lines 5-7), the global maximum level is computed through the comparison of each maximum local level of each thread. In the final stage (lines 8-10), as the number of levels of the graph is already computed, thus a range of levels is assigned to each thread that, in turn, counts how many nodes were computed by all threads in its

respective range. The result is stored in the global *counts* array.

Figure 4 describes an example of the parallel process of counting nodes per level. The respective level of each node is stored in the array of Figure 4(a). In Figure 4(b), a range of the levels is assigned to each one of three threads ( $th_1$ ,  $th_2$ ,  $th_3$ ) and the number of nodes by level is locally computed. The Figure 4(c) presents the final array as a result of the merge of each locally counting carried out by the threads.

### C. Prefix Sum (Step 3)

In this work, the Algorithm 4 was implemented for the prefix sum<sup>3</sup> calculus. It is based on the algorithm proposed by [21]. Initially, each thread computes the prefix sums of the  $\frac{n}{p}$  elements it has locally (lines 3-5). The total number of elements ( $n$ ) corresponds to the maximum level (*max\_level*) accounted for by the previous step of the Unordered RCM algorithm. The value  $p$  is related to the number of threads.

---

#### Algorithm 4 Parallel Prefix Sum Algorithm

---

**Input:** Array counts, int max\_level

**Output:** Array prefix\_sum

```

1: int num_changes = log2(threads.size());
2: int chunk = threads.size() / max_level;
3: for (int i = thId; i < thId + chunk; i++) {
4:   prefix_sum[i] = prefix_sum[i-1] + counts[i];
5: }
6: cPrefix[thId] = cTotal[thId] = prefix_sum[thId + chunk];
7: lPrefix[thId] = lTotal[thId] = prefix_sum[thId + chunk];
8: for (i = 0; i < num_changes - 1; i++) {
9:   thId' = thId ⊗ 2i;
10:  if (thId' < threads.size() ∧ thId' ≠ thId) {
11:    if (thId' < thId) {
12:      lPrefix[thId'] += cTotal[thId];
13:      lTotal[thId'] += cTotal[thId];
14:    } else
15:      lTotal[thId'] += cTotal[thId];
16:  }
17:  cPrefix[thId] = lPrefix[thId];
18:  cTotal[thId] = lTotal[thId];
19: } }
20: for (int i = thId; i < thId + chunk; i++)
21:   prefix_sum[i] += lPrefix[i];
22: return prefix_sum;

```

---

In the second phase of the algorithm, the last prefix sum of each thread is assigned to four arrays (lines 6-7) which are responsible for guiding the data exchanging process among the threads. In fact, the local prefix sum values are exchanged and each thread accumulates the respective received value (lines 8-19). The rule to determine a pair of threads that are going to communicate is through a XOR (exclusive OR, denoted by  $\otimes$ )

<sup>3</sup>The prefix sum operation takes a binary associative operator  $\oplus$ , and an ordered set of  $n$  elements  $[a_0, a_1, \dots, a_{n-1}]$  and returns the ordered set  $[a_0, (a_0 \oplus a_1), \dots, (a_0 \oplus a_1 \oplus \dots \oplus a_{n-1})]$ .

bitwise operation between the unique identifier of the sender thread and a constant related to the group of the receiver thread (line 9). Finally, each thread combines the result from the accumulated prefix sums with each local prefix sum initially computed (lines 20-21).

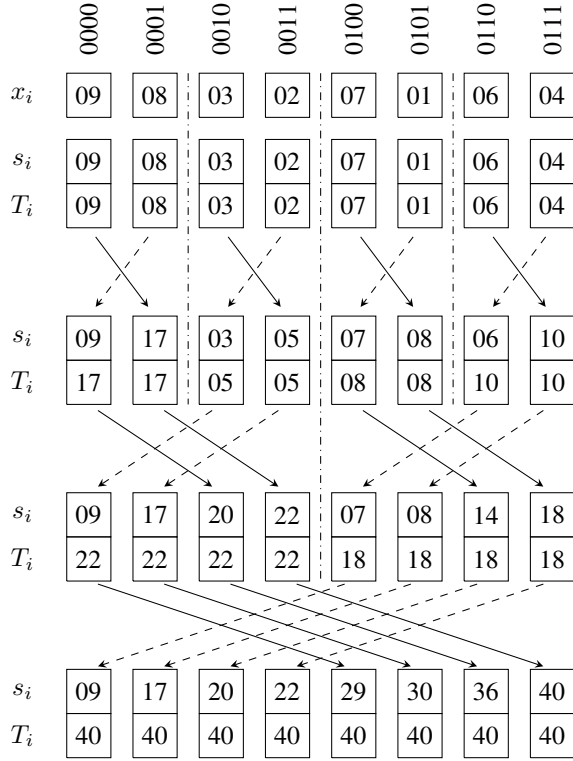

Fig. 5: Parallel prefix sum example.

Figure 5 presents an example of the implemented parallel prefix sum algorithm. The prefix sum is carried out by a set of eight threads (the unique identifier of each thread is shown in binary notation). The values indicated by  $x_i$  line correspond to the values initially assigned to each thread  $i = 1, \dots, 8$ . In the other words, the prefix sum is going to be executed on the ordered  $x_i$  set. Each line labeled with  $s_i$  is related to the prefix sum value stored by the thread  $i$ . The label  $T_i$  indicates the total sum value calculated by a thread  $i$ . The parallel prefix sum is executed in three phases of data exchanging. In the first one, threads are divided among groups of size two, and the data exchanging carries out inside each group. In the second and third phases, the group size is increased to four and eight respectively. When the unique identifier of a sender thread is lower than a receiver thread, both the values of local prefix sum and local total sum are updated. Otherwise, only the local prefix sum of the receiver thread is incremented.

#### D. Nodes Placement (Step 4)

The fourth step is described by the Algorithm 5. It was originally proposed by [7]. The underlying concept behind the operation of this phase is the pipelining of threads actions among the levels of the graph. For this, one thread is assigned

for each level, and the communication among them takes place in pairs: a thread responsible for a level  $l$  plays a producer (writer) role, while a thread assigned to the level  $l + 1$  acts as a data consumer (reader). Every read/write operation happens over the permutation array. The controller of this implemented producer/consumer paradigm is done through the prefix sum array ( $sums$ ) generated in the previous step. Two copies ( $read\_offset$  and  $write\_offset$ ) of this array are created (line 1) in order to control the number of nodes to read from a level, and the number of nodes to write from the next level. The original  $sums$  array is never changed once its values are used as bounds for threads operations.

The process starts assigning the source node to the first position of the permutation array. As there is a write operation related to the level 0, the corresponding position in  $write\_offset$  array is incremented (line 3). Thereafter, every time the  $read\_offset[l]$  is different of  $sums[l + 1]$  (line 6), the thread assigned to the level  $l$  becomes able to read the node from the permutation array at position  $read\_offset[l]$  (line 8). Actually, this condition indicates that there are  $sums[l + 1] - read\_offset[l]$  nodes whose children must be placed in the permutation array. In this way, the reading of each node at level  $l$  generates an increment of the  $read\_offset$  array at position  $l$  (line 9). Next, the respective thread gets the neighbors of the read node (line 10), sort them by degree (line 11), and place them in the permutation array (line 13). Each write operation produces an increment of the  $write\_offset$  array at position  $l + 1$  (line 14). Therefore, this pipeline makes possible the construction of the permutation array in a parallel way: while a thread writes the children nodes from a level  $l$  in the permutation array, another thread reads these ones in order to write the corresponding neighbors of them at level  $l + 1$  in the permutation array.

---

#### Algorithm 5 Parallel Nodes Placement Algorithm

---

**Input:** Graph G, Node source, int dist, Array sums

**Output:** Array perm

```

1: int read_offset = write_offset = sums;
2: int perm[0] = source;
3: write_offset[0] = 1;
4: foreach (int thread : threads) {
5:   for (int l = thread; l < dist; l += threads.size()) {
6:     while (read_offset[l] != sums[l + 1]) {
7:       while (read_offset[l] == write_offset[l]) { }
8:       Node n = perm[read_offset[l]];
9:       ++read_offset[l];
10:      children = G.neighborsAtLevel(n, level+1);
11:      sort(children); // Sort children by degree
12:      foreach (Node c : children) {
13:        perm[write_offset[l+1]] = c;
14:        ++write_offset[l+1];
15:      } } }

```

---

## V. EXPERIMENTAL RESULTS

The program was coded in the *C* language and the parallelism was supported by OpenMP framework - version 4.0. The experiments were performed on a PC running Ubuntu Linux, version 14.04.5 LTS, with Kernel version 3.19.0-31. It consists of one Intel i7-3610QM processor of 4 cores (two threads per core), operating at 2.3 GHz. Each core has a unified 256KB L2 cache and each processor has a shared 6MB L3 cache. The PC contains 8GB of main memory and the code was compiled with GCC version 5.4.0, and with the *-O3* optimization flag turned on. The complete source code is available on GitHub repository [22].

### A. Methodology

A set of twenty structural symmetric and square matrices was selected from the University of Florida Sparse Matrix Collection [23]. These matrices cover multiple types of problems in order to increase the dataset variety and the percentage of sparsity of each one is higher than 99.95%. The set of tested matrices is shown in Table I. The columns tabulate the matrix's name, as well as the dimension, the number of non-zeros, and the average of non-zeros per row (NNZ/row) of them.

TABLE I: Tested sparse matrices.

#	Matrix	Dimension	Non-zeros	NNZ/row
01	m_t1	97,578	9,753,570	100
02	filter3D	106,437	2,707,179	25

The algorithms were performed five times for each pair  $(m_i, t_j)$ , where  $m_i$  is a sparse matrix, and  $t_j$  is the number of threads between 1 and 12 (in steps of 2). For each  $(m_i, t_j)$  tested pair, the average was calculated from the reported values. In order to confront the algorithms, for each matrix  $m_i$ , it was selected the number of threads  $t_j$  that reached the best value considering the CPU time. The Compressed Sparse Row format (Section II) was the mechanism used to store each tested matrix. For the starting point of the algorithms (source node), it was used a pseudo-peripheral node obtained by the heuristic described in Section III. Moreover, the speedup  $S$  computed for the parallel RCM algorithm was calculated according to expression  $S(n) = \frac{T_1}{T_n}$ , where  $T_1$  is the run-time

of the parallel RCM executed with one thread, and  $T_n$  is the run-time of the same algorithm executed with  $n$  threads.

### B. Environment Variables Setup

Some OpenMP variables that affect the execution of OpenMP programs were configured to guide the threads behavior. According to OpenMP Language Working Group [24], all settings must be done before the program has started. Otherwise, modifications to the environment variables are ignored. In this work, the OpenMP configured variables are described below.

- **OMP\_DYNAMIC**: This environment variable controls dynamic adjustment of the number of threads inside parallel regions. As the executed experiments involve a specific number of threads, this variable was set to **FALSE**.
- **OMP\_WAIT\_POLICY**: It provides a hint to the OpenMP implementation about the desired behavior of waiting threads. For all experiments of this work, the behavior of waiting threads was set to **PASSIVE**. This value specifies that waiting threads should mostly be passive, not consuming cycles, while waiting.
- **OMP\_PROC\_BIND**: It enables or disables threads binding to processors. In this work, the value **TRUE** was defined for this variable. With this configuration, the execution environment does not move OpenMP threads between OpenMP places.

### C. Reordering Quality

Table II shows reordering quality (final bandwidth columns) comparison between the serial HSL library and the implemented Unordered Parallel RCM algorithm (URCM). Columns reduction display the bandwidth percentage reduction attained by each algorithm in relation to the original bandwidth value.

TABLE II: Bandwidth Comparison after Reordering

Matrix		Final Bandwidth		Reduction (%)	
Name	Bandwidth	HSL	URCM	HSL	URCM

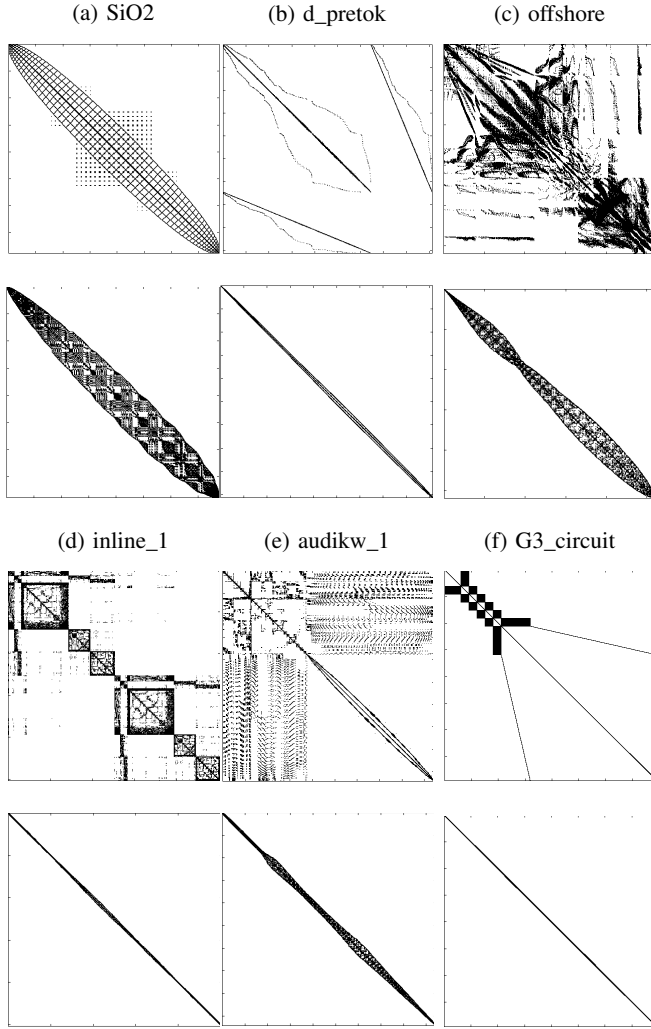

Fig. 6: Sparse matrix pattern yielded by the Unordered RCM.

The results displayed in Table II highlight the efficiency of the implemented algorithms for solving the bandwidth minimization problem. The HSL's sequential RCM and the Unordered RCM produce very similar bandwidth numbers. The HSL library reached a better solution only for four matrices. For eleven matrices, the percentage of bandwidth reduction attained by the URCM algorithm was higher than 90%. For the other matrices, there was a lower bound of 15.07% for the bandwidth reduction. Just three exceptions were observed: (i) Despite the URCM has not reached any bandwidth reduction with the *m\_t1* matrix, the result achieved by HSL was worse. The library increased the matrix bandwidth; (ii) For the *boneS10* matrix, both algorithms produced a bandwidth higher than the original; and (iii) For the *Serena* matrix, the URCM algorithm also generated a final bandwidth worse than the original.

The reordering quality produced by the implemented algorithm may also be graphically attested through Figure 6. It

presents some examples of sparse matrix pattern yielded by the URCM algorithm. The first row of each subfigure presents the matrix sparsity before reordering. In the below rows, each respective matrix is exhibited as result of a permutation of rows and columns. The first set of matrices (Figures 6(a), 6(b), and 6(c)) are samples out of smallest matrices (order up to around 500.000). The second group of matrices (Figures 6(d), 6(e), and 6(f)) corresponds to some of the highest ones (with order of 1.500.000 approximately). The bandwidth reduction reached with these six matrices varied from 64.46% (*SiO2*) to 99.46% (*G3\_circuit*).

#### D. Reordering Performance

Table III shows a performance comparison of the two algorithms. The reordering times are presented in scale of  $10^{-3}$  seconds, and the best values in terms of CPU time are highlighted in bold. The numbers in parentheses indicate the number of threads used to reach the respective value. The column Reduction presents the time reduction percentage achieved by the Unordered RCM in comparison with HSL.

TABLE III: CPU time comparison ( $\times 10^{-3}$  sec.)

Matrix Name	Reordering Time		
	HSL	URCM	Reduction (%)
m_t1	0.871	<b>0.628 (04)</b>	28.64
filter3D	0.880	<b>0.394 (04)</b>	54.76
SiO2	2.339	<b>1.668 (04)</b>	28.69
d_pretok	0.746	<b>0.585 (04)</b>	21.58
CO	2.095	<b>1.020 (08)</b>	51.31
offshore	2.432	<b>1.082 (06)</b>	55.51
Ga41As41H72	3.988	<b>1.794 (04)</b>	55.02
F1	3.394	<b>2.414 (04)</b>	28.87
mario002	1.507	<b>1.349 (06)</b>	10.48
msdoor	2.381	<b>1.838 (08)</b>	22.81
inline_1	4.140	<b>3.100 (08)</b>	25.12
gsm_106857	5.780	<b>2.840 (08)</b>	50.87
Fault_639	3.250	<b>2.900 (08)</b>	10.77
tmt_sym	<b>2.040</b>	2.290 (06)	-12.25
boneS10	10.480	<b>4.420 (08)</b>	57.82
audikw_1	12.590	<b>5.910 (08)</b>	53.06
nlpkt80	8.320	<b>3.670 (08)</b>	55.89
dielFilterV2real	10.390	<b>5.170 (08)</b>	50.24
Serena	11.170	<b>5.920 (08)</b>	47.00
G3_circuit	5.120	<b>4.750 (06)</b>	07.22

As displayed in Table III, the Unordered RCM achieved outstanding performance results. In fact, the rate of time reordering reduction of the algorithm varies from 10.48% (*mario002*) to 57.82% (*boneS10*). The time reordering improvement presented by five matrices was very significant. With these matrices, the algorithm reached speedups superior to 3.0X, i.e., 3.84X (*boneS10*), 3.64X (*msdoor*), 3.40X (*audikw\_1*), 3.15X (*inline\_1*), and 3.12X (*Fault\_639*).

Figure 7 shows two sets of speedup curves generated by experiments with the Unordered RCM processing ten matrices. Figure 7(a) presents the five matrices that have shown the best speedup ratio out of the smallest ones tested (matrix order up to five hundred thousand). In this set of matrices, the performance improvement was more impacted by the matrices order than by the number of non-zeros per row. Actually,

the best speedup ratios observed in this set of matrices were 3.64X (*msdoor*), 2.93X (*F1*), and 2.88X (*Ga41As41H72*). Although the matrix *SiO2* has the most significant average of NNZ/row among these five ones (about 76 - see Table I), the Unordered RCM achieved the lowest speedup ratios with this matrix (1.81X running with just 4 threads).

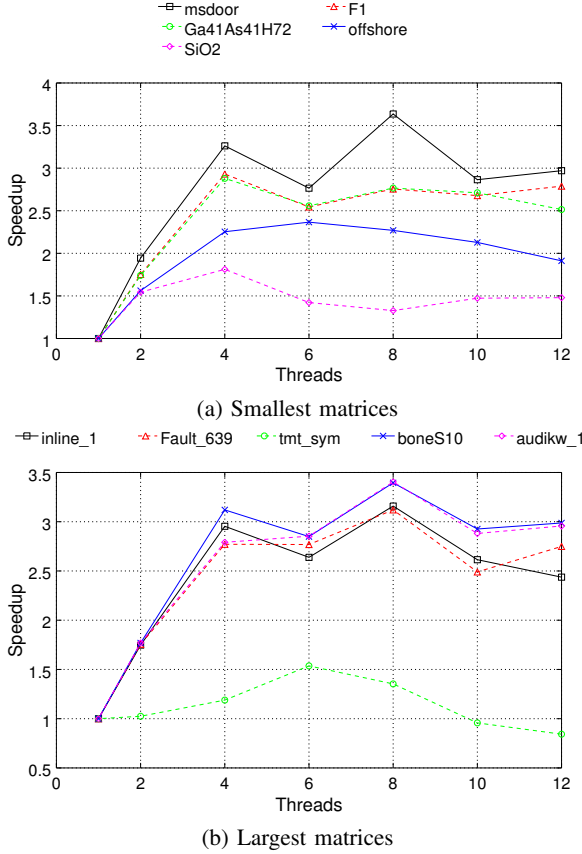

Fig. 7: Speedup of Unordered RCM.

A different behavior was observed with largest matrices. Figure 7(b) shows the speedup of a second set of five matrices whose order varies from 500,000 to 1,500,000 approximately. The best performance improvement was reached with the matrices with a high average of non-zeros per row. It was the case of *inline\_1*, *Fault\_639*, *boneS10*, and *audikw\_1*. The same was not observed with *tmt\_sym* matrix - it has an average of just 7 nonzeros per row. These different ratios of performance observed with matrices of distinct orders and distinct average of non-zeros per row suggest that speedups of parallel algorithms like Unordered RCM, which are based on a BFS approach, are higher for graphs with a larger number of edges per node. Nevertheless, for lower order graphs, the parallelism overhead impacts heavily on the CPU time improvement.

## VI. CONCLUSION

This paper analyzed a parallel strategy for a traditional reordering algorithm. The obtained results show the benefits

related to improving reordering time. In fact, for the set of tested matrices, the attained time reduction varies between 10.48% and 57.82%. Other significant results show the unordered RCM algorithm achieving speedups up to 3.84X with 6 threads. About the quality of solutions, the bandwidth reduction reached by the implemented algorithm was not superior to HSL just for one tested matrix. Therefore, the new parallel implementation proposed by the RCM algorithm may be considered as an efficient approach for the bandwidth minimization problem applied on large sparse matrices.

Some works in the literature have addressed the reordering problem through the use of other data structures and alternative breadth-first search (BFS) strategies have been proposed for the parallelism of RCM. As example, relevant results have been reached with a wavefront BFS implementation [18], and a novel implementation of a worklist data structure, called bag, has been used in place of FIFO queue usually employed in BFS algorithms [25]. The use of these new structures and strategies may promote more improvements to the algorithm studied in this work.

# Least Square Method Robustness of Computations

## What is not usually considered and taught

Vaclav Skala

**Abstract** — There are many practical applications based on the Least Square Error (LSE) approximation. It is based on a square error minimization “on a vertical” axis. The LSE method is simple and easy also for analytical purposes. However, if data span is large over several magnitudes or non-linear LSE is used, severe numerical instability can be expected.

The presented contribution describes a simple method for large span of data LSE computation. It is especially convenient if large span of data are to be processed, when the “standard” pseudoinverse matrix is ill conditioned. It is actually based on a LSE solution using orthogonal basis vectors instead of orthonormal basis vectors. The presented approach has been used for a linear regression as well as for approximation using radial basis functions.

**Keywords**—Least square error; approximation regression; radial basis function; approximation; condition number; linear algebra; geometric algebra; projective geometry.

### I. INTRODUCTION

Wide range of applications is based on approximation of acquired data and the LSE minimization is used, known also as a linear or polynomial regression. The regression methods have been heavily explored in signal processing and geometrical problems or with statistically oriented problems. They are used across many engineering fields dealing with acquired data processing. Several studies have been published and they can be classified as follows:

- “standard” Least Square Error (LSE) methods fitting data to a function  $y = f(x)$ , where  $x$  is an independent variable and  $y$  is a measured or given value,
- “orthogonal” Total Least Square Error (TLSE) fitting data to a function  $F(x) = 0$ , i.e. fitting data to some  $d - 1$ -dimensional entity in this  $d$ -dimensional space, e.g. a line in the  $E^2$  space or a plane in the  $E^3$  space [1][6][8][21][22],
- “orthogonally Mapping” Total Least Square Error (MTLSE) methods for fitting data to a given entity in a subspace of the given space. However, this problem is much more complicated. As an example, we can consider data given in and we need to find an optimal line in  $E^d$ , i.e. one dimensional entity, in this  $d$ -dimensional space fitting optimally the given data. Typical problem: Find a line in the  $E^d$  space that has the minimum orthogonal distance

from the given points in this space. This algorithm is quite complex and solution can be found in [18].

It should be noted, that all methods above do have one significant drawback as values are taken in a squared value. This results to an artifact that small values do not have relevant influence to the final entity as the high values. Some methods are trying to overcome this by setting weights to each measured data [3]. It should be noted that the TLSE was originally derived by Pearson [16](1901). Deep comprehensive analysis can be found in [8][13][21][22]. Differences between the LSE a TLSE methods approaches are significant, see Fig. 1.

Fig. 1.a: Least Square Error

Fig. 1.b: Total Least Square Error

In the vast majority the Least Square Error (LSE) methods measuring vertical distances are used. This approach is acceptable in the case of explicit functional dependences  $f(x, y) = h$ , resp.  $f(x, y, z) = h$ . However, it should be noted that a user should keep in a mind, that smaller differences than 1.0, will have significantly smaller weight than higher differences than 1.0 as the differences are taken in a square resulting to dependences in scaling of data approximated, i.e. the result will depend on physical units used, etc. The main advantage of the LSE method is that it is simple for fitting polynomial curves and it is easy to implement. The standard LSE method leads to over determined system of linear equations. This approach is also known as polynomial regression.

Let us consider a data set  $\Omega = \{(x_i, y_i, f_i)\}_{i=1}^n$ , i.e. data set containing for  $x_i, y_i$  and measured functional value  $f_i$ , and we want to find parameters  $\mathbf{a} = [a, b, c, d]^T$  for optimal fitting function, as an example:

$$f(x, y, \mathbf{a}) = a + bx + cy + dxy \quad (1)$$

Minimizing the vertical squared distance  $D$ , i.e.:

$$D = \min_{a,b,c,d} \sum_{i=1}^n (f_i - f(x_i, y_i, \mathbf{a}))^2 = \min_{a,b,c,d} \sum_{i=1}^n (f_i - (a + bx_i + cy_i + dx_i y_i))^2 \quad (2)$$

Conditions for an extreme are given as:

$$\frac{\partial f(x, y, \mathbf{a})}{\partial \mathbf{a}} = [1, x, y, xy]^T \quad (3)$$

Applying this on the expression of  $D$  we obtain

$$\frac{\partial D}{\partial \mathbf{a}} \sum_{i=1}^n (f_i - (a + bx_i + cy_i + dx_i y_i)) \frac{\partial f(x, y, \mathbf{a})}{\partial \mathbf{a}} = 0 \quad (4)$$

It leads to conditions for  $\mathbf{a} = (a, b, c, d)$  parameters in the form of a linear system of equations  $\mathbf{A}\mathbf{x} = \mathbf{b}$ :

$$\mathbf{A} = \begin{bmatrix} n & \sum_{i=1}^n x_i & \sum_{i=1}^n y_i & \sum_{i=1}^n x_i y_i \\ \sum_{i=1}^n x_i & \sum_{i=1}^n x_i^2 & \sum_{i=1}^n x_i y_i & \sum_{i=1}^n x_i^2 y_i \\ \sum_{i=1}^n y_i & \sum_{i=1}^n x_i y_i & \sum_{i=1}^n y_i^2 & \sum_{i=1}^n x_i y_i^2 \\ \sum_{i=1}^n x_i y_i & \sum_{i=1}^n x_i^2 y_i & \sum_{i=1}^n x_i y_i^2 & \sum_{i=1}^n x_i^2 y_i^2 \end{bmatrix} \quad (5)$$

$$\mathbf{x} = [a, b, c, d]^T$$

$$\mathbf{b} = \left[ \sum_{i=1}^n f_i, \sum_{i=1}^n f_i x_i, \sum_{i=1}^n f_i y_i, \sum_{i=1}^n f_i x_i y_i \right]^T$$

The selection of bilinear form was used to show the LSE method application to a non-linear case, if the case of a linear function, i.e.  $f(x, y, \mathbf{a}) = a + bx + cy$ , the 4<sup>th</sup> row and column are to be removed. Note that the matrix  $\mathbf{A}$  is symmetric and the function  $f(\mathbf{x})$  might be more complex, in general.

Several methods for LSE have been derived [4][5][10], however those methods are sensitive to the vector  $\mathbf{a}$  orientation and not robust in general as a value of  $\sum_{i=1}^n x_i^2 y_i^2$  might be too high in comparison with the value  $n$ , which has an influence to robustness of a numerical solution. In addition, the LSE methods are sensitive to a rotation as they measure vertical distances. It should be noted, that rotational and translation invariances are fundamental requirements especially in geometrically oriented applications.

The LSE method is usually used for a small size of data and span of a domain is relatively small. However, in some applications the domain span can easily be over several decades, e.g. in the case of Radial Basis Functions (RBF) approximation for GIS applications etc. In this case, the overdetermined system can be difficult to solve.

## II. NUMERICAL STABILITY

Let us explore a simple example, when many points  $\mathbf{x}_i \in E^2$ , i.e.  $\mathbf{x}_i = (x_i, y_i)$ , are given with relevant associated values  $b_i, i = 1, \dots, n$ . Expected functional dependency can be expressed (for a simplicity) as  $y = a_1 + a_2 x + a_3 y$ . The LSE leads to an overdetermined system of equations

$$\mathbf{A}^T \mathbf{A} \boldsymbol{\xi} = \mathbf{A}^T \mathbf{b} \quad (6)$$

where  $\mathbf{b} = (b_1, \dots, b_n)$ ,  $\boldsymbol{\xi} = (\xi_1, \dots, \xi_m)$  and  $m$  is a number of parameters,  $m < n$ .

If the values  $x_i, y_i$  over a large span, e.g.  $x_i, y_i \in \langle 10^0, 10^5 \rangle$ , the matrix  $\mathbf{A}^T \mathbf{A}$  is extremely ill conditioned. This means that the reliability of a solution depends on the distribution of points in the domain. Situation gets worst when a non-linear polynomial regression is to be used and dimensionality of the domain is higher.

As an example, let us consider a simple case, when points form regular orthogonal mesh and values are generated using  $R5$  distribution scheme (equidistant in a logarithmic scale) as  $(x_i, y_i) \in \langle 10, 10^5 \rangle \times \langle 10, 10^5 \rangle$ . It can be easily found using MATLAB that conditional number  $\text{cond}(\mathbf{A}^T \mathbf{A}) \cong 10^{11}$ .

In the following, we will show how the condition number might be decreased significantly using orthogonal basis vectors instead of the orthonormal ones.

## III. PROJECTIVE NOTATION AND GEOMETRY ALGEBRA

The LSE approximation is based on a solution of a linear system of equations, i.e.  $\mathbf{A}\mathbf{x} = \mathbf{b}$ . Usually the Euclidean representation is used. However if the projective space representation is used [19], it is transformed into homogeneous linear system of equations, i.e.  $\mathbf{B}\boldsymbol{\zeta} = \mathbf{0}$ . Rewriting the Eq.(6), we obtain

$$\mathbf{B}\boldsymbol{\zeta} = \mathbf{0} \quad (7)$$

where

$$\mathbf{B} = [-\mathbf{A}^T \mathbf{b} | \mathbf{A}^T \mathbf{A}] \quad (8)$$

$$\boldsymbol{\zeta} = (\zeta_0, \zeta_1, \dots, \zeta_m)$$

and  $\xi_i = \zeta_i / \zeta_0, i = 1, \dots, m$ ;  $\zeta_0$  is the homogeneous coordinate in the projective representation, matrix  $\mathbf{B}$  size is  $m \times (m + 1)$ . Now, a system of homogeneous linear equations is to be solved.

It can be shown that a system of homogeneous linear equations  $\mathbf{A}\mathbf{x} = \mathbf{0}$  is equivalent to the extended cross-product, actually outer-product [19][20]. In general, solutions of the both cases  $\mathbf{A}\mathbf{x} = \mathbf{0}$  and  $\mathbf{A}\mathbf{x} = \mathbf{b}$ , i.e. homogeneous and non-homogeneous system of linear equations, is the same and no division operation is needed as the extended cross-product (outer product) does not require any division operation at all. Applying this we get:

$$\boldsymbol{\zeta} = (\zeta_0, \zeta_1, \dots, \zeta_m) = \boldsymbol{\beta}_1 \wedge \boldsymbol{\beta}_2 \wedge \dots \wedge \boldsymbol{\beta}_{m-1} \wedge \boldsymbol{\beta}_m \quad (9)$$

where

$$\boldsymbol{\beta}_i = [-b_{i0} : b_{i1}, \dots, b_{im}]^T \quad i = 1, \dots, m \quad (10)$$

The extended cross-product can be rewritten using determinant of  $(m + 1) \times (m + 1)$  as

$$\boldsymbol{\zeta} = \det \begin{bmatrix} \mathbf{e}_0 & \mathbf{e}_1 & \mathbf{e}_2 & \dots & \mathbf{e}_m \\ -b_{10} & b_{11} & b_{12} & \dots & b_{1m} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ -b_{m0} & b_{m1} & b_{m2} & \dots & b_{mm} \end{bmatrix} \quad (11)$$

where  $\mathbf{e}_0$  are orthonormal basis vectors in the  $m$ -dimensional space. As a determinant is a multilinear, we can multiply any  $j$  column by a value  $q_j \neq 0$

$$\zeta' = \det \begin{bmatrix} \mathbf{e}'_0 & \mathbf{e}'_1 & \mathbf{e}'_2 & \cdots & \mathbf{e}'_m \\ -b'_{10} & b'_{11} & b'_{12} & \cdots & b'_{1m} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ -b'_{m0} & -b'_{m1} & -b'_{m2} & \cdots & -b'_{mm} \end{bmatrix} \quad (12)$$

where

$$\mathbf{e}'_j = \frac{\mathbf{e}_j}{q_j} \quad b'_{*j} = \frac{b_{*j}}{q_j} \quad (13)$$

where  $\mathbf{e}'_j$  are orthogonal basis vectors in the  $m$ -dimensional space.

From the geometrical point of view, it is actually a “temporary” scaling on each axis including the units. Of course, a question remains – how to select the  $q_j$  value. The  $q_j$  is to be selected as

$$q_j = \max_{i=1,\dots,m} \{ |b_{ij}| \} \quad (14)$$

where  $j = 1, \dots, m$ . Note that the matrix  $\mathbf{B}$  is indexed as  $(0, \dots, m) \times (0, \dots, m)$ .

Applying this approach, we get a modified system

$$\zeta' = (\zeta'_0, \zeta'_1, \dots, \zeta'_m) = \beta'_1 \wedge \beta'_2 \wedge \dots \wedge \beta'_{m-1} \wedge \beta'_m \quad (15)$$

where

$$\beta'_i = [-b'_{i0}: b'_{i1}, \dots, b'_{im}]^T \quad (16)$$

where  $\beta'_i$  are coefficients of the matrix  $\bar{\mathbf{B}}' = [-\mathbf{A}^T \mathbf{b} | \overline{\mathbf{A}^T \mathbf{A}}]$ , i.e. modified matrix  $\mathbf{B}$  as described above, for the orthogonal (not orthonormal) vector basis.

The approximated  $f(x, y)$  value is computed as

$$f(x, y) = aq_1 + bq_2x + cq_3y \quad (17)$$

in the case of  $f(x, y) = a + bx + cy$ , or

$$f(x, y) = aq_1 + bq_2x + cq_3y + dq_4xy \quad (18)$$

in the case  $f(x, y) = a + bx + cy + dxy$  and similarly for the general case of a regression function  $y = f(\mathbf{x}, \mathbf{a})$ .

The above presented modification is simple. However, what is the influence of this operation?

#### IV. MATRIX CONDITIONALITY

Let us consider a recent simple example again, when points are generated from  $(x_i, y_i) \in \langle 10, 10^5 \rangle \times \langle 10, 10^5 \rangle$ . It can be found that conditional number  $\text{cond}(\mathbf{A}^T \mathbf{A}) \cong 6 \cdot 10^{10}$  using MATLAB, Fig.2, if  $f(x, y) = a + bx + cy$  is used for the LSE.

Fig.2: Conditionality histogram of the original matrix depending on number of data set size, i.e. number of points

Using the approach presented above, the conditional number was decreased significantly to  $\text{cond}(\bar{\mathbf{A}}^T \bar{\mathbf{A}}) \cong 2 \cdot 10^6$ .

Fig.3: Conditionality of the modified matrix depending on number of data set size, i.e. number of points

Comparing the condition numbers of the original and modified matrices, we can see significant improvement of matrix conditionality as

$$v = \text{cond}(\mathbf{A}^T \mathbf{A}) / \text{cond}(\bar{\mathbf{A}}^T \bar{\mathbf{A}}) \cong \frac{6 \cdot 10^{10}}{2 \cdot 10^6} = 3 \cdot 10^4 \quad (19)$$

In the case of a little bit more complex function defined by Eq.(1), i.e.  $f(x, y) = a + bx + cy + dxy$  we obtain

Fig.4: Conditionality of the original matrix depending on number of data set size, i.e. number of points

Fig.5: Conditionality of the modified matrix depending on number of data set size, i.e. number of points

In this case of the LSE defined by Eq.(1) the conditionality improvement is even higher, as

$$v = \text{cond}(\mathbf{A}^T \mathbf{A}) / \text{cond}(\bar{\mathbf{A}}^T \bar{\mathbf{A}}) \cong \frac{6 \cdot 10^{20}}{6 \cdot 10^{11}} = 10^9 \quad (20)$$

It means that better numerical stability is obtained by a simple operation. All graphs clearly shows also dependency on a number of points used for the experiments (horizontal axis).

The geometric algebra brings also an interesting view on problems with numerical solutions. Let us consider vectors  $\hat{\beta}_i$  with coordinates of points, i.e.

$$\hat{\beta}_i = [b_{i1}, \dots, b_{im}]^T \quad i = 1, \dots, m \quad (21)$$

Then  $\hat{\beta}_i \wedge \hat{\beta}_j = \hat{\gamma}_{ij}$  defines a bivector, which is an oriented surface, given by two vectors in  $m$ -dimensional space and  $\|\hat{\gamma}_{ij}\|$  gives the area represented by the bivector  $\hat{\gamma}_{ij}$ .

So, the proposed approach of introducing orthogonal basis functions instead of the orthonormal ones, enable us to “eliminate” influence of “small” bivectors in the original LSE computation and increase precision of numerical computation.

Of course, if the regression is to be applied, the influence of the  $q_j$  values must be applied. By the presented approach we actually got values  $\zeta'_i$  using the orthogonal basis vectors instead of orthonormal. It means, that the estimated value by a regression, using recent simple example, is

$$f(x, y) = q_1 a_1 + q_2 a_2 x + q_3 a_3 y \quad (22)$$

## V. LEAST SQUARE METHOD WITH POLYNOMIALS

In the case of the least square approximation, we want to minimize using a polynomial of degree  $n$ .

$$\min_{P_n(x)} \|f(x) - P_n(x)\|$$

$$P_n(x) = \sum_{i=0}^n a_i x^i \quad (23)$$

The  $L_2$  norm of a function  $f(x)$  on an interval  $\langle a, b \rangle$  is defined

$$\|f(x)\| = \sqrt{\left( \int_a^b f(x) dx \right)^2} \quad (24)$$

Minimizing square of the distance of a function of  $k+1$  parameters  $\varphi(\mathbf{a}) = \varphi(a_0, \dots, a_n)$  and using “per-partes” rule, we obtain

$$\begin{aligned} \varphi(\mathbf{a}) &= \int_a^b [f(x) - P_n(x)]^2 dx \\ &= \int_a^b [f(x)]^2 dx - 2 \sum_{i=0}^n a_i \int_a^b x_i f(x) dx \\ &\quad + \sum_{i=0}^n \sum_{j=0}^n a_i a_j \int_a^b x^{i+j} dx \end{aligned} \quad (25)$$

For a minimum a vector condition

$$\frac{\partial \varphi(\mathbf{a})}{\partial \mathbf{a}} = \mathbf{0} \quad (26)$$

must be valid. It leads to conditions

$$\begin{aligned} \frac{\partial \varphi(\mathbf{a})}{\partial a_k} &= 0 - 2 \int_a^b x^k f(x) dx + \sum_{i=0}^n a_i \int_a^b x^{i+k} dx \\ &\quad + \sum_{j=0}^n a_j \int_a^b x^{j+k} dx \end{aligned} \quad (27)$$

and by simple algebraic manipulations we obtain:

$$2 \left[ - \int_a^b x^k f(x) dx + \sum_{i=0}^n a_i \int_a^b x^{i+k} dx \right] = 0 \quad (28)$$

and therefore

$$\sum_{i=0}^n a_i \int_a^b x^{i+k} dx = \int_a^b x^k f(x) dx \quad (29)$$

where  $k = 1, \dots, n$ .

It means that the LSE problem is the polynomial (what has been expected)

$$P_n(x) = \sum_{i=0}^k a_i x^i \quad (30)$$

However, there is a direct connection with well known Hilbert’s matrix. It can be shown that elements of the Hilbert’s matrix  $(H_{n+1}(a, b))_{i,k}$  of the size  $(n+1) \times (n+1)$  are equivalent to

$$(H_{n+1}(a, b))_{i,k} = \int_a^b x^{i+k} dx = \frac{1}{1+i+k} \quad (31)$$

If interval  $\langle a, b \rangle = \langle 0, 1 \rangle$  is used, standard Hilbert’s matrix  $H_n(0, 1)$  is obtained, which is extremely ill-conditioned.

## VI. HILBERT’S MATRIX CONDITIONALITY

We should answer a question, how the conditional number of the Hilbert’s matrix can be improved if orthogonal basis is used instead of orthonormal one as an experimental test.

A simple experiment can prove that the proposed method does not practically change the conditionality of the Hilbert’s matrix  $H_n(0, 1)$ . However, as the LSE approximation is to be used for large span of data, it is reasonable to consider a general case and explore conditionality of the  $H_n(a, b)$  matrix, e.g.  $H_5(0, b)$ , for demonstration.

Fig.6: Conditionality of the  $H_5(0, b)$  for different values of  $b$  using MATLAB (numerical problems can be seen for  $b > 650$ )

Fig.7: Conditionality of the  $H_5(0, b)$  for different values of  $b$  using logarithmic scaling for vertical axis

It can be seen, that  $\text{cond}(H_5(0, 800)) = 6 \cdot 10^{23}$ . If the proposed approach is applied  $\text{cond}(\hat{H}_5(0, 800)) = 2,5 \cdot 10^{14}$  for the modified matrix, Fig.8 - Fig.9.

Fig.8: Conditionality of the modified  $H_5(0, b)$ Fig.9: Conditionality of the modified  $H_5(0, b)$  using logarithmic scaling for vertical axis

It means that the conditionality improvement

$$v = \frac{\text{cond}(H_5(0,800))}{\text{cond}(H_5(0,800))} \cong \frac{6.10^{23}}{2.5.10^{14}} \approx 10^9 \quad (32)$$

This is a similar ratio as for the simple recent examples.

A change of the size of bivectors  $\|\beta_i \wedge \beta_j\|$  can be used as a practical result using RBF approximation, which changes from the interval  $\langle \epsilon ps, 10^{10} \rangle$  to  $\langle \epsilon ps, 8.10^2 \rangle$ , which significantly increases robustness of the RBF approximation, Fig.10.

Fig.10: Bivector histogram sizes for original LSE matrix and modified one

The proposed approach has been used for St.Helen's volcano approximation by 10 000 points instead of 6 743 176 original points, see Fig.11.

Fig.11: LSE approximation error with RBF approximation of St.Helen's (image generated in MATLAB by Michal Smolik)

## VII. CONCLUSIONS

The proposed method of application orthogonal vector basis instead of the orthonormal one decreases conditional number of a matrix used in the least square method. This approach increases robustness of a numerical solution especially when domain data range is high. It can be used also for solving systems of linear equations in general, e.g. if radial basis function interpolation or approximation is used.

## ACKNOWLEDGMENT

The author would like to thank to colleagues at the University of West Bohemia in Plzen for fruitful discussions and to anonymous reviewers for their comments and hints, which helped to improve the manuscript significantly. Special thanks belong to Zuzana Majdišová and Michal Šmolík for independent experiments, images and generation in MATLAB.

# 4<sup>th</sup> International Conference on Cryptography and Security Systems

**C**RYPTOGRAPHY and security systems are two fields of security research that strongly interact and complement each other. The International Conference on Cryptography and Security Systems (CSS) is a forum of presentation of theoretical, applied research papers, case studies, implementation experiences as well as work-in-progress results in these two disciplines.

## TOPICS

The main topics of interests include:

- network security
- cryptography and data protection
- peer-to-peer security
- security of wireless sensor networks
- security of cyber physical systems
- security of Internet of Things solutions
- heterogeneous networks security
- privacy-enhancing methods
- covert channels
- steganography and watermarking for security applications
- cryptographic protocols
- security as quality of service, quality of protection
- data and application security, software security
- security models, evaluation, and verification
- formal methods in security
- trust and reputation models
- reputation systems for security applications
- intrusion tolerance
- system surveillance and enhanced security
- cybercrime: threats and countermeasures
- 5G Security
- DDoS attacks: detection and mitigation
- Security of Smart Grid systems

# Enhancing the Imperceptibility of Image Steganography for Information Hiding

Mohamed M. Fouad, *Member, IEEE*

Department of Computer Engineering, Military Technical College, Cairo, Egypt  
Email: mmafoad@mtc.edu.eg

**Abstract**—In this paper, an image steganography approach is presented dividing the cover image into  $2 \times 2$  non-overlapping pixel blocks. The upper-left pixel of that block embeds a certain number of bits of the secret bit stream. Whereas, the remaining pixels of the same block embed the secret data using a modified version of the pixel-value-differencing (PVD) method that considers embedding secret data into both horizontal and vertical edges; unlike traditional image steganography approaches. The experimental results show that the proposed approach perceptually outperforms competing approaches in terms of the standard PSNR and the complex wavelet SSIM index. In turn, the imperceptibility of the stego-image is improved with a comparable bit-embedding capacity.

## I. INTRODUCTION

INFORMATION security has attracted a great attention in the past few decades due to its importance in the growing communication field. Various cyber crimes such as forgery, modification, duplication and interception have reached alarming levels. So, information security issue requires immediate and reasonable solutions, such as cryptography and/or steganography. Cryptography is a well known solution to protect data using the concept of encrypting the message to become unreadable. Encrypting digital media, such as audio, image, video achieves higher secrecy performance. However, such encrypted media become, then, attractive to eavesdroppers (*i.e.*, information attackers) as the encrypted media are presented in a perceptible manner. Instead, steganography can be considered as an alternative to overcome the perceptibility issue.

The main aim of the steganography process is to conceal the information being transferred within some digitally covered media avoiding the attention of eavesdroppers. This makes steganography a good manner to communicate secret information through digital cover media, such as audio, image, video, text *etc.* Steganography process has many challenges due to transferring a secret text information within a digitally covered media [1]. The main challenge is to transfer a higher size of a secret text information within a limited image size without changing the image quality; at least to the human visual system. Therefore, the steganography process is a trade-off problem. The steganography process can be performed in either frequency domain or spatial domain.

In the frequency domain, the joint photographic experts group (JPEG) format is frequently used, due to its small size being easily transferred on the internet. After changing the *RGB* color representation to the *YUV* representation, the

color component, *V*, can be then downsampled to decrease the file size. In turn, the resulting image file is transformed using the discrete cosine transform (DCT), or the discrete Fourier transform (DFT). Finally, the transformed image is compressed with a lossless Huffman encoding. As the DCT and quantization steps are lossy, the secret text information using the least significant bit (LSB) embedding step can be performed right before the Huffman encoding step, yielding a stego-image [2]. Whereas, in [3], [4], authors use sparse decomposition of one level using the Haar wavelet transform to hide text information within non-overlapping blocks in combination with the LSB-based substitution method with increasing the transmission capacity on the secret messages perceptibility in the stego-image.

In the spatial domain-based approaches, the steganography process is performed by generating the LSB-based substitution matrices. Then, the secret text information is distributed among all pixels in a gray-scale or colored image; the digitally covered media. Ultimately, the stego-image is generated with a certain image quality. So, the spatial domain-based approaches can be partitioned into three categories: (i) high embedding capacity approaches with barely acceptable image quality (*e.g.*, [5]–[7]), (ii) high image quality approaches with reasonable hiding capacity (*e.g.*, [8]–[10]), and (iii) restricted embedding capacity approaches with a slight distortion in the image (*e.g.*, [11]–[13]).

In [11], authors use the optimal pixel adjustment procedure (OPAP) in combination with a modified Hamming method to improve the imperceptibility of the stego-image, however, with a limited size of the hidden text. In [12], an adaptive LSB substitution method using uncorrelated color space, increasing the property of imperceptibility to embed the encrypted data inside the *V*-plane of HSV color model based on secret key. Encryption is performed to sensitive contents using iterative magic matrix-based encryption algorithm. In [10], an image steganographic method is presented based on the LSB substitution with a typical pixel value differencing (PVD) method, a modified version of PVD method, and an 8-neighboring (8nPVD) method, respectively, for gray-scale cover image in order to improve the embedding capacity with a reasonable imperceptible stego-image. In [13], the image is partitioned into  $2 \times 2$  pixel blocks in a non-overlapping fashion and scanned in raster-scan order having correlated the left-upper and bottom-right corner pixels. Although both horizontal and vertical edges are considered in the approach of [13], more

bit-hiding capacity is achieved at the cost of image quality.

Although, those aforementioned approaches have reached a reasonable level of information hiding, all resulting stego-images are highly perceptible, thus assuring the existence of hidden information and attracting eavesdroppers. In this paper, we propose a spatial-based image steganography approach to hide text information with higher imperceptibility to avoid the information attackers. Unlike conventional approaches, the proposed approach makes use of hiding secret information in both horizontal and vertical edges with enhancing the visual quality of the stego-image, thus achieving higher imperceptibility. The proposed approach exploits the LSBMR method in combination with the optimal-pixel-adjustment process (OPAP) method to embed secret data into the cover images. In the embedding step of the proposed approach, the cover image is partitioned into non-overlapping  $2 \times 2$  pixel blocks. The upper-left pixel is embedded with  $k$ -bits of the secret data using the LSB substitution method and is adjusted accordingly by the OPAP method to recover data on the recipient. Each of the other three pixels are then embedded with a certain number of bits using the LSBMR method. In the second stage, the data is extracted from stego-image.

The rest of this paper is organized as follows. In Section II, the proposed spatial-based image steganography approach is presented using a modified version of the PVD method in combination with both the LSBMR and OPAP methods. Section III presents the performance evaluation metrics, implementation setup of competing approaches and the experimental results. Finally, conclusions are given in Section IV.

## II. THE PROPOSED APPROACH

This section presents the proposed image steganography approach for gray-level cover image with a modified PVD method. The embedding and extraction steps are shown in Section II-A and Section II-B, respectively.

### A. The Proposed Embedding Step

In the proposed embedding step of the proposed approach, the cover image is divided into  $2 \times 2$  non-overlapping pixel blocks in a raster scan order. The modified PVD method divides the gray level range  $[0, 255]$  into only six subranges, such that  $R_1=[0,7]$ ,  $R_2=[8,15]$ ,  $R_3=[16,31]$ ,  $R_4=[32,63]$ ,  $R_5=[64,127]$ , and  $R_6=[128,255]$ . Note that the modified PVD method, subranges  $R_1$  through  $R_4$  are categorized as a lower gray-level, whereas the subranges  $R_5$  and  $R_6$  are categorized as a higher gray-level. Given that the subrange of gray-level is  $R_j = [L_j, U_j]$ , where  $j = 1, 2, 3 \dots 6$ , its width can be cast as  $W_j = U_j - L_j + 1$ . Also note that the maximum number of bits,  $t_j$ , to be embedded in the pixel pair is determined, such that  $t_j = a_1, a_2, a_3, a_4, a_5$ , and  $a_6$  for  $R_j = R_1, R_2, R_3, R_4, R_5$ , and  $R_6$ , respectively. Also, note that the first pixel (i.e., the upper-left pixel) can be referred to  $B_{ib}$  as the base point of block  $i$ . As well, the second pixel,  $B_{i2}$ , the third pixel,  $B_{i3}$ , and the fourth pixel,  $B_{i4}$ , can be referred to as the upper-right pixel, the bottom-left pixel, and the bottom-right

pixel, respectively. The method of hiding a secret bit-stream into non-overlapping blocks is as follows:

- 1) Convert the  $k$  LSBs of  $B_{ib}$  to decimal,  $w_i$ .
- 2) Replace the  $k$  LSBs with the  $k$  leftmost secret bits to obtain  $B_{ib}^n$ .
- 3) Determine the decimal value  $v_i$  for  $k$  bits from the secret bit-stream.
- 4) Determine the difference value:  $d = w_i - v_i$ .
- 5) Update  $B_{ib}^n$ , such as

$$B_{ib}^n = \begin{cases} B_{ib}^n + 2^k, & \text{if } d > 2^{k-1} \text{ and } B_{ib}^n + 2^k \leq 255 \\ B_{ib}^n - 2^k, & \text{if } d < -2^{k-1} \text{ and } B_{ib}^n - 2^k \leq 255 \\ B_{ib}^n, & \text{Otherwise} \end{cases} \quad (1)$$

- 6) Determine the difference between the second pixel,  $B_{i2}$ , of the pixel block and  $B_{ib}^n$  as,  $D_{i1} = |B_{i2} - B_{ib}^n|$ .
- 7) Determine the difference between the third pixel,  $B_{i3}$ , of the pixel block and  $B_{ib}^n$  as,  $D_{i2} = |B_{i3} - B_{ib}^n|$ .
- 8) Determine the difference between the fourth pixel,  $B_{i4}$ , of the pixel block and  $B_{ib}^n$  as,  $D_{i3} = |B_{i4} - B_{ib}^n|$ .
- 9) For the differences,  $D_{i1}$ ,  $D_{i2}$  and  $D_{i3}$ , find the corresponding subranges as shown above in this subsection. Then, find out the corresponding number of bits to be hidden from the secret bit stream;  $t_{i1}$ ,  $t_{i2}$  and  $t_{i3}$  as well as their lower bound;  $L_{i1}$ ,  $L_{i2}$  and  $L_{i3}$ .
- 10) Having read the  $t_{i1}$ ,  $t_{i2}$  and  $t_{i3}$  bits from the secret bit stream, determine their decimal values;  $v_{i1}$ ,  $v_{i2}$  and  $v_{i3}$ , respectively.
- 11) Determine the new difference values,  $D_1^n$ ,  $D_2^n$  and  $D_3^n$ , such as

$$D_1^n = L_{i1} + v_{i1}, \quad D_2^n = L_{i2} + v_{i2}, \quad D_3^n = L_{i3} + v_{i3}. \quad (2)$$

- 12) The new values,  $B_{i2}^n$ ,  $B_{i3}^n$ ,  $B_{i3}^n$ ,  $B_{i3}^n$ ,  $B_{i4}^n$ , and  $B_{i4}^n$  can be determined as,

$$B_{i2}^n = B_{ib}^n - D_1^n, \quad B_{i2}^n = B_{ib}^n + D_1^n, \quad (3)$$

$$B_{i3}^n = B_{ib}^n - D_2^n, \quad B_{i3}^n = B_{ib}^n + D_2^n, \quad (4)$$

$$B_{i4}^n = B_{ib}^n - D_3^n, \quad \text{and } B_{i4}^n = B_{ib}^n + D_3^n. \quad (5)$$

- 13) Determine the difference values:
$$d_{i2}^n = |B_{i2} - B_{i2}^n|, \quad d_{i2}^n = |B_{i2} - B_{i2}^n|,$$

$$d_{i3}^n = |B_{i3} - B_{i3}^n|, \quad d_{i3}^n = |B_{i3} - B_{i3}^n|,$$

$$d_{i4}^n = |B_{i4} - B_{i4}^n|, \quad d_{i4}^n = |B_{i4} - B_{i4}^n|.$$
- 14) Determine the new value of the second pixel,  $B_{i2}^n$ , such as

$$B_{i2}^n = \begin{cases} B_{i2}^n, & \text{if } d_{i2}^n < d_{i2}^n \text{ and } 0 \leq B_{i2}^n \leq 255 \\ B_{i2}^n, & \text{Otherwise.} \end{cases} \quad (6)$$

15) Determine the new value of the third pixel,  $B_{i3}^n$ , such as

$$B_{i3}^n = \begin{cases} B_{i3}^{n2}, & \text{if } d_{i3}^{n2} < d_{i3}^{n3} \text{ and } 0 \leq B_{i3}^{n2} \leq 255 \\ B_{i3}^{n3}, & \text{Otherwise.} \end{cases} \quad (7)$$

16) Determine the new value of the fourth pixel,  $B_{i4}^n$ , such as

$$B_{i4}^n = \begin{cases} B_{i4}^{n2}, & \text{if } d_{i4}^{n2} < d_{i4}^{n3} \text{ and } 0 \leq B_{i4}^{n2} \leq 255 \\ B_{i4}^{n3}, & \text{Otherwise.} \end{cases} \quad (8)$$

The same steps above should be repeated for all neighboring pixels of each pixel block to obtain a stego-block. Then, all stego-blocks form the stego-image, until all secret bits have been hidden.

### B. The Proposed Extraction Step

In the proposed extraction Step of the proposed approach, the stego-image is divided into  $2 \times 2$  non-overlapping blocks by scanning the image in a raster scan order. Note that the first pixel (*i.e.*, the upper-left pixel) can be referred to  $B_{ib}^n$  as the base point of the stego-block  $i$ . As well, the second pixel,  $B_{i2}^n$ , the third pixel,  $B_{i3}^n$ , and the fourth pixel,  $B_{i4}^n$ , can be referred to as the upper-right pixel, the bottom-left pixel, and the bottom-right pixel, respectively. The method of extracting the secret bit-stream from the non-overlapping stego-blocks is as follows:

- 1) Extract the  $k$ -rightmost LSBs of the pixel  $B_{ib}^n$ , and name it  $v_{ib}$ .
- 2) Determine the difference values, such as

$$d_{i1}^n = |B_{i2}^n - B_{ib}^n|, d_{i2}^n = |B_{i3}^n - B_{ib}^n|, d_{i3}^n = |B_{i4}^n - B_{ib}^n|. \quad (9)$$

- 3) Find out the appropriate range,  $R_j$ , for the difference values  $d_{i1}^n$ ,  $d_{i2}^n$ , and  $d_{i3}^n$  from the subranges  $R_1$  through  $R_6$  as listed in Section II-A. Then, determine the corresponding values  $t_{i1}$ ,  $t_{i2}$  and  $t_{i3}$ , given their lower bounds, such as  $L_{i1}$ ,  $L_{i2}$  and  $L_{i3}$ , respectively.
- 4) Extract the  $t_{i1}$ ,  $t_{i2}$  and  $t_{i3}$ -rightmost LSBs of the difference values  $d_{i1}^n$ ,  $d_{i2}^n$ , and  $d_{i3}^n$ , respectively.
- 5) Determine and concatenate a segment of the secret bit stream, such as

$$s_{i1} = d_{i1}^n - L_{i1}, s_{i2} = d_{i2}^n - L_{i2}, \text{ and } s_{i3} = d_{i3}^n - L_{i3}.$$

Repetition of the above procedure for each stego-block will give the exact retrieval of the secret bit stream.

### III. PERFORMANCE EVALUATION & EXPERIMENTAL RESULTS

This section presents the evaluation metrics and the experimental results of the proposed image steganography approach compared to competing approaches shown in [10] and [13]. A set of standard gray-level images [14] with a different sizes have been chosen as cover images to check on the effectiveness of the competing approaches. Whereas, the secret image is taken in gray level square dimension.

Note that our main aim in this paper is to enhance the imperceptibility (*i.e.*, improve the image visual quality) of the stego-image with hiding a secret bit-stream of higher capacity. Therefore, three performance metrics are used to evaluate the performance of the competing image steganography approaches:

- 1) The embedding capacity: in bits; on the basis of the higher the better.
- 2) The stego-image visual quality: using both the standard peak-signal-to-noise (PSNR) ratio (in dB) [15, Ch. 3] on the basis of the higher the better.
- 3) The complex wavelet structural similarity (CWSSIM) index [16] is used, where 1 is a perfect match and 0 is a mismatch.

Normally the more the embedding capacity using an image steganography approach, the lower the perceptual image quality. In turn, the image distortions occurred are slight and imperceptible. Table I shows the embedding capacity (in bits) as well as the corresponding PSNR values and CWSSIM indexes using the competing approaches. Table I shows that the proposed approach outperforms the approaches shown in [10] and [13], by an average of 1.4 dB and 0.9 dB, respectively, in terms of the standard PSNR value. As well, the proposed approach surpasses the competing approaches by an average of 11.6% and 8.5% in terms of the CWSSIM index. In addition, Table I shows that the bit-embedding capacity using the proposed approach outperforms the approach in [10] by an average increase of 13.6%. While the proposed approach is comparable to that in [13]. Given the experimental results, one can notice that the stego-image using the proposed approach perceptually seems the same as the original one. Thus, the eavesdroppers avoidance can be achieved in case that non-standard Web-image has been used as a cover image instead of those standard images used. We can analyze that this enhancement is due to considering both horizontal and vertical edges, not only either of them as shown in competing approaches.

### IV. CONCLUSIONS

In this paper, we present an image steganography approach dividing the cover image into  $2 \times 2$  non-overlapping pixel blocks. The upper-left pixel of that block embeds a certain number of bits of the secret bit stream. Whereas, the remaining pixels of the same block embed data using a modified version of the pixel-value-differencing (PVD) method that considers embedding secret data into both horizontal and vertical edges. The experimental results show that the proposed approach outperforms competing approaches shown in [10] and [13], by an average of 1.4 dB and 0.9 dB, respectively, in terms of the standard PSNR value and by an average of 11.6% and 8.5% in terms of the complex wavelet SSIM index. The enhanced stego-image obtained implies improving the imperceptibility with a comparable embedding capacity compared to that in

**Abstract**—The huge number of malware introduced each day demands methods and tools for their automated analyses. Complex and distributed infrastructure of malicious software and new sophisticated techniques used to obstruct the analyses are discussed in the paper based on real-life malware evolution observed for a long time. Their impact on both toolsets and methods are presented based on practical development of systems for malware analyses and new features for existing tools.

## I. INTRODUCTION

**A**TTACKERS must continuously improve the tactics used to lure more and more users. An attempt to send an executable attached to an e-mail is well known to the most users and can be easily stopped by any anti-virus software. Nowadays attackers divide infection process into two stages. At the *first stage* some kind of executable code is delivered to the victim. Often it can be a simple macro embedded in a document or a link to an URL with malicious script. This code is responsible for downloading a *second stage* that contains the main malicious code, which is responsible for further hostile activity. In the most cases the second stage code is hosted on web servers (sites hacked without the knowledge of their owners). The more detailed description of attack techniques used nowadays can be found in [1] [2]. Some of them are also discussed with a QNAP NAS vulnerability case study presented in [3].

The next section presents an overview of the authors' analytical infrastructure and the background for the development of some new systems due to the growing malware complexity as well as the obfuscation and other hinder techniques used. Some practical solutions are proposed and discussed.

Section III presents in details the authors' analyses of the *Locky* malware campaigns evolution since March 2016 until January 2017. The authors have observed mainly two aspects of changes: related to the code used for downloading the second stage and to some hinder techniques. These changes had a significant impact on the methods and tools used in the analyses (discussed in Section IV).

To allow continues analyses of the new tricks introduced by the *Locky* authors, some changes to the used analytical tools and a completely new tool called *StealthGuardian* were developed. Section V presents its details and the techniques used. The paper concludes in Section VI.

## II. OVERVIEW OF THE ANALYTICAL INFRASTRUCTURE

The first problem is the acquisition of malware samples. The well known solution utilized for years are *HoneyPot* systems [4][5]. In a *HoneyPot* the whole attacker's activity is carefully monitored and recorded for further analysis. Over the time a special kind of *HoneyPot* systems were introduced for direct gathering of malware samples (e.g. *Nepenthes* [6] or *Dionaea* [7]). *HoneyPot* systems can be of high- or low-interaction level [4]. Depending on the type, a *HoneyPot* can cover different types of malware distribution and sometimes also conduct preliminary dynamic analysis of the malware behaviour. Indisputably, *HoneyPots* are very useful.

However, to handle dynamically changing first stage malware distribution and attack vectors, *HoneyPots* have to be continuously developed. Another difficulty is introduced by obfuscation and anti-analysis techniques (e.g. multi-stage infection process) used by the malware. The authors faced these problems during this research (see further sections). Most of the papers describe *HoneyPot* systems itself and a malware analyses as separate tasks (e.g. [8][9]). Obviously, such an approach is not practical as the whole process depends on iterative improvements of *HoneyPots* to allow deeper analysis of multi-stage attack scenarios. Each stage of the attack require some specific actions to be made by the *HoneyPot*.

It is reasonable to extend the set of the sample sources and use more than just own *HoneyPots*. The results given in further sections are based on samples freely available in *malwr.com* service [10]. Everyone can send a suspicious sample to this service and it will be executed in the controlled environment (*Cuckoo* sandbox [11]). The popularity of the *malwr.com* service guarantees a very rich set of different kind of malicious software in a wide range of technologies and attack techniques. Currently 67% of more than 720 thousands of samples analysed by the *malwr.com* (as of May 2017) are public and available for security researchers. It is worth to note that *malwr.com* service is not a substitution of *HoneyPots* as a source of samples but their valuable complement.

As there is no direct data accessibility API in *malwr.com* service, the paper's authors have developed a *Malwr-Scraper* system. It downloads and parses HTML analyses description pages (details of the analysis are stored in internal database).

After manual analyses of the most recently added samples, some dedicated queries are prepared to identify all the samples of a given malware family and these samples are downloaded from the *malwr.com*. During the conducted research (further described in Section III), the whole process of data gathering lasted for 6 days (more than 620 thousands analyses of the *malwr.com* service was downloaded and parsed - more than 815 GiB of HTML). The analysis revealed more than 5900 samples associated with the *Locky* ransomware family.

In the next step a malicious code is investigated with static and/or dynamic analyses. During static analysis a malicious code is carefully investigated by a security researcher. This process gives much valuable information concerning code internal structure, used libraries and overall functionality. However, it is a very time consuming one.

Contrary, a dynamic analysis approach can reveal useful information automatically [11], almost without any security researcher activities. The gathered sample is executed in a specially crafted environment, often called a *sandbox*. All activities of the malicious code are carefully monitored (e.g. created processes, files downloaded from the Internet and all of the network communication). The evident hostile activity (e.g. sending SPAM or working exploits) are denied by the environment protection mechanism. Of course, the Internet traffic cannot be completely denied due to the fact that modern malware, during the infection, downloads further elements from the Internet (e.g. the second stage of *Locky* ransomware) or contact Command and Control servers (C&C) [12]. The security researcher must determine the trade off between the risk introduced and collection of possibly valuable information when some protection mechanisms are loosen.

One of the most notable sandbox environment is *Cuckoo* [11]. In the most cases *Cuckoo* uses *VmWare* or *Virtual Box* virtualization hypervisors. Unfortunately, due to the great popularity of this system, these two virtual environments are the most often detected by the malware (in such case it simply stops its hostile activity). To deal with that, during our research we have developed two different environments dedicated for dynamic analysis - *Maltester* [13] and *MESS* [12].

Both systems have similar structure. The management system receives commands from the user. In effect, a clean virtual machine is created (a sandbox system) – a snapshot feature of the hypervisor is used. Launched sandbox machine has a custom software responsible for receiving a malware sample for the analysis and its execution. Due to security concerns all the traffic between the Internet and the sandbox system (with a suspicious file) is forwarded by an additional gateway system which implements Firewall and NAT services. Any hostile activity is stopped at this system. The overall infrastructure of the developed *Maltester* and *MESS* systems is very similar to the one used by the *Cuckoo* sandbox. However, our systems utilize not so common (in a security world) hypervisors: respectively *Xen* and *Microsoft Hyper-V*. Our research shows that for some malware samples the analysis has failed in well known systems but they were successfully evaluated in our custom dynamic analysis environments.

### III. LOCKY CASE STUDY

The results presented in this paper are continuation of the previous works associated with the analysis of the *CryptoWall* ransomware conducted at the beginning of 2015 [13]. Because of unknown reasons new samples of the *CryptoWall* were not observed in the January 2016 and later the whole *CryptoWall* infrastructure was shut down. However, around the middle of the February a new ransomware family appeared - called *Locky*. Like its predecessor, it encrypts user data and uses asymmetric cryptography. Public key used for the encryption is downloaded from a C&C server. Contrary to the *CryptoWall*, the *Locky* family uses more complicated schema for C&C access. Each sample has a few hard-coded C&C IP addresses. If they are shutdown, *Locky* uses domain generation algorithm (DGA) for finding other working C&C servers.

Since the middle of the March 2016 to the beginning of the January 2017 more than 5900 samples associated with *Locky* malware were reported in the *malwr.com* service. Around 700 of them are in Windows executable (PE32) format. In the remaining 5200 samples of the first stage we identified 278 hostile Excel and 753 hostile Word documents (around 20% of samples).

The characteristic for *Locky* campaigns is that the first stage code is very often in JavaScript and is sent to the victims as files with *.js* and *.wsf* extensions. The conducted research revealed that in more than 75% of the *Locky* first stage code samples. What should be emphasized, Microsoft Windows silently executes JavaScript code if given file extension is *.js*.

Among all the analysed JavaScript-based *Locky* samples, the simplest and the shortest code is contained in 17 lines (693 bytes)<sup>1</sup>. In more recent samples, this first stage code become obfuscated using various methods. In effect, the code became longer and more complicated for analysis. The longest observed *Locky* first stage code has a length slightly more than 1 Megabyte - exactly 1064661 bytes<sup>2</sup>. The code presented in the Fig. 1 as Original Code with high probability was manually de-obfuscated by a security analyst (used variables, function names and all parameters use human readable names). However, obfuscated code with the same functionality can be observed in real samples sent to the victims. Fig. 1 presents a few sample obfuscation techniques (parts A, B, and C).

In all three presented cases variables with strange names (*Njofagi*, *DqWgVQeF*, and *JBGUHYm2e*) represents ActiveXObject *MSXML2.XMLHTTP*, which is used for preparation of a HTTP request and downloading of the *Locky* second stage code. The first obfuscated excerpt code presented in the Fig. 1 obfuscate only variable names. Code presented in excerpt B encodes parts of JavaScript code using Unicode. Despite complicated appearance, this code can be easily de-obfuscated even using Unicode decoding services freely available online<sup>3</sup>. The last excerpt in Fig. 1 presents a technique in which the program text parts (like web server address and

function names as well) are divided into short chunks and dynamically concatenated before use. Code excerpts are taken from the samples with code lengths of 2468<sup>4</sup>, 1707<sup>5</sup>, and 533256<sup>6</sup> bytes.

A huge span of sizes of the *Locky* first stage code sizes was observed - from below 1000 bytes to more than 1 MiB during the analyses period. The most evident strange behaviour which was observed between April and May concerns a sharp rise of the JavaScript code size. Analysis of these samples revealed that core part of the code is similar to the already observed. However, some random text is placed in variously defined comments<sup>7</sup>. Further samples, with even larger sizes have introduced various lines of random text, for example, a repeated pattern of '12345667890'<sup>8</sup>. We suspected that these changes in code utilize some flaws in security software, for example, anti-virus software which cannot properly detect malware in such a big JavaScript code.

Analysing another sharp rise in the size of the exploits (from a few kibibytes to more than 10 KiB) showed that a new kind of obfuscation was introduced by the attackers: the whole protected JavaScript code is partitioned into some small chunks and concatenated just before the execution<sup>9</sup>.

In the third case, instead of partitioning the code into chunks, a final code is included as an encrypted text. The simple mono-alphabetic cipher is used. The most characteristic part of this type of downloader is a slightly obfuscated array used in decryption procedure of the final downloader code.

In another case a completely different kind of the first stage code was identified. Previously used *Locky* downloader was directly downloading a second stage executable. However, around 24th of May this behaviour changed: *Locky* started to download a second stage malware which was encrypted.

During the conducted research we observed the evolution of the used encryption techniques. The first encrypted samples (which appeared first on distribution servers at 24th of May) were using a simple mono-alphabetic substitution cipher. Decryption code implementation uses *XOR* function with a single byte key - even during viewing of such file in hex-editor, the repeating strings of the same byte can be observed (due to many 0-valued bytes in the Windows executable format). To hinder the analysis, the attacker reverses the whole file and adds a few random bytes at the end of the file. Due to the used key - 0x73, which represents in the ASCII letter *s*, a downloaded second stage file in hex-editor have a catching in the eye numerous strings of letter *s*.

In the following weeks some longer keys were observed. The longest one was automatically generated from two numbers and have a length of 256 bytes. However, from the June 2016 in most cases some shorter keys were observed - in the most cases using 32 bytes of ASCII characters. Due to the fact that most hex-editors presents in one line multiplicity of 8 or 16 bytes, this size of a key produce repeatable pattern easily visible in the viewed file, which in effect simplify reproduction of the original key. Despite these drawbacks, this behaviour was most common to the end of the year. However, occasionally other key lengths appear, but all of them are only within ASCII characters range.

Additional change in the downloaded second stage of the *Locky* malware, which appears together with encryption, concerns a format of the executable which takes the form of DLL library. The DLL-based second stage samples appeared for the first time at the 29th of August 2016. Usage of the DLL is well known hinder behaviour used nowadays by the attackers. However, owners of the *Locky* have extended this technique. In the previously analysed malware, the samples distributed as a DLL required a usage of the *rundll32* utility - *Locky* samples do not run by the execution of a standard DLL entry function executed by the *rundll32*. To make it difficult, *Locky* malware uses additional entry function, which name is included in the encrypted first stage code. Moreover, the name of that secret entry function was not given in the exported functions table. After some initial investigation, we suspect that the used entry function is dynamically decrypted by some other standard entry function. In effect, to run *Locky* malware sample, this entry function must be discovered before any further analyses. So, to conduct dynamic analysis of such sample, some modifications of the analysing environment have to be introduced.

To the end of the November only one simple entry function name was used ("qwerty"). Later, this entry function was changed more and more often - at the end almost on daily basis. The last analysed *Locky* campaign used 25 of such functions.

#### IV. MALWARE DEFENCE TECHNIQUES

Malware evolution is driven not only by new attack possibilities, but also by the need to obstruct analysis efforts. The longer analyses of malware behaviour means longer activity in the environment – infection of thousands of additional machines. So, the obstruction of analysis is a natural next step in the evolution of any malware.

To overcome static analysis efforts, malware can use various mixes of encoding, encryption, mutation and other operations (some real-life examples are presented in Sec. III). This made the dynamic analysis more and more important in the past years, yet malware creators are aware of that and also enhanced their software. The most basic, but very effective, malwares' defence strategy is to detect the fact of being analysed and just stop to do anything. Because dynamic analysis requires some supervisor software to be present, the easiest way for malware to detect the analysis is to check if it runs in a supervised environment or not. For example, a debugger connected to the infected process or execution on a virtual machine can mean that the software is being analysed. Malware does not need to make any additional checks for the potential reasons of debugging or presence of virtual environment – vast majority of users does not use debuggers and works on a real hardware, so, even if malware will loose some targets, it still gains a lot more.

Some common supervision detection techniques targeting Microsoft Windows operating system are described below. Nevertheless, variations of the same techniques can be also used by malware working on any other system.

1) *Checking for debugger presence using system API:* Standard Windows API library *kernel32* provides two functions which can be used by any software to detect debugger connected to the current process: *IsDebuggerPresent* and *CheckRemoteDebuggerPresent*. It is one of the simplest check a malware can perform, but will be effective against simple debugging of infected process.

2) *Checking for remote debugger presence:* Instead of relying on system API, a process can retrieve remote debugger information by directly querying the kernel using *NtQueryInformationProcess* from *ntdll* library. This method is used to retrieve *EPROCESS* structure that contains information about potentially connected remote debuggers.

3) *Checking PEB structure:* Low level check of debugger presence can be achieved by direct read of *BeingDebugged* flag from the *PEB* structure which is available at a predefined address for each process (i.e. *fs:[0x30]* on 32-bit system and *gs:[0x60]* on 64-bit). Reading this flag requires some assembly code, but makes software independent from any external library.

4) *Instruction execution time measurement:* It is harder to determine if a program executes in a virtual or real machine, as, in theory, virtualization should be transparent to the guest system (end its processes). However, the simplest check can be achieved by measuring the execution time of a single processor instruction - in a virtual system this time is longer. Using the *RDTSC* instruction a program can read *TSC* registry

value, which contains the number of cycles since the last processor power-on. Comparing two consequent reads with some expected difference can hint the presence of additional virtualization layer between the hardware and the software. Although simple, this method is not very accurate and can yield many false positives.

5) *Validating machine and user name:* Names of machines used by analysis systems can contain strings like *maltest*, *sandbox*, *virus* etc. Malware can compare current machine or user name against dictionary to quickly get hint for being analysed. Library *advapi32* provides the method *GetUserName* for reading user name while the *kernel32* library provides machine name via *GetComputerName* method.

6) *Validating peripherals properties:* Various hypervisors can use some predefined names for emulated peripherals. For example *Hyper-V* uses its name in the name of some peripherals, including BIOS name and version. Other properties which can be used by a malware include MAC address of a network card, which usually comes from a pool assigned for the virtual machine manufacturer. Reading those values usually requires checking various keys from *Windows Registry*.

7) *Checking parent process name:* Usually a malware after infection is executed on each user login (parent process: *explorer.exe*) or as a system service (parent process: *svchost.exe*). Other parent processes can mean that malware sample was executed by some kind of a supervisor process, which is sometimes needed even in virtualized environment. Process parent can be found in *PROCESSENTRY32* structure, which can be queried using *Process32First* and *Process32Next* functions from the *kernel32* library.

8) *Expecting cursor movements:* Some malware tries to detect if there is any real live user interaction ongoing before deciding to attack the system. One of the easiest techniques malware uses is to check a mouse cursor position on the screen. Basic, virtual machine based, sandboxes, executed in automated way for the analysis do not simulate mouse cursor movements. Process can acquire cursor status using *GetCursorInfo* provided by the *user32* library.

#### V. STEALTHGUARDIAN

Overcoming malware counter-analysis efforts is required to continue with efficient dynamic analysis of future samples. The idea is to enhance the system for the analysis in such a way that it will appear as stealth to the analysed sample as possible. Various techniques of achieving that goal were developed, tested and implemented in the authors' Institute as a *StealthGuardian* software. It wraps the execution of a sample providing additional layer upon the operating system. It can be integrated with any analysis system as it does not introduce any new requirements for the supervisor system. In our Institute it became a part of the MESS infrastructure - a supervisor program running inside a sandbox virtual machine, which is used in MESS to launch the analysed sample, can now launch *StealthGuardian* which then executes the sample for the analysis.

First tested solution was based on attaching to the executed sample as a debugger and switching into *single-step* execution mode. However, this extremely reduces the performance of the analysis – sample execution can take even a couple of thousand times longer. This technique could still be used if a *single-step* would be turned on only for some critical parts of the sample execution, but some preliminary analysis of the sample has to be performed to determine these parts.

The obstruction techniques described in Section IV can be divided into two groups based on a method of implementation: 1) direct processor instruction execution, 2) Windows API methods call. Using a debugger can handle the first group and some of the calls from the second group - those which can be easily recognized as assembly instruction sequence. But recognizing all the calls using a debugger seems to be too complicated and costly in terms of the performance. So, the proposed solution requires capturing all the calls of API functions and temper with their results before providing them to the analysed sample. It will not cover all the techniques used by malware but it is effective and efficient.

Capturing Windows API calls can be achieved using *inline hooking* technique. It involves replacing the code of the selected library functions with the calls to the substituted functions, which then can call the original functions. A *trampoline* is quite well known and popular technique, so various implementations are available. *StealthGuardian* uses *MinHook* library<sup>10</sup> to intercept Windows API calls responsible for malware defence techniques described in Section IV. To make it work properly, it was necessary to prepare both *x32* and *x64* versions of *StealthGuardian*, so it can work with all architectures used by different malware. It was also necessary to overcome some other technical issues, like supporting both ASCII and UTF versions of some API functions and hooking libraries loaded by direct calls to the *LoadLibrary* function, even in new threads or processes spawned by the original (parent) process. Proper behaviour of the hooked methods had to be designed – returning completely random values may not trick smart malware (e.g. user name can be random, but has to be constant for the whole sandbox execution).

Final version of *StealthGuardian* was able to trick special sample prepared in the Institute, which was using all supported by *StealthGuardian* defence techniques. Following experiments on some real samples also proved usefulness of this solution. For example, it allowed to observe the whole known behaviour of the *Win32/Urnsnif*<sup>11</sup>.

## VI. CONCLUSION

For the last few years we observe arms race between black hats and security community. Cybercriminals introduce new attack tactics which later are discovered, analysed and mitigated using new security mechanisms. When more and more users start using these mitigation mechanisms, cybercriminals introduce new methods and the cycle starts once

again. However, the time between the next cycle is decreasing. Few years ago we observed a new sample of a given malware family once a few weeks. During the analysis of the *Locky* we observed from two to three distinct samples daily.

These rapid changes of cybercriminal tactics are challenging for the security community. Conducted research showed that the usage of dynamic analysis could reduce the time needed for performing the analysis of a new malware sample. However, sometimes the changes introduced by the malware are so significant that the environment for the analysis must be upgraded. This paper describes with details some of these developments which allow the analysis of the most recently appearing malware samples.

**Abstract**—In this paper, a novel quantum encryption algorithm for color image is proposed based on multiple discrete chaotic systems. The proposed quantum image encryption algorithm utilize the quantum controlled-NOT image generated by chaotic logistic map, asymmetric tent map and logistic Chebyshev map to control the XOR operation in the encryption process. Experiment results and analysis show that the proposed algorithm has high efficiency and security against differential and statistical attacks.

## I. INTRODUCTION

QUANTUM information processing is a great of current interest for computer, mathematics, and physical scientists. It is a discipline devoted to the development of novel quantum protocols/algorithms for storing, processing, and retrieving visual information [1]. It will likely lead to a new way of technological innovations in computation, communication, image processing and cryptography since the quantum computation could overcome the inefficiency on classical computers [2].

The feature of quantum parallelism is utilized in quantum image processing to speed up various processing tasks such as quantum image encryption [3-11], quantum image steganography [12, 13], quantum image watermarking [14] and so on. Quantum image encryption is widely used to assure security in the information hidden into those images [3]. The algorithms for quantum image encryption could be mainly classified into three types: quantum scrambling, quantum diffusion and combination between them. The first task of quantum image processing is to capture and store the image on quantum computers. Quantum image can be represented for flexible processing by several methods like NEQR, FRQI, NCQI, etc. [15, 16].

In 2013, a quantum image encryption algorithm based on quantum Fourier transform and double random-phase encoding is proposed in Yang et al.'s work [4]. In 2014, based on color and restricted geometric transformations, Song et al. [3] presented a new quantum image encryption algorithm. One year later, based on double random-phase encoding and generalized Arnold transform, a quantum image encryption algorithm is proposed by Zhou et al. [8]. In 2016,

based on image XOR operations, Gong et al. [9] designed a quantum image encryption algorithm in which Chen's hyper-chaotic system is used to control the controlled-NOT operation. Also in the same year, Liang et al. [7] proposed a quantum image encryption algorithm based on generalized affine transform and image XOR operations controlled by logistic map. In 2017, by using iterative Arnold transforms and a hyper-chaotic system to control image cycle shift operations, a quantum image encryption algorithm is presented in Zhou et al.'s work [10]. However all quantum image encryption algorithms mentioned above used to encrypt only quantum gray-level images not quantum color images. In 2016, based on Chen's hyper-chaotic system, a quantum color image encryption algorithm is proposed in Tan et al.'s work [11]. To the best of our knowledge, in the earlier works, there is no quantum image encryption algorithm based on multiple discrete chaotic systems (e.g. logistic Chebyshev map and asymmetric tent map) for color images to increase the security of the encryption algorithm. So, the study of utilizing multiple discrete chaotic systems in quantum color image encryption algorithms is required.

In this paper, a novel quantum color image encryption algorithm is proposed based on multiple discrete chaotic maps. The proposed algorithm utilized the quantum controlled not image generated by logistic map, asymmetric tent map and logistic Chebyshev map. The quantum circuit of the proposed algorithm is devised based on NCQI [16] quantum color image representation. Based on simulations results and numerical analyses, the proposed quantum color image algorithm demonstrates the efficiency as well as security against differential and statistical attacks.

## II. BASIC RECALLS AND PRELIMINARY KNOWLEDGE

### A. Quantum color image representation

In this section, we give a brief overview of the novel quantum representation for color images (NCQI) [16], which is the basis of the proposed algorithm. For each pixel in an image, the NCQI model consists of color

information  $|c_i\rangle$  and its corresponding position information  $|i\rangle$ . The representative expression of a quantum color image can be expressed as follows.

$$|I\rangle = \frac{1}{2^n} \sum_{i=0}^{2^{2n}-1} |c_i\rangle \otimes |i\rangle, |c_i\rangle = |c_i^{23} \dots c_i^1 c_i^0\rangle, c_i^k \in \{0,1\} \quad (1)$$

For more details about NCQI representation see [16].

### B. Chaotic systems

#### 1) The logistic map

The definition of the logistic map can be seen as in Eq (2).

$$x_{i+1} = \delta x_i (1 - x_i)$$

(2)

where  $x_0 \in (0,1)$  and  $\delta \in (0,4)$  are the initial value and control parameter respectively.

#### 2) The asymmetric tent map

The definition of the asymmetric tent map can be seen in Eq.(3) which is the enhanced version of the tent map.

$$y_{i+1} = \begin{cases} \frac{y_i}{\beta} & \text{for } y_i < \beta \\ \frac{(1-y_i)}{(1-\beta)} & \text{for } y_i \geq \beta \end{cases}$$

(3)

where  $\beta \in (0,1)$  and  $y_0 \in (0,1)$  are the control parameter and initial value in the map respectively [17].

#### 3) The logistic Chebyshev map

The definition of the logistic Chebyshev map [18] can be seen in Eq(4).

$$z_{i+1} = \left[ \alpha z_i (1 - z_i) + \frac{(4 - \alpha) \cos(a \times \arccos(z_i))}{4} \right] \bmod 1 \quad (4)$$

where  $z_0 \in (0,1)$  is the initial value and  $\alpha \in (0,4)$  is a control parameter.  $a \in N$  refers to the degree of the Chebyshev map.

### III. PROPOSED QUANTUM IMAGE ENCRYPTION ALGORITHM

In this section, we introduce a quantum color image encryption algorithm utilizing quantum controlled not image which is obtained by the multiple discrete chaotic systems. In the proposed algorithm, multiple chaotic maps are used to generate the controlled not image, such as chaotic logistic map, asymmetric tent map and logistic Chebyshev map

shows the quantum circuit of the proposed encryption algorithm.

The encryption procedures of the proposed algorithm are illustrated as following:

**Step 1:** select initial value for  $x_i$  and value for  $\delta$  where  $x_0 \in (0,1)$ ,  $3.85 \leq \delta \leq 4$  as a secret key in the Logistic map.

$x_{i+1} = \delta x_i (1 - x_i)$ , where  $i = 0, 1, 2, \dots, 2^{2n}$ , ( $2^{2n}$  is the image size).

**Step 2:** select initial value for  $y_i$  and value for  $\beta$  where  $y_0 \in (0,1)$ ,  $\beta \in (0,1)$  as a secret key in the asymmetric tent map.

$$y_{i+1} = \begin{cases} \frac{y_i}{\beta} & \text{for } y_i < \beta \\ \frac{(1-y_i)}{(1-\beta)} & \text{for } y_i \geq \beta \end{cases}$$

where  $i = 0, 1, 2, \dots, 2^{2n}$ , ( $2^{2n}$  is the image size).

**Step 3:** select initial value for  $z_i$  and value for  $\alpha$  where  $z_0 \in (0,1)$ ,  $\alpha \in (0,4)$  as a secret key in the logistic Chebyshev map.

$$z_{i+1} = \left[ \alpha z_i (1 - z_i) + \frac{(4 - \alpha) \cos(a \times \arccos(z_i))}{4} \right] \bmod 1$$

where  $i = 0, 1, 2, \dots, 2^{2n}$ , ( $2^{2n}$  is the image size).

**Step 4:** transform the three sequences  $\{x_i\}$ ,  $\{y_i\}$  and  $\{z_i\}$  that generated from chaotic maps into integer sequences as follows:

$$x_i^* = \lfloor \text{fix}((x_i - \text{fix}(x_i)) \times 10^{14}) \rfloor \bmod 256$$

$$y_i^* = \lfloor \text{fix}((y_i - \text{fix}(y_i)) \times 10^{14}) \rfloor \bmod 256$$

$$z_i^* = \lfloor \text{fix}((z_i - \text{fix}(z_i)) \times 10^{14}) \rfloor \bmod 256$$

**Step 5:** generate the three layers of controlled color image using the three sequences  $\{x_i^*\}$ ,  $\{y_i^*\}$  and  $\{z_i^*\}$  then transformation it to quantum color image.

$$|J\rangle = \frac{1}{2^n} \sum_{j=0}^{2^{2n}-1} |c_j\rangle \otimes |j\rangle, |c_j\rangle = |c_j^{23} \dots c_j^1 c_j^0\rangle, c_j^k \in \{0,1\}$$

**Step 6:** Transform the original image into quantum form as follows:

$$|I\rangle = \frac{1}{2^n} \sum_{i=0}^{2^{2n}-1} |c_i\rangle \otimes |i\rangle, |c_i\rangle = |c_i^{23} \dots c_i^1 c_i^0\rangle, c_i^k \in \{0,1\}$$

**Step 7:** The quantum color image  $|I\rangle$  encrypted by applying the controlled-not operations controlled by the quantum color image  $|J\rangle$  as shown in Fig. 1.

#### IV. NUMERICAL RESULTS

To simulate the proposed quantum color image algorithm, a personal computer with Intel Core™ 2Duo CPU 3.00 GHz and 4 GB RAM equipped with software MATLAB R2009b (version 7.9.0.529) are used to perform operations on quantum images. Lena and baboon images of size  $(256 \times 256)$  are used as the test images (see Figure 2). The simulation parameters as a secret keys used in logistic map are  $x_0 = 0.321$  and  $\delta = 3.9842$ , in asymmetric tent map  $y_0 = 0.5678$  and  $\beta = 0.7$  and in logistic Chebyshev map  $z_0 = 0.345$ ,  $a = 222$  and  $\alpha = 3.2$ .

##### A. Correlation of adjacent pixels

In ordinary images each two pixels are highly correlated with each other, so correlation coefficients in each direction (vertical, horizontal and diagonal) close to 1 while in encrypted images using a good encryption algorithm close to 0. Table 1 stated the correlation coefficients between adjacent two pixels in each direction for the encrypted images and their corresponding original images. Figs 3, 4 and 5 show the correlations of two neighboring horizontal, vertical and diagonal pixels in red, green and blue values, respectively for Lena image. It is obviously that the correlations coefficients for the encrypted images are close to 0. So that, there is no information obtained about the original image by analysis the correlations of neighborhood pixels for encrypted image.

##### B. Histogram analysis

Image histogram is an essential tool to assess the performance of any image encryption algorithm. It demonstrates the frequency distribution of pixel values in one image. The good secure encryption algorithm should resist against various brute force attacks by ensuring the uniform histograms in different encrypted images. The histograms of RGB pixel values for image Lena before and after encryption process are shown in Fig. 6. It can be seen from Fig. 6, the histograms of RGB pixel values for original image are completely different from the histograms of their corresponding encrypted image and the histograms that belong to encrypted image are very similar with each other. So we can conclude that the histogram analysis attacks can be resisted in the proposed quantum color image algorithm.

##### C. Key space analysis

Key space is the space of several keys that can be used in attack process. Large key space to resist the brute-force attack is an another tool to evaluate the security for a good image encryption algorithm. The proposed algorithm has six initial values that have infinite decimals points for  $x_0$ ,  $y_0$ ,  $z_0$ ,  $\delta$ ,  $\beta$  and  $\alpha$  in addition to  $a$  as a secret keys. The key space of  $x_0$  only is  $10^{14}$ . Also  $y_0$  and  $z_0$  each of them have key space  $10^{14}$ . Thus the total key space 1

proposed algorithm is  $10^{42}$ , in addition the key spaces of  $\delta$ ,  $\alpha$  and  $\beta$ .

Fig. 6: Histograms of original and encrypted image Lena.

$$\begin{aligned} x_0 &= 0.321, \delta = 3.9842, \\ y_0 &= 0.5678, \beta = 0.7, \\ z_0 &= 0.345, a=222 \\ &\& \alpha = 3.2 \end{aligned}$$

$$\begin{aligned} x_0 &= 0.322, \delta = 3.9842, \\ y_0 &= 0.5679, \beta = 0.7, \\ z_0 &= 0.346, a=222 \\ &\& \alpha = 3.2 \end{aligned}$$

$$\begin{aligned} x_0 &= 0.321, \delta = 3.9843, \\ y_0 &= 0.5678, \beta = 0.8, \\ z_0 &= 0.345, a=222 \\ &\& \alpha = 3.3 \end{aligned}$$

$$\begin{aligned} x_0 &= 0.322, \delta = 3.9843, \\ y_0 &= 0.5679, \beta = 0.8, \\ z_0 &= 0.346, a=223 \\ &\& \alpha = 3.3 \end{aligned}$$

Fig. 7: Decrypted image Lena with several keys

TABLE I.  
CORRELATION COEFFICIENTS OF ADJACENT PIXELS

image	direction								
	Vertical			Horizontal			Diagonal		
	R	G	B	R	G	B	R	G	B
Original (Lena)	0.9512	0.9496	0.9408	0.9796	0.9639	0.9649	0.9279	0.9179	0.9190
Encrypted (Lena)	0.0282	0.0035	-0.0137	-0.0348	0.0207	-0.0357	0.0212	-0.0464	-0.0422
Original (baboon)	0.9460	0.8634	0.9281	0.9089	0.8582	0.9203	0.9011	0.7992	0.8876
Encrypted (baboon)	-0.0088	-0.0206	0.0215	0.0305	0.0296	0.0101	-0.0128	-0.0279	0.0146

#### D. Key sensitivity analysis

Key sensitivity is known as the sensitivity of the secret key to decrypt effect which is the essential property for good image encryption algorithm. To ensure the key sensitivity in the proposed algorithm, the following tests were carried out with several keys as shown in Fig. 7.

#### V. CONCLUDING REMARKS

This paper has presented a quantum color image encryption algorithm by utilizing multiple discrete chaotic maps. It used the quantum controlled not image generated by multiple maps. Based on NCQI quantum color image representation, the quantum circuit of the proposed quantum encryption algorithm for color image is devised. The simulations results and numerical analyses show that the proposed algorithm has high efficiency and security against several attacks.

#### ACKNOWLEDGMENT

The authors would like to extend their sincere appreciation to the Deanship of Scientific Research at King Saud University for funding this Research group NO.(RGP#229). Also, this work is supported by Guangdong Natural Science Foundation: 2015A030310172.

**Abstract**—In this paper, we present the TARZAN platform, an integrated platform for analysis of digital data from security incidents. The platform serves primarily as a middleware between data sources and data processing applications, however, it also provides several supporting services and a runtime environment for the applications. The supporting services, such as a data storage, a resource and application registry, a synchronization service, and a distributed computing platform, are utilized by the TARZAN applications for various security-oriented analyses on the integrated data ranging from an IT security incident detection to inference analyses of data from social networks or crypto-currency transactions. To cope with a large amount of distributed data, both streamed in real-time and stored, and for the need of a large scale distributed computing, the platform has been designed as a big data processing system ensuring reliable, scalable, and cost-effective solution. The platform is demonstrated on the case of a security analysis of network traffic.

## I. INTRODUCTION

THE ABUNDANCE of data sources and the exponential growth in the volume they produce represents new challenges for many traditional ICT fields. Digital forensics and security incident analysis is not an exception. Every day, security analysts and investigators face the problem of insufficient tool support. The roots of this problem lie in the fact that this dramatic change in the heterogeneity and volume of data makes the existing methods obsolete.

Traditional workflow of digital forensic consists of the well-defined procedure of data identification, acquisition, preservation, analysis, and reporting. This workflow was devised and refined in the 1990s when the environment regarding computing technology and software was rather uniform. Also, the amount of data that needs to be processed was from our perspective rather small. For most cases, it was possible to perform all above-mentioned steps using a single forensic workstation. Because of the rapid technology advances in the ICT, this is no longer true. Not only the increasing amount of data caused by the drop of storage cost and dissemination of broadband connectivity represents the challenge for digital

forensics. Often even the data acquisition phase is difficult to achieve with the existing tools and considering the usual methods of creating the forensic image of the disk drive. Completing this operation for nowadays common terabyte hard drive lasts several hours.

Investigators also need to face the problem of high diversity of computing devices. Smartphones, tablets and other connected smart devices massively penetrate the market. Cloud services are another emerging technology that changes the requirements on the digital forensics methods. All of this means that classical approach represented by well-defined workflow and considering the use of a single forensics workstation cannot meet the current demands. In many cases, the amount of data that to be processed exceeds several terabytes. Also, some forms of cyber crime comprise of the combination of several sophisticated techniques, and for their investigation, it is necessary to process and correlate information from several big datasets. To cope with this problem, several researchers suggested to apply big data approach, e.g. [1], and this field has become an active research area.

In this paper, an integrated platform for analysis of digital data from security incidents (a TARZAN platform) is proposed to address the issues mentioned above. The platform allows to gather, store, and process digital forensic data as big data to perform various security-oriented analyses that range from an IT security incident detection to inference analyses of data from social networks or crypto-currency transactions.

The paper is organized as follows. Section II discusses related work on data security analysis and processing platforms. In Section III, we provide a case study of a PCAP analysis tool utilizing the proposed platform for real-time security analysis of network traffic. Section IV introduces the TARZAN platform and describes its architecture and core services. The results of the case study implementation on the platform are discussed in Section V. Finally, we draw conclusions in Section VI.

## II. RELATED WORK

Several approaches were already proposed to perform security, forensic, and inference analyses. Because conventional technologies are not always adequate to support long-term, large-scale analytics [2], big data approaches to the digital

This work was supported by Ministry of Interior of the Czech Republic project “Integrated platform for analysis of digital data from security incidents” VI20172020062; Ministry of Education, Youth and Sports of the Czech Republic from the National Programme of Sustainability (NPU II) project “IT4Innovations excellence in science” LQ1602; and by BUT internal project “ICT tools, methods and technologies for smart cities” FIT-S-17-3964.

forensics started to emerge addressing their own challenges (see [3], [1]). However, the most of the existing approaches focused on particular selected topics of IT security, related often only to networking security, rather than providing a general framework to support and integrate various forensic data to analyse them and their inferences in a broader context, such as in the cases of [4] and [5].

In [4], a digital forensic data reduction process were proposed based on a selective imaging, to speed up the forensic process by locating evidences, or by providing examiners with a quick understanding of the data to enable a better focus for full analysis (e.g., for a cross-device or cross-case analysis). Although the proposed process is general enough to support the examination of various types of the stored big data, it is not designed for custom autonomous big data analyses.

Feature Collection and Correlation Engine (FCCE, [5]) was introduced to find correlations across a diverse set of data types spanning over large time windows with very small latency and with minimal access to raw data. The engine entailed a complete framework for ingesting, aggregating, storing, as well as retrieving big data, by implementing feature extraction, aggregation, storage, and retrieval APIs, respectively. It was applied in IT security to detect fluxing domain names and identify persistent threat infections. However, the engine did not provide an implementation platform to build system utilizing the implemented APIs.

Network forensic analysis, which is the subject of the case study presented in this paper to demonstrate the TARZAN platform (see Section III), comprises of methods for capturing, collecting and analysing network data for information gathering, evidence identification, or security incident investigation. A new generation of Internet services opens space for new cybercrime activities. Security analyst and Law Enforcement Agency officers have to act accordingly to detect unlawful or unauthorized activities efficiently. The investigation is not possible without the tool support. While technology advances provide hardware technology able to capture communication at speeds that match current wire speed the software equipment for analysis of captured traffic has difficulties with packet traces of several gigabytes.

Network forensic analysis methods were implemented in various tools. General purpose tools include network analysers (Wireshark, TCP dump), IDS systems (Snort, Bro), fingerprinting tools (Nmap, p0f), and tools to identify and analyse security threats.

Tools dedicated to network forensic analysis implement specific features to aid investigation process. They can capture an entire network traffic and allow an investigator to analyse it and reconstruct the communication. Several widely used open source tools exist. In the following, we briefly overview three freely available tools that employ the typical features. Survey of network forensic tools can be found in [6].

PyFlag is a general purpose forensic package which can be used as disk forensics, memory forensics, and network forensics tool. This tool was developed by M. Cohen of Australian Federal Police in 2005 [7]. PyFlag is designed around the

Virtual File System concept. For each supported data source a specific loader is implemented. To deal with PCAP files, the PCAP filesystem loader opens PCAP file, parses and dissects individual packets up to lower layer protocols, collects related TCP packets into streams and finally applies higher level protocol dissectors. A forensic investigator is usually interested in high-level information that can be extracted from the communication. PyFlag enables to reassemble the content of communication, e.g., web pages, email conversation, etc.

Network Miner<sup>1</sup> is an open source tool that integrates packet sniffer and higher-layer protocol analysers into a tool for passive network traffic monitoring and analysis. Because captured traffic can be processed in the same way, Network Miner is also a valuable tool for network forensics analysis. Network Miner offers several useful features, such as the possibility of operating system identification, traffic classification, and reassembling the transferred files for HTTP, FTP, TFTP and SMB protocols.

Xplico<sup>2</sup> is a modular tool aimed at the reconstruction of the data content carried in the network traffic. The software consists of the input module handling the loading source data, decoding module equipped with protocol dissectors for decoding the traffic and exporting the content, and the output module organizing decoded data and presenting them to the user. Contrary to PyFlag and NetworkMiner, Xplico is not a typical desktop application but it is deployed as a server service with the web-based interface. The authors claim the possibility to analyze large PCAP files of many gigabytes. Because the Xplico design is a classical client-server architecture, the performance of the tool is limited by the hardware configuration of the server running the Xplico backend.

To analyse the network traffic as big data, a scalable internet traffic analysis system was presented in [8]. The system, which was able to process multi-terabytes libpcap dump files, utilized Apache Spark for data processing to analyse captured transmitted data and protocol fields. Unfortunately, the system did not allow to integrate non-network data and perform the analyses of the network data in broader contexts.

Another approaches to the network traffic security big data analysis were presented in [9], [10], [11], and [12]. Apache Metron [13] and Apache Spot [14] projects are more interesting. They try to form general frameworks for security analyses of IT threats, secondary processing also firewall and application logs, emails, intrusion-detection reports, etc. However, analogously to the first case, also the all of these approaches were focused primarily and narrowly on the network data and unable to find correlations with other forensic data or to provide a comprehensive platform for big data forensics.

### III. CASE STUDY: PCAP ANALYSIS

Digital investigators process network traffic as a source of evidence in many types of computer crimes. Captured traffic can be analyzed to obtain the content and also to show

<sup>1</sup><http://www.netresec.com/?page=NetworkMiner>

<sup>2</sup><https://github.com/xplico/xplico>

the actions taken by the offender. Network traffic can also be important for corroborating evidence. Obtaining network traffic as a source of evidence is usually more complicated than other digital evidence. Transmitted data are only available on the network device for a limited amount of time. Inappropriate collection method can lead to data corruption or incomplete capture. As messages exchanged between applications are segmented into many pieces, it is important to gather all relevant packets and be able to combine them again into data streams. When collecting data on shared links, there may be a huge amount of traffic from which only a fraction is relevant to the investigation. Moreover, many different protocols are in use which requires applying corresponding decoding algorithms. Although existing tools for information security can be adapted for a forensics investigation, they usually lack features for evidence collecting and preservation. For the forensic investigation, there are two important activities, namely examination and analysis [15]. The examination is characterized by the mostly automatic data processing that ends with a collection of relevant data extracted from the data source. The analysis follows examination, and it is often a manual or more interactive activity that interprets the significance and meaning of the extracted data. Also, data correlation, finding links and patterns in the extracted data is the desired result of the analysis.

From the examination viewpoint, the important features of network forensic tools are as follows:

- *Flow reconstruction.* Because network conversation is split into many packets exchanged by communicating applications, the first step of data examination is to combine these fragments to form flows again.
- *Protocol identification.* Network communication is governed by protocols. There are many protocols in the Internet communication. The ability to identify which protocol was used to data exchange is crucial for further processing. Protocol identification is difficult for encrypted traffic where traditional pattern based methods may be less accurate results.
- *Protocol decoding.* To understand the communication we often need to extract data from protocol header fields and data payload. Network forensic tools support a wide variety of protocols. Sometimes these decoders can identify anomalous packets that do not conform to the protocol specification.
- *Data reduction.* Not all data needs to be analyzed. Data reduction can filter out uninterested data. The filter applied depends on the information obtained from the protocol decoding step. We can be, for instance, interested only in Web traffic.
- *Data recovery.* If communication is not encrypted, the communication payload is visible. This gives us the possibility to recover digital objects from the communication such as web pages, images, e-mail messages.
- *Pattern search.* The common investigative approach is to search for occurrences of known patterns, e.g., email

addresses, keywords, etc. Pattern search in network traffic needs to consider specifics of various protocols, such as encoding, compressing, etc.

Forensic data analysis can involve different methods and procedures. The following techniques are commonly applied:

- Developing the *timeline* from significant events offers investigators a high-level view on the extracted data. Different kinds of communication can contribute to timeline by various events, such as e-mail delivery, web search, file download, etc.
- The *temporal analysis* aims to identify patterns or anomalies that are often processed by the further and deeper analysis. For instance, we are seeking for the periods of peak data transfer or occurrences of an unusual protocol.
- The *relation analysis* provides links among different entities. Relations can be analyzed on different layers, linking devices, services, or end-users
- *Classification* methods assign extracted data to different classes according to the predefined criteria, such as system traffic, web traffic, suspicious traffic, malware related traffic, etc.
- *Clustering* techniques can deal with a lot of entities by grouping them according to some essential characteristics. Often these methods do not require learning and thus are easily applicable.
- *Correlation* is a statistical technique that can identify the relation between different entities. It is, for instance, possible to identify the same activity recorded in various data sources.

Digital investigation is a time-consuming and labor-intensive process. Thus, there is a strong emphasis on using tools that can reduce the examination time and improve the automatization of analysis activities. In the next section, we will show, how the proposed platform can achieve both requirements. First, examination time can be reduced by allocating more computation nodes. Second, some analysis can be automated by applying machine learning algorithms.

The complex PCAP analysis requires processing of a huge amount of data. The processing must be done both in real-time to detect security incidents or to perform security audits, and later on large stored datasets to answer queries of an analyst. As the such processing is difficult to do by conventional centralized approaches in highly scalable, high-throughput, and fault-tolerant way [2], the PCAP analysis tool will be implemented on the TARZAN platform.

#### IV. THE TARZAN PLATFORM

To ensure communication of TARZAN applications and provide them with required services and a runtime environment, the TARZAN platform consists of three core components, namely, *Platform Bus* which implements a distributed communication bus for the applications and the components, *Platform Storage* which provides a distributed storage service (NoSQL databases, distributed filesystem, resource registries, etc.), and *Platform Computation* component to provide the

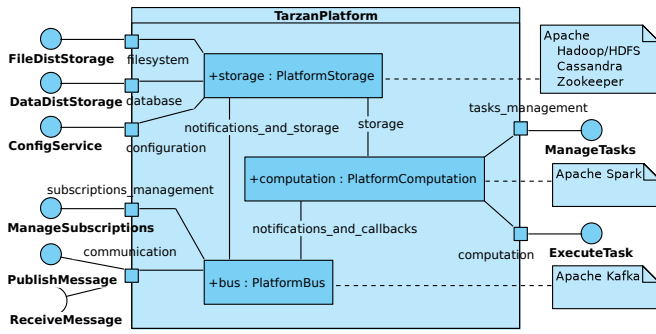

Fig. 1. The TARZAN platform architecture.

runtime environment for distributed computation tasks of TARZAN applications.

In Figure 1, architecture of the TARZAN platform is modelled in an UML composite structure diagram. Each of the three core components provides its services to TARZAN applications by the platform's external interfaces. Moreover, the components communicate and cooperate inside the platform. The individual components are described in the following sections.

#### A. Platform Bus

The main goal of the platform bus core component is to enable asynchronous communication of other TARZAN components. More specifically, the platform bus implements a *publisher-subscriber* communication model based on *message queues*. A client is able to publish messages to particular topics acting as a producer, or to subscribe to receive messages of particular topics as a consumer (see the corresponding interfaces in Figure 1). The platform bus guarantees delivery of the published messages to their appropriate consumers.

The communication via the bus is utilized by both external TARZAN applications and the core TARZAN components. In the first case, the applications can connect themselves to various data sources to ingest sensor data, events, logs, etc.; interconnect their components into data processing topologies to perform data parsing, normalizing, validating, marking, enrichment, etc.; and consume or feed data from/into the platform storage components. In the second case, the platform bus helps the other core components to send/receive their data, for example, to store the transmitted data into the platform storage and deliver the storage update notifications, or to deliver input data and pass output data of tasks of the platform computation including callbacks.

To achieve high-throughput message passing in highly scalable distributed environments, the platform bus is based on *Apache Kafka* [16]. In Kafka, messages are communicated in topics. Each topic, as a general category of particular messages, consists of multiple partitions (queues). A producer submits a message to a particular topic (or topics) where in each topic, the message is assigned to a particular single partition (automatically for load-balancing or as required by the producer). A consumer can belong to a particular consumer

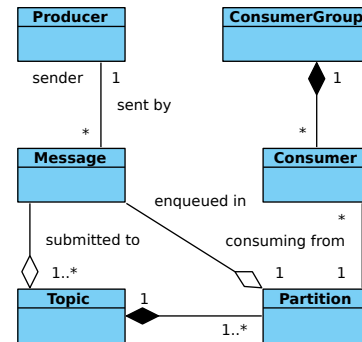

Fig. 2. A conceptual model of basic entities in Apache Kafka.

group and subscribes to one or more topics. In each of the subscribed topics, the consumer has assigned particular partition for exclusive reception. For relationships of these concepts, see Figure 2.

In TARZAN, Kafka's concepts of a message, topic, partition, producer, consumer, and consumer group are utilized for consuming data sources and communication with computation tasks as follows.

1) *Broadcasting from data sources*: A data source (producer) submits data (a message) of a particular type (topic) under the data source's identification (partition). A subscriber (consumer) listens to a particular topic and a particular partition, that is for messages of the particular type from the particular data source. A message will be received by (broadcasted to) all subscribed consumers in different consumer groups.

- Messages = data produced by the sources.
- Topics = individual data source types (e.g., PCAP).
- Partitions = particular data sources (e.g., a sensor monitoring a network traffic on a particular network interface).
- Consumer groups = subscribers for data produced by a particular data source (e.g., a component for processing/analysing/storing PCAPs).

2) *Load-balancing of data processing tasks*: A client (producer) submits a task invocation (message) to a particular service (topic) without any partition (it will be assigned automatically by Kafka for load-balancing). In the case of a request-reply task invocation, the message should contain also the client's identifier which will be utilized for the callback (a particular partition name in "callback" topic).

- Messages = task invocations including data payloads and callback addresses if needed.
- Topics = names of individual services (e.g., PCAP Analyzer).
- Partitions = individual instances of a particular service (e.g., a particular process of the PCAP Analyzer).
- Consumer groups = single-member groups representing the instances as above.

3) *Delivery of the tasks' replies*: A particular service task instance (producer) submits a reply/result (message) to the previously received task invocation as a callback. The reply (message) will be delivered to a particular client who sent the

task invocation (to his partition in “callback” topic).

- Messages = replies/results to the previously submitted task invocations.
- Topics = a single topic with name "callback" only.
- Partitions = one partition for each individual client.
- Consumer groups = single-member groups representing the clients as above.

### B. Platform Storage

While the platform bus described in the previous section is necessary for data processing, the platform storage implements the data persistence in distributed environments. The distributed data storage is the necessary requirement of distributed data processing to be able to scatter and deliver data across processing nodes. Three types of data storage services are supported: a distributed filesystem, a distributed database, and a distributed and synchronized configuration service (see the corresponding interfaces in Figure 1).

The platform storage services are utilized by both external TARZAN applications to provide a shared storage and by the core TARZAN components to store the platform runtime data. In the second case, the storage services are utilized for a resource registry of various resources accessed and manipulated by the platform (e.g., topic and partition names for the platform bus, or declarations and definitions of tasks in the platform computation components).

For the distributed filesystem and the distributed and synchronized configuration service, Hadoop Distributed File System (HDFS) from *Apache Hadoop* [17] and *Apache Zookeeper* [18] were adopted, respectively. Both software products are widely utilized in the TARZAN platform and well-integrated with other components. For example, the platform bus based on Apache Kafka is utilizing Zookeeper for message queue management and the platform computation component based on Apache Spark is utilizing HDFS for a data storage and Hadoop for a cluster management.

Although the distributed database service is not designated for a particular NoSQL database, *Apache Cassandra* [19] is the preferred database in the TARZAN platform. The main reason for this preference is a perfect integration of Cassandra with the rest of the software stack (e.g., well-established Cassandra-Spark and Cassandra-Kafka connectors). Moreover, Cassandra provides an optimal storage for large sensor data [20].

### C. Platform Computation

To support distributed computing on data communicated and stored in the TARZAN platform, the platform computation core component is provided. The component allows TARZAN applications to run tasks, e.g., to process (normalize/aggregate), enrich, label, combine, etc. the data and to utilize other TARZAN components.

Tasks for the platform computation component are registered by external application components and then they can be executed by TARZAN applications (for the corresponding interfaces, see Figure 1) as demonstrated in Figure 3 to perform malware or data-breach detections, or to analyse

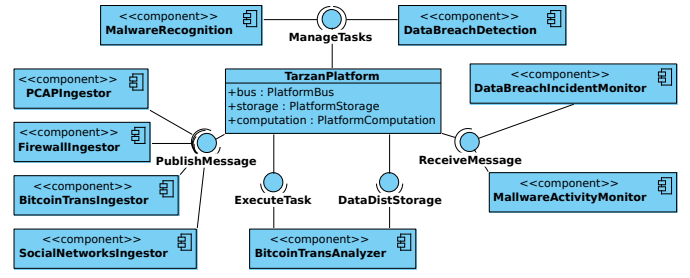

Fig. 3. An example of external application components utilizing the TARZAN platform (the ingesters on the left side are feeding data to the platform, computation tasks and an application on the top and bottom are processing the data, and the monitors on right side are passing results to clients).

Bitcoin transaction based on capture network traffic, firewall logs, Bitcoin blockchain, and social network profiles.

As the most of the use-cases for data processing in the TARZAN platform operate on big data (in the sense of data characterized by four Vs: volume, variety, velocity, and value [21]), the platform computation tasks must be able to do big data processing. The applications need to process both data streams and data batches (e.g., to do a real-time analysis of firewall logs and to execute on-demand tasks, respectively). Therefore, *Apache Spark* [22] has been selected as the implementation technology for the platform computation component and its tasks, as it supports both the stream and batch processing of big data.

For the batch data processing in Spark, computation tasks can utilize a data abstraction called *Resilient Distributed Dataset* (RDD) to execute various parallel operations on a Spark cluster and to gather resulting data in shared broadcast variables and accumulators provided by Spark on the cluster's nodes. In the case of the stream data processing, Spark Streaming provides computation tasks with *Discretized Stream* (DStream) abstraction where each stream is represented by a continuous series of RDDs that is divided into micro-batches and processed by the tasks in the similar way as in the batch processing above. Because DStreams follow the same processing model as batch systems, the two can naturally be combined [23] and the platform computation component and its tasks can implement identical algorithms for both the stream and batch processing.

## V. EVALUATION

The TARZAN platform has been evaluated by means of the PCAP analysis case study described in Section III. A corresponding TARZAN application has been implemented to read and analyse data of network traffic monitoring stored in the PCAP format. After the PCAP data are read from input PCAP files or real-time generated by network traffic monitoring tools, they are transferred (including their related meta-data) via platform bus for a primary analysis by tasks of platform computation. The tasks also ensure that both the input data and the output primary analysis results are stored in platform storage. Afterwards, a secondary analysis can

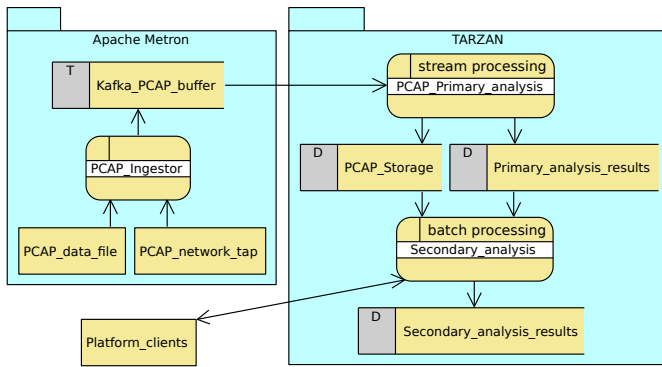

Fig. 4. Architecture of the PCAP Analysis tool with data-flows (including processes, data storages, and external data sources and entities).

be executed on the stored data and the previous results to perform various security and forensic analyses, e.g., to detect communication patterns, apply clustering methods for data mining, etc.

The primary analysis is operating on continuously incoming data and the primary analysis tasks implement real-time stream processing to quickly extract traffic basic features such as source and destination IP addresses and port numbers, defragment fragmented packets into network flows, analyse flow properties, application protocols, etc. These tasks utilize the Spark Streaming extension of the core Apache Spark API to process DStreams. In Spark, tasks are scalable, high-throughput, fault-tolerant, so the ability to process the incoming live data in real-time can be improved, if necessary, by an appropriate cluster configuration and the application deployment. However, the primary analysis must perform only basic analytical tasks.

Contrary to the primary analysis which employs real-time stream processing, the secondary analysis can implement a batch processing of the previously stored data and the primary analysis results. Therefore, the stored inputs can be represented as RDDs and processed by means of Spark RDD API, Spark SQL, and also machine learning algorithms provided by Spark's machine learning library (MLlib) can be applied. The secondary analysis is executed on demand as required by the platform's client applications, e.g., to provide data for visualisations, analyse network communications related to security incidents under investigation, or related to cryptocurrency transactions or malware activities.

The overall architecture of the PCAP Analysis tool is depicted in Figure 4. To feed input PCAP data into the system, several modules were adopted and adapted from the *Apache Metron* project [13], namely: *metron-sensors*, *metron-pcap*, and *metron-api*. In the first module, Apache Metron brings into TARZAN the integration of *Data Plane Development Kit*<sup>3</sup> (DPDK) probes for high speed packet capture and *Yet Another Flowmeter*<sup>4</sup> (YAF) to processes packet data from

PCAP dumpfiles (as generated by *tcpdump* or *libpcap*). The next two Metron modules provide a topology for streaming network packets into HDFS and low-level analytics/filtering on the PCAP files in HDFS before they are submitted into a Kafka message queue acting as a buffer for further processing. Then, a continuous stream processing in the primary analysis and an on-demand batch processing in the secondary analysis is performed by utilizing the TARZAN platform components as described above.

In comparison with the *Apache Metron* [13] or *Apache Spot* [14] discussed in Section II, the current implementation of the PCAP analysis tool in TARZAN provides the same basic functionality, however, it enables a better integration with the other TARZAN applications into a seamless security analysis framework where results of the PCAP analyses may contribute to various security investigations, e.g., to trace cryptocurrency transactions or malware activity.

In comparison with the existing approaches and the related work (see Section II), the TARZAN platform is a step further in the design and development of open forensic platform capable of processing big data. As we demonstrated in the PCAP analysis case study, our approach is compatible and easily integrated with other approaches to big data forensic. TARZAN applications can utilize HDFS as suggested in a conceptual model of big data forensics by Zawoad and Hasan [24]. Also a framework for the forensic analysis of big heterogeneous data presented by Mohammed et al. [25] can be realized using the TARZAN platform. Their framework has three layers that follow acquisition, examination, and analysis approach to extract metadata from acquired data sources and build a semantic web-based model for further analysis. While they do not specify the particular implementation of such system, the presented concepts are in accordance with the architecture of the TARZAN platform. Analogously, Irons and Lallie [26] discussed the shortcomings of the current analysis methods and suggested to use more intelligent techniques and demonstrated the possible application of artificial intelligence (AI) to computer forensics. The TARZAN platform can easily integrate the AI investigative methods because the underlying components provide rich libraries of various AI algorithms.

## VI. CONCLUSION

In this paper, we have introduced a TRAZAN platform, an integrated platform for analysis of digital data from security incidents. The architectural design has been presented to explain which core component are available in the platform and which services are provided to TARZAN applications. The platform allows to gather, store, and process digital forensic data as big data to perform various security-oriented analyses.

As a sample case study, a PCAP analysis tool has been implemented on the platform utilizing the platform bus component to integrate individual modules, the platform storage component to store input data and analyses results, and the platform computation component to perform both stream and batch processing of big data.

<sup>3</sup><http://dpdk.org/>

<sup>4</sup><https://tools.netsa.cert.org/yaf/>

It has been concluded that the TARZAN platform constitutes an open forensic platform capable of processing big data and provides a sufficient framework for further integration of various existing approaches. The integration of various existing approaches and existing tools for forensic analyses as external TARZAN components and applications is a part of ongoing work.

# High-Level Malware Behavioural Patterns: Extractability Evaluation

Jana Šťastná, Martin Tomášek  
Department of Computers and Informatics  
Technical University of Košice  
Letná 9, 042 00 Košice, Slovakia  
Email: {jana.stastna, martin.tomasek}@tuke.sk

**Abstract**—Many promising malware research projects focus on malware behaviour analysis, however, in the end they tend to build new detection systems and stick to measuring detection ratios. Our approach focuses on malware behavioural analysis for defining (characterising) malicious software on rather high level of abstraction, in order to break the endless cycle of evolving malware and malware analysts trying to catch up on new threats. As our research outlines, even such high-level behavioural information as numbers of occurrences of some behavioural events, can be successfully extracted from program samples and interpreted for extraction of repeating behavioural patterns. While this may seem simple at the first glance, there are plenty variables entering the process of behavioural data acquisition and pattern extraction.

## I. INTRODUCTION

A TRANSITION from syntactic to semantic view on malicious software leads the research in several last years. The reason for this change is quite simple: Traditional detection signatures, built upon fragments of executable code extracted from malicious samples, characterise a specific malware type on a syntactic level. However, syntactic features are relatively easy to obscure or modify, as also pointed out by Moser et al. [1], mainly by techniques of encryption, packing [2], [3], [4], polymorphism, metamorphism, and code obfuscation, implemented on control-flow or data-flow of a program [5].

Malware researchers try to deal with code morphism by behavioural detection. Yet, Borojerdi and Abadi point out in their work [6] that not every semantics-based technique is successful. The level of abstraction on which program's behaviour is captured plays an important role. They mention that patterns of system calls on low level of abstraction can be circumvented but behavioural patterns related to utilisation of specific system resources provide more optimistic results.

We believe that when malware and security researchers don't focus primarily on creating new detection mechanisms but on defining (characterising) malicious software on rather high level of abstraction, they will gain solid foundations for such detection mechanisms, which will not lose applicability after short usage - and that is also our main goal: searching for various forms for characterising malware, on varied levels of abstraction and detail.

The aim of our work, presented in this paper, is summarised as follows:

- We look for proper form of malware behaviour representation on high level of abstraction. Our current formulation of behavioural pattern is presented (Section II).
- We try to find out whether representation of malicious behaviour on high level of abstraction is feasible, in order to improve detection precision or expand scope of detected malicious behaviour in future research. We present behavioural data extraction (Section III) and success rate of behavioural pattern extraction (Section IV).

## II. HIGH-LEVEL MALWARE BEHAVIOURAL PATTERNS

Concerning level of abstraction for malware features extraction, in our research we decided for a strategy to start with the most general, abstract features describing behaviour, with a possibility to gradually employ more detailed features and lower the level of abstraction later, when appropriate. At the current state of our research we aim at categories of behaviour, based on the area of influence on the infected operating system, such as behaviour affecting filesystem, actions on processes, network activity, modifications on registry entries (Table I). Analysis of behaviour regarding these categories is quantitative, i.e. we observe how many times each category of behaviour occurred in analysed program sample.

On this level of abstraction, which is quite high, we managed to observe repetitions in amounts of behaviour occurrences among behavioural categories. As it turned out, there were groups of distinct malicious samples, belonging to the same types of infiltrations (malware signatures), which performed actions according to some pattern. In our initial

TABLE I  
12 CATEGORIES OF PROGRAM BEHAVIOUR WHICH TAKE PART IN  
FORMATION OF HIGH-LEVEL BEHAVIOURAL PATTERNS.

<i>FC</i>	file creation
<i>FD</i>	file deletion
<i>MC</i>	mutex creation
<i>PC</i>	process creation
<i>SC</i>	service creation
<i>SS</i>	service starting
<i>RE</i>	registry entry
<i>D</i>	DNS
<i>WD</i>	Winsock DNS
<i>HG</i>	HTTP get
<i>HP</i>	HTTP post
<i>TF</i>	TCP flow

work concerning this matter [7] we used formal notation to define high-level behavioural patterns as 12-tuple  $p_{label}$  of elements:

$$p_{label} = (n_{FC}, n_{FD}, n_{MC}, n_{PC}, n_{SC}, n_{SS}, n_{RE}, n_D, n_{WD}, n_{HG}, n_{HP}, n_{TF}), \quad (1)$$

$$n_{FC}, n_{FD}, \dots, n_{TF} \in \mathbb{N}^0,$$

where  $n_{FC}, \dots, n_{TF}$  are numbers of occurrences of behaviours, listed in Table I, and  $label$  is a name or an identifier of malicious signature with which is the pattern  $p$  associated.

The 12-tuple, as given in the definition (Equation 1), describes a case, when all samples of one type of infiltration (malware signature) show the same amounts of behaviour occurrences in behavioural categories, listed in Table I.

As we discovered by analysing behavioural data, such uniformity in behaviour is not that common and even if pattern is clearly recognisable, slight variability is present in some of behavioural categories. Thus, variability of behaviour occurrences was introduced in our work [7] by defining a set  $V_{label}$  of n-tuples  $v_k^l$ , which capture behaviour with varied occurrence and possibly group behaviours with potential interdependence (Equation 2):

$$V_{label} = \begin{cases} \emptyset, & \text{iff no variability in behaviour is present,} \\ \{v_1^l, v_2^l, \dots, v_k^l \mid v_k^l = (x_1, \dots, x_n), \\ x \in \mathbb{N}^0, \quad k, n \in \{1, 2, \dots, 12\}, \quad l \in \mathbb{N}^+, \\ \text{otherwise.} \end{cases} \quad (2)$$

Behavioural patterns can be graphically visualised for improved readability, e.g. Fig. 1 describes behavioural pattern with variability in behaviour occurrences.

The definition of pattern with variability of behaviour occurrences (Equation 2) is further explained and practical application is demonstrated in our work [7].

As the previous work showed, there are malware instances definable on high level of abstraction, by patterns comprising numbers of executed actions from 12 behavioural categories.

Fig. 1. Behavioural pattern of malicious program samples with signature labelled internally as E. Analysed samples demonstrated minor variability in number of behaviour occurrences regarding categories: *Registry entries*, *DNS*, *HTTP GET* and *TCP flows*. We avoid stating the real signature label on purpose, because disclosing such details may negatively influence employability of presented behavioural patterns in potential detection mechanisms.

### III. MALWARE BEHAVIOURAL DATA EXTRACTION AND SOURCES

In the work aimed at defining malware, the nature of analytic data resources, their quality, and process of extraction, determine the end results of research experiments.

In several last years a form of crowdsourcing gains popularity concerning malware data acquisition. Online analytic services like *Totalhash*<sup>1</sup> or *VirusTotal*<sup>2</sup> provide numerous anti-virus engines or analytic tools to analyse user-provided suspicious files and assemble all analytic results. Not only they provide the analytic service, they serve also as a repository of previous analyses.

Our initial research in high-level malware behavioural patterns employed online analytic service *Totalhash*. First, we investigated what kinds of data are provided by the service and which of them have a potential for determining whether behavioural patterns are present among samples of the same type of malware. We succeeded in our efforts and behavioural patterns on high-level of abstraction have been found [7]. The research continued with advanced inspection of data from malware analyses that we gathered.

Online analytic service *Totalhash* provides various data in a form of a report, summarising results of analysis. Not all the reports contain the same types of information, it depends on the type of file that was analysed (Windows executable file, text document, image, script, ...) and the process of analysis itself - whether a certain stage of analysis was successful or not.

Analytic reports are quite extensive, so processing all of their data would be complicated and time consuming. That is why we resorted to simplification of behavioural data in a form of abstracting amounts of executed actions per sample, in accordance with the list of considerable program activity (Table I).

Assembling of behavioural data from *Totalhash* service is carried out by our custom software tool, which serves as a mediator for accessing the vast database in a simple and automatized way. The tool and its usage are described in our other papers [7] [8].

### IV. EXTRACTABILITY OF MALWARE BEHAVIOURAL PATTERNS

As mentioned in Section II, a malware behavioural pattern was defined as a 12-tuple (Equation 1), stating numbers of occurrences for actions from each of 12 behavioural categories (Table I). At the time of writing of this paper, we have managed to process 34 099 analytic reports obtained from *Totalhash* service, even though assembling of more data is still in the process - over 200 000 entries of behavioural data are currently in our database, ready for future inspection.

Advanced analyses of data set with 34 099 samples have been made to assess employability of our approach for extracting malware behavioural patterns. Results of anti-virus analyses cannot be taken as a 100% reliable detection authority,

<sup>1</sup>Available at: <http://totalhash.com/>

<sup>2</sup>Available at: <https://virustotal.com/>

and to our knowledge, no such authority exists yet. With this in mind, we figured relative maliciousness and harmfulness of samples from the data set as follows:

- amount of samples detected by *each* of (at that time) available anti-virus engines as malicious with some malware signature was 664,
- amount of samples detected as malicious with some malware signature by 16 anti-virus engines, which were selected as highly reliable based on independent anti-virus comparisons made by AV-Comparatives<sup>3</sup>, AV-test<sup>4</sup> and VB100<sup>5</sup>, was 1969,
- amount of samples detected as potentially malicious, i.e. detected with some malware signature by *at least one* anti-virus engine, was 34 016, so from the set of 34 099 samples, only 83 were "absolutely safe" - detected with *no virus*,
- amount of samples detected as potentially harmless, i.e. all of 16 highly reliable anti-virus engines, which were selected based on independent anti-virus comparisons made by AV-Comparatives, AV-test and VB100, detected no threat in those samples, was 739,

Each anti-virus engine assigns a specific malware signature to the sample which was positively detected as malicious, thus numerous samples may belong to the same malware signature. Investigation of the data set revealed significant differences in amounts of malware signatures recognised among samples. Fig. 2 summarises these differences for 16 selected anti-virus engines, which were also mentioned above in the list. We do not mention names, just anonymised labels 1-16, of anti-virus engines on purpose, since it is not relevant information for this research.

By looking at Fig. 2, the difference between anti-virus engines is evident. While there is an engine which recognised totally 11 338 different malware signatures among 34 099 samples, on the opposite side of the chart, the other engine recognised only 1 656 malware signatures among the same

Fig. 2. Amount of malware types recognised under unique malware signatures for 16 anti-virus engines, selected as highly reliable based on independent anti-virus comparisons made by AV-Comparatives, AV-test and VB100.

set of samples. This situation probably only mirrors known issues regarding inconsistency of malware signatures labelling [9] among anti-virus products and also malware researchers.

In addition to amount of malware signatures recognised by various anti-virus engines, we had a look at amount of behavioural patterns found among analysed samples, separately for each of anti-virus engines. The numbers we obtained are separated into two groups:

- all behavioural patterns in total, where a pattern has at least one value of the 12-tuple common for all the samples which belong to malware signature corresponding with the pattern. In other words, these patterns may show variabilities in 11 behavioural categories from the 12-tuple, or less, even no variabilities at all,
- plain behavioural patterns, which have no variabilities in behaviour among samples at all, i.e. they correspond with the notation from the basic behavioural pattern definition (Equation 1).

The amount of patterns, when we looked at behavioural data in accordance with various anti-virus labelling systems, is summarised on Fig. 3. While there have been significant differences between amounts of recognised malware signatures, the relation between amount of recognised signatures and extractable behavioural patterns is quite similar for most of the considered anti-virus engines. The percentage of extractable behavioural patterns from recognised malware signatures is on average 10.72%, although much lower value 2.12% occurred with one anti-virus engine (number 6 on Fig. 3), and value significantly above average, more than 15%, occurred with three anti-virus engines (numbers 13, 15 and 16 on Fig. 3).

## V. RELATED WORK

To our current knowledge, our approach to defining malware behaviour by patterns, comprising amounts of occurrences of actions from defined behavioural categories, is unique. However, there are research works worth mentioning, with which we share some techniques and research ideas.

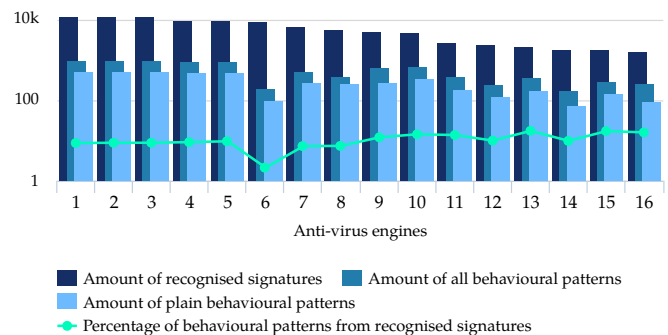

Fig. 3. Amount of malware types recognised under unique malware signatures, amount of all behavioural patterns extracted from samples corresponding with these signatures, amount of plain behavioural patterns (with no variations), and percentage of all behavioural patterns from amount of recognised signatures, for 16 anti-virus engines, selected as highly reliable based on independent anti-virus comparisons made by AV-Comparatives, AV-test and VB100.

Research of malware behaviour on the level of system function calls is discussed in work of Canzanese, Kam and Mancoridis [9]. They observed the amount of calls to system kernel API per second for each kernel function separately or for a sequence - two unique kernel functions. This is quite similar to our approach, however, they observed amounts of function calls for 235 different system functions, and we used higher level of abstraction - instead of system functions themselves as categories, we used types of actions based on the area of their influence in the infected operating system.

Cho and Im use in their work [10] analysis of system API call sequences for extracting patterns of API calls, which should define malware samples belonging to the same malware family. Authors were inspired by techniques of DNA sequencing from bioinformatics. Very interesting from our perspective is that they categorised API functions into 13 categories, according to their influence on host system resources: *registry, file system, process, service, network, socket, synchronization, system, device, threading, hooking, misc., Windows*. They could serve as an inspiration for enhancing our categorisation of behaviour.

Hellal and Romdhane statically extract function calls of system API from analysed programs and divide them into 32 main categories of behaviour, with additional 4 subcategories for 4 types of actions - open, read, write and close, so in total 128 behaviour categories are used [11]. They also observe sequence of function calls, which is statically extracted from a program as an API call graph. In comparison to our work, they use more detailed description of behaviour, but mainly their extensive *fine-grained* categorisation may serve for our inspiration.

Various approaches of behaviour analysis in the area of network security share the idea of pattern extraction, e.g. work of Konorski et al. [12]. Despite similarity of the concept, it is crucial to note that analysing network traffic and events initiated through network is markedly different from analysing actions performed during software execution.

## VI. FUTURE WORK PROPOSAL

Regarding assembling of behavioural data from online analytic service, our software tool which carries out the task will be adjusted for cooperating with more analytic services which provide data, not only with Totalhash.

Beside 12 behavioural categories which are currently included in our analytic system, also readable strings extracted from executable code are available for each malware sample which analytic report has been obtained from Totalhash service. These readable strings have not yet been analysed.

We also considered to enhance number of analysed behavioural categories, e.g. by taking inspiration from work of Cho and Im [10], mentioned in Related Work (Section V), who use 13 behavioural categories in their experiments.

An interesting inspiration comes also from work of Hellal and Romdhane, which was also mentioned in Related Work (Section V). We could observe behavioural patterns built on

several different levels of malware behaviour categorisation, and compare those patterns. Currently we employ 12 behavioural categories, but inspired by Hellal and Romdhane, we could try to build patterns on  $32 \times 4 = 128$  behavioural categories from the same data set, and compare extractability and relevance of those two levels of patterns.

From a long-term perspective, in our research we would like to proceed with more detailed information about malware behaviour, not only to observe amounts of behaviour occurrences in 12 behavioural categories, but to track e.g. which specific system functions implement the behaviour, or whether malware samples, belonging to the same malware signature, use the same types of system functions.

## ACKNOWLEDGMENT

This work was supported by the Slovak Research and Development Agency under the contract No. APVV-15-0055 and by project KEGA no. 079TUKE-4/2017.

# 2<sup>nd</sup> Workshop on Constraint Programming and Operation Research Applications

THE aim of the CPORA-Workshop on Constraint Programming and Operation Research Applications is to bring together interested researchers from constraint programming/constraint logic programming (CP/CLP), operations research (OR) and artificial intelligence (AI) to present new techniques or new applications in decision support, combinatorial optimization, modeling and control processes arising in manufacturing, transportation, telecommunication, computer networks, logistic systems etc. and to provide an opportunity for researchers in one area to learn about techniques in the others. The aim of this workshop is share ideas, projects, researches results, models, experiences etc. associated with CP/CLP/OR/AI and to give researchers the opportunity to show how the integration of techniques from different fields can lead to interesting results on large and complex problems. Additionally, we would like to stimulate the communication between researchers working on different fields and practitioners who need reliable and efficient modelling and computational methods for industrial and business processes.

Contributions containing of both: the theoretical and practical results obtained in this area are welcome.

**Abstract**—Scheduling production jobs in the real production system requires considering a number of factors which may prove to exert a negative effect on the production processes. Hence the need for the identification and compensation of potential disruptions as early as at the production planning stage. The aim of this paper is to employ the survival and the hazard function to anticipate potential disruptions of the schedule so that they could be absorbed to produce a robust job schedule.

## I. INTRODUCTION

SCHEDULING of production jobs has received much attention from academic researchers, which has led to numerous works published in the field. Authors have proposed various solutions aimed at creating effective production schedules [1]–[5]. Many current solutions, however, are of a purely theoretical character and are frequently unfeasible in existing production systems [6]–[7].

Practice shows that each production process involves a variety of factors impede the performance [7]–[8]. It is for that reason that we can observe the trend referred to as robust scheduling, which describes job scheduling under uncertainty [7].

This paper describes the development of a robust job schedule based on empirical data regarding the selected technological machine failure. In order to determine the selected reliability parameters, we have employed the Life-time Data Analysis, also referred to as the Survival Analysis [9]. Moreover, we have proposed new service buffer input method.

## II. SCHEDULING UNDER MACHINE FAILURE CONSTRAINT

Robust scheduling represents a process that produces a schedule that is able to absorb disruptions, *i.e.* can account for changing parameters of the production process [7–8]. This type of scheduling is composed of the predictive phase (pertaining to the planning stage) and the reactive phase (pertaining to the production stage) [10]–[11].

Researchers indicate several sources of uncertainty in the production process, including: job processing times, preparation and completion times, works transport availability and times, machine availability, workers and tools availability, raw material/semi-finished product shortage or delay [7], [12]–[14]. Although they are largely

of random character, the knowledge of the character of uncertainty factors is of crucial importance in robust scheduling [8], [15].

An increasing number of studies into robust scheduling of production jobs regard resource availability as the major source of disruption in the production process. In practice, this is strictly connected with the failure of machines processing production jobs [10], [16]–[17]. Various solutions are proposed in this area of research.

In his study, M. T. Jensen [16] adopts a deterministic approach and regards machine failure as the times of failure occurrence, and subsequently tests the developed schedules for various numbers of machines and jobs. A. Davenport *et al.* [17], S. Gürel *et al.* [18] and V. J. Leon *et al.* [19] include in their works a typical probability distribution and apply the obtained data in developing robust schedules. Many authors suggest employing the times pertaining to the field of Preventive Maintenance (PM) [20]. Deepu [21], Hong Gao [22], W. M. Kempa [23] or B. Skolud [24] employ MTTF, MTBR, MTTR and MTFF factors in prediction of potential failure, with a view to developing robust schedules. These authors make use of the redundancy-based techniques, which are widely applied in the research in the field. An extensive body of literature [16]–[17], [21]–[22] emphasises the need for acquisition and analysis of historical data of machine failure as an invaluable source of knowledge in robust scheduling of production jobs.

## III. PROBLEM FORMULATION

Formulation of the job scheduling problem under uncertainty demands establishing the following [25]:

- set of processed jobs  $J$ , which is the set of  $n$  technological processes (jobs) to carry out:

$$J = \{J_1, J_2, \dots, J_n\}, \quad (1)$$

- set of machines  $M$ , which is the set  $m$  of technological machines processing production jobs:

$$M = \{M_1, M_2, \dots, M_m\}, \quad (2)$$

- $m \times n$  matrix of machine orders  $MO$  representing the rank of jobs on particular machines:

$$MO = [o_{ij}], \quad (3)$$

where:  $o_{ij}$  – ranking of jobs  $i$  on the machine  $j$  taking the value of:  $o_{ij} = 0$  – when the operation  $i$  is not processed on the machine  $j$ ,  $o_{ij} = \{1, \dots, m\}$  – when the operation  $i$  is processed on the machine  $j$ ;

- matrix of processing times  $PT$  containing data regarding processing times of particular technological operations:

$$PT = [p_{ij}], \quad (4)$$

where:  $p_{ij}$  – processing time of job  $i$  on the machine  $j$ , while for  $o_{ij} = 0$ , also  $p_{ij} = 0$ .

The general problem with scheduling in job-shop conditions consists in ordering jobs from the set of jobs  $J$  between the machines from the set of machines  $M$ , accounting for the technology described in the matrix  $MO$ , so that the resulting schedule corresponds to the furthest extent with the defined objective criterion.

In order to produce the robust schedule, which will absorb potential disruptions in the stock of machines, it is crucial to determine for each  $m$  of the uncertain machines:

- the set of failure times of machines  $FT_m$  containing data on machine failure times:

$$FT_m = \{f_{m1}, f_{m2}, \dots, f_{mi}\}, \quad (5)$$

where:  $f_{mi}$  – is a factor determining the probable machine failure times;

- the set of time buffers  $TB_m$ , which contains data on the machine servicing time buffers that must be included in the development of the robust schedule:

$$TB_m = \{t_{m1}, t_{m2}, \dots, t_{mi}\}. \quad (6)$$

To determine the specified values of the sets which are crucial to developing the robust schedule of production jobs we have employed selected Survival Analysis techniques. The applied techniques enable the determination of the survival model of a given object or phenomenon, and produce data that may be used in the prediction of survival patterns [10]. It was resolved that the analysis of the character of the technological machine failure occurrence will be conducted by means of the survival and hazard functions in the robust schedule.

#### IV. SURVIVAL AND HAZARD FUNCTIONS

Let  $T$  be a non-negative random variable with the probability density function  $f(t)$ ,  $t > 0$  and the cumulative distribution function

$$F(t) = P(T < t). \quad (7)$$

Below we assume, that the random variable  $T$  represents the waiting time until the failure (death of plant). In the literature the variable  $T$  denotes the survival time [26]. The value  $F(t)$  determines the probability that the failure (breakdown) occurs by duration. The survival function

$$S(t) = P(T \geq t) = 1 - F(t) = \int_t^\infty f(s) ds \quad (8)$$

presents the probability of correct work of a machine just before duration  $t$  (the probability of surviving to duration  $t$ ), generally the probability that the failure (breakdown) does not occur by duration  $t$ . The survival characteristic of a machine may be presented by a hazard function

$$h(t) = \lim_{dt \rightarrow 0} \frac{P(t \leq T < t+dt | T \geq t)}{dt} = \lim_{dt \rightarrow 0} \frac{\int_t^{t+dt} f(s) ds}{dt P(T \geq t)} = \frac{f(t)}{S(t)} \quad (9)$$

The value of this function represents an instantaneous rate of occurrence of failure [9]. From (8) the formula (9) we may rewrite as

$$h(t) = -\frac{d}{dt} \ln S(t) \quad (10)$$

By solving the expression (10) we obtain a formula for the survival function

$$S(t) = \exp(-H(t)) \quad (11)$$

where  $H(t) = \int_0^t h(s) ds$  is called the cumulative hazard

function. The cumulative hazard function represents the sum of risks occurring from the duration 0 to  $t$  [9].

#### V. NUMERICAL EXAMPLE

The techniques for developing robust schedules presented in the preceding sections will be now presented in practice, to analyse the machine failure and servicing times at one of the representatives of the automotive industry. The data obtained from the analysis was afterwards employed in the scheduling of production jobs.

##### A. The Survival and Hazard Function

Let  $\{(t_i, d_i)\}_{1 \leq k \leq n}$  be a sequence of described failures, where  $t_i$  is a time after which the failure occurred but  $d_i$  – number of this events. We assume that times  $\{t_i\}_{1 \leq k \leq n}$  are ordered,  $0 < t_1 < \dots < t_k$ . Fig. 1 presents the empirical cumulative distribution function

Fig. 1 The cumulative distribution function of failure

The survival function (8) is usually obtained with the Kaplan-Meier method. The estimate of the survival function is given by the following formula

$$\hat{S}(t) = \begin{cases} 1, & t < t_1, \\ \prod_{t_i \leq t} \frac{r_i - d_i}{r_i}, & t_1 \leq t \end{cases} \quad (12)$$

where  $r_i$  represents the number of individuals at risk at time  $t_i$ ,  $1 < i < k$  (number of individuals who die at time  $t_i$  or later)

and is calculated as  $r_i = \sum_{j=i}^k d_j$ . Fig. 2 presents the survival function with 95% confidence intervals. From (11) the estimate of cumulative hazard function may be obtained as

$$\hat{H}(t) = -\ln(\hat{S}(t)) \quad (13)$$

The full black curve with jumps in Fig. 3 represents the values of estimate of the cumulative hazard function  $\hat{H}(t)$ . Another method of estimating the cumulative hazard function is the Nelson-Aalen estimator

$$\bar{H}(t) = \sum_{t_i \leq t} \frac{d_i}{r_i} \quad (14)$$

which is represented in Fig. 3 by the red broken curve with jumps.

Fig. 2 The survival function – Kaplan-Meier estimate

Fig. 3 The cumulative hazard function and Nelson-Aalen estimate

The data obtained from both the survival and hazard functions may be used in the robust schedule development. Decreasing survival translates to a longer life of the object, and consequently higher probability of machine failure. In terms of hazard, the abrupt jumps denote numerous instances of failures in given periods. High values of intensity function denote high risk of machine failure [10].

### B. Applied Survival Analysis Results in Robust Scheduling

The presented analyses provided data that was subsequently employed in the robust schedule development for the following scenarios  $m \times n$ :  $3 \times 2$ ,  $3 \times 3$ ,  $3 \times 4$ ,  $4 \times 3$ ,  $4 \times 5$  and  $4 \times 6$ . The values of  $MO$  and  $PT$  were randomly generated. The obtained data was used to elaborate standard Schedule. The scheduling method applied was the dispatching rules, whereas the objective criterion was the maximum makespan ( $C_{\max}$ ) – LiSA software was used in the study. The data form enterprise obtained from the failure analysis was applied to produce the robust schedule. The application of the survival and hazard functions is presented in Fig. 4.

Fig. 4 The hazard function employed in the development of the robust schedule (S – machining servicing buffers)

It was established that the resulting plot of function determines the failure characteristics of the machine  $M_1$ . The set of failure times  $FT_1$  was obtained from the results of analysis of the survival and hazard functions:

$$f_{11} = 108 \text{ [h]}; f_{12} = 216 \text{ [h]} \quad (15)$$

and the values of the machine servicing time buffer  $TB_1$ :

$$t_{11} = t_{12} = 55 \text{ [min]} \approx 0.92 \text{ [h]} \quad (16)$$

The values of machine servicing time buffers were obtained from the empirical indicator MTTR.

In scheduling it was established that the machine  $M_1$  worked for 100 h prior to commencement of production, hence the machine servicing time buffer  $f_{11}$  was set to occur after 8 h, and the buffer  $f_{22}$  occurred after 116 h (if necessary). The machines worked to 65% capacity, which provided the basis for the generation of the elements of matrix  $MO$ . The maximum job processing time was 16 h, therefore elements of matrix  $PT$  were also randomly generated from the range of  $p_{ij} \in \langle 0; 16 \rangle$ . The results of analysis are presented in Table I.

TABLE I.  
RESULTS OF ROBUST SCHEDULING USING SURVIVAL AND HAZARD FUNCTIONS

Dispatching rules	Nominal schedule $C_{\max}$ [h]						Robust schedule $C_{\max}$ [h]					
	3×2	3×3	3×4	4×4	4×5	4×6	3×2	3×3	3×4	4×4	4×5	4×6
LPT	35	41	28	51	51	54	44	41	29	51	60	54
SPT	47	43	31	51	50	67	47	43	31	51	56	67
FCFS	47	43	31	51	53	54	47	43	31	51	62	54
LQUE	35	41	28	51	51	54	44	41	29	51	60	54
EDD	47	41	31	51	50	54	47	41	31	51	56	54

## VI. CONCLUSION

The analysis of results obtained from the robust scheduling of production jobs indicates that the inclusion of the machine servicing time buffer  $M_1$  did not exert a considerable effect on  $C_{\max}$ . In the majority of the analysed scenarios the difference between the standard and the robust schedule was negligible (approx. 1 h), or practically non-existent. It was only in the case of 3×2 scheduling problem (scheduling with dispatching rules) and problem 4×5 that a substantial discrepancy of schedule makespans was observed (on average 8.14 h). The difference in question resulted from the fact that in these particular cases, the machine  $M_1$  was heavily burdened with jobs, and simultaneously the values of processing times were considerably high.

Further investigations should concentrate on introducing a procedure limiting the machine servicing time buffers in job processing, with a view to obtaining lower values of scheduling assessment. That help to implement proposed method it the real production systems. Job scheduling under uncertainty requires further development and employing various inference and analysis engines.

**Abstract**—This study deals with modelling and optimization of handling jobs (orders) in groups. All jobs in a group should be delivered at the same time after processing. The authors present a novel hybrid method, which includes the modelling and optimization of the problem in the hybrid environment composed of MP (Mathematical Programming) and CLP (Constraint Logic Programming). Due to the large complexity of the optimization problem, dedicated heuristic is also proposed instead of MP. The paper also presents an author's model for optimization scheduling groups of jobs. The model has been implemented in several environments: Hybrid (CLP/MP), Hybrid (CLP, heuristic), MP and heuristic. The obtained results of numerical experiments confirm the high efficiency and usefulness of the hybrid approach to optimize such problems.

## I. INTRODUCTION

MANY issues in the area of manufacturing, logistics and services are characterized by handling and processing problems with groups of jobs (orders) and operations, especially when these jobs are to be completed at the same time.

A very good illustration of the handling of jobs (orders) in groups is the process of preparing and serving food in a restaurant [1]. Guests enter the restaurant in different groups at different moments. Each group chooses a table and all jobs of the group members are taken simultaneously. After the accomplishment of these processes, all meal items ordered by a group are served simultaneously. The quality of service and the rate of customer satisfaction are raised if a meal item is served as soon as it is ready. In a restaurant, a group of meal items ordered by guests sitting at a table should be delivered together. Thus, the cooked meal items for a specific group have to wait until the last item of that group is cooked and is ready to be served.

The proposed research problem finds many applications in industrial companies, including but not limited to food, ceramic tile, textile production industries, distributions, supply chain, installation of bulky equipment, manufacturing of complex devices, etc. It can be noticed in many production and logistic industries that have different customers. Assume that each customer has different jobs. Each job has a different handling process function and resources, but all items ordered by a customer or group of

customers should be delivered at the same time in one package to reduce the transportation costs, subsequent processing steps time and costs or/and assure proper quality of the product/service and customer satisfaction.

The remainder of the article is organized as follows. Section II presents a literature review. Problem statement, research methodology, mathematical model and contribution are provided in Section III. Computational examples, tests of the implementation platform and discussion are presented in Section IV. Possible extensions of the proposed approach as well as the conclusions are included in Section V

## II. LITERATURE REVIEW

To best meet customers' expectations (Section I), multiple decision problems have to be solved. These include processes of food preparation and delivery, proper arrangements of customers at the tables, etc. Due to the number and character of the problems (multimodal, asynchronous, parallel) as well as constraints related to resources, time, etc., they are considered at different decision making levels. At the strategic level, problems of optimal configuration of the order processing/handling environment occur. In the case of a restaurant, these include the selection, configuration and arrangement of tables, known as the Table Mix Problem (TMP) [1,2]. The "best" table mix is influenced by several factors such as: the expected number of each size party that will be potential customers; the expected meal duration of each party; the dimensions and the layout of the restaurant, which limit the number and type of tables that can be used, and the possibility of combining tables of different dimensions. Once the TMP is solved, i.e. the number of tables, their size, etc. are decided, it is necessary to assign tables to customers in the most profitable way. Operational decisions are mainly concerned with the most profitable assignment of customers to specific tables. The "Parties Mix Problem" consists of deciding on accepting or denying a booking request from different groups of customers, with the aim of maximizing the total expected revenue [3]. The revenue management RM problem is dealt with in multiple papers as the overarching question [3,4]. Scheduling methods for optimal and simultaneous provision of service to groups of customers are proposed most often in the flexible flow-shop

system (FFS). In the FFS system, processing is divided into several stages with parallel resources at least in one stage. All of the tasks should pass through all stages in the same order (preparing meals) [5,6]. The exemplified objectives of the problem [6] are minimizing the total amount of time required to complete a group of jobs and minimizing the sum of differences between the completion time of a particular job in the group and the delivery time of this group containing that job (waiting period).

Our motivation was to develop a method that allows problem modeling and optimization for handling incoming jobs in groups with the same date of completion for various forms of organization. Development of optimization models, whose implementation using the proposed method will allow obtaining optimal answers to key questions asked by managers and executive levels.

### III. PROBLEM STATEMENT AND METHODOLOGY

The majority of models presented in the literature (Section II) refer to a single problem and optimization according to the set criterion. Fewer studies are devoted to multiple-criteria optimization by operations research (OR) methods [6]. One paper [7] applies constraint programming, but it is used only to solve the static problem of restaurant configuration. Declarative environments such as CLP facilitate problem modeling and introduction of logical and symbolic constraints [8-14]. Unfortunately, high complexity of optimization models and their integer nature contribute to poor efficiency of modeling in OR methods and inefficient optimization in CLP. Therefore, a novel approach to modeling and solving these problems was developed. A

declarative environment was chosen as the best structure for this approach [8,10]. Mathematical programming environment was used for problem optimization [15]. This hybrid approach is the basis for the creation of the implementation environment to optimization scheduling groups of jobs. In addition to optimizing particular decision making problems connected with groups of jobs, such environment allows asking various questions while processing the jobs.

The main contribution of this research is the new method for the modeling, support and optimization of decision-making problems for handling jobs in groups. It is based on the integration of CLP and MP/Heuristic. In addition, the linearization and transformation optimization model was built using the CLP environment. Based on the proposed method and model, we designed the framework that allows modeling and optimization the process of handling groups of jobs. The presented method makes it possible to solve the larger size problems in a much shorter time in relation to mathematical programming (MP).

The general concept of hybrid framework (Figure 1) consists in modeling and presolving of a problem in the CLP environment with the final solution (optimization) found in the MP environment or feasible by heuristic algorithm. In all its phases, the platform uses the set of facts having the structure appropriate for the problem being modeled and solved (Figure 2). The set of facts is the informational layer of the framework, which can be implemented as relational database, XML files, etc. Description of the facts for the problem has been shown in Appendix A.

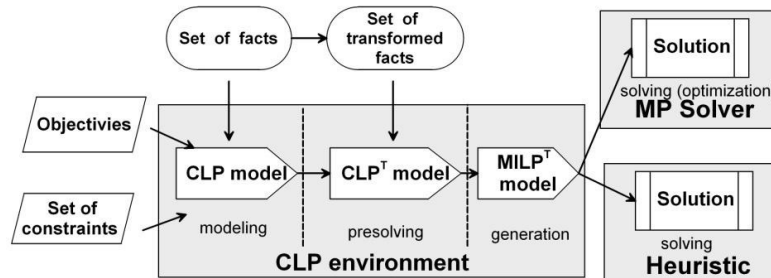

Fig. 1 The concept of hybrid framework

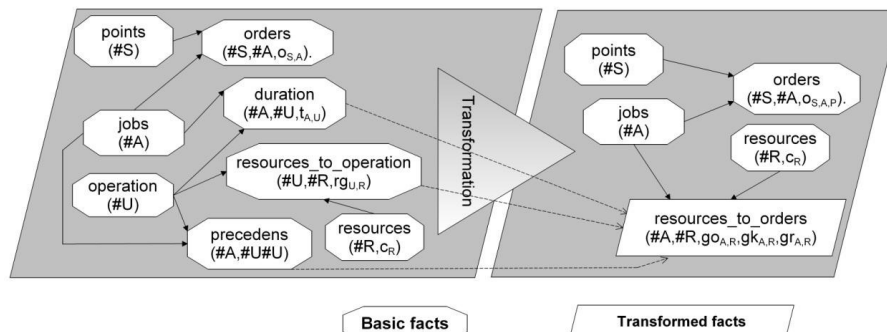

Fig. 2 The scheme of facts for the problem of handling jobs (orders). (#-key attribute of fact)

### A. Problem description

This problem can be stated as follows (Figure 3, Table I). Jobs ( $a=1..LA$ ) enter the system in groups. Each jobs consists of operations ( $b=1..LB$ ) and should be processed by specific resources, including parallel resources ( $r=1..LR$ ). The jobs ( $a=1..LA$ ) in each group should be delivered at the same time. It is assumed that all processors in the last stage are eligible to process all jobs. This assumption is valid due to the fact that processors in the last stage (waiters at restaurants who deliver meals or packers in a factory, or quality control) are the same in most of the application areas of the proposed problem. Special points at which orders are submitted and then delivered are introduced /e.g. tables/ ( $s=1..LS$ ). The problem does not cover configuration of the points but relates to handling jobs, as many jobs may come from one customer/jobs several items from the menu/. Each job may be processed by a different resource set in any order.

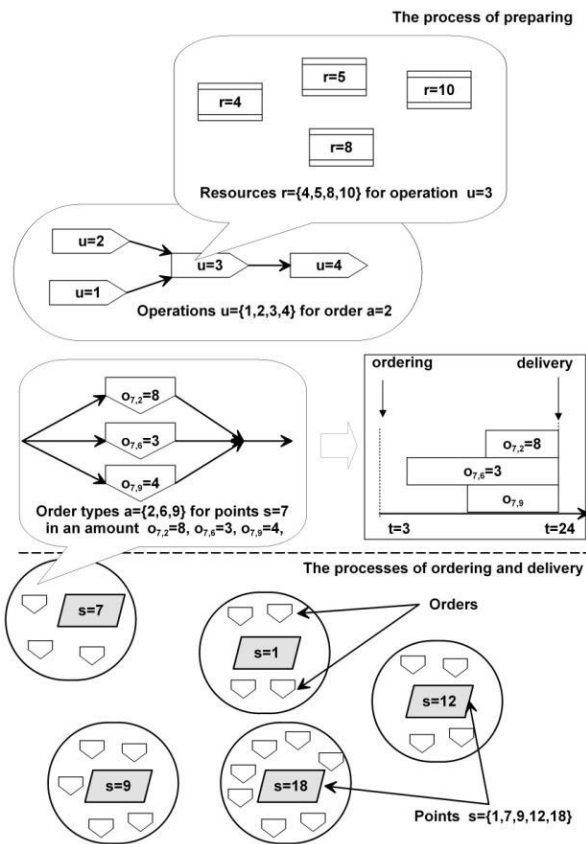

Fig. 3 Scheme for the problem of handling jobs (orders) in a restaurant

The transformation of the problem consisted in the transition from the classical representation in the form of operations to the representation in the form of resources. For this purpose, a corresponding CLP predicates were developed, which based on precedence and resource constraints as well as on the duration of particular operations determined the demand times and sizes for each resource. This transformation allows reductions in the size of the problem by the dimension of operation  $u$ . The

transformation is performed based on the assumption that all the operations for the job are performed without interruption. Transformation is the key element in the hybrid approach. It allows the reduction in the problem size thus reducing combinatorial search space through the reduction of decision variables and constraints (see Appendix B).

TABLE I.  
SETS, INDICES, PARAMETERS AND DECISION VARIABLES FOR  
MATHEMATICAL MODEL

Sets	
Set of points (tables)	LS
Set of jobs (orders)	LA
Set of resources	LR
Set of operations	LU
Number of periods	LT
Indices	
Points (tables)	$s=1..LS$
Jobs (Orders)	$a=1..LA$
Resources	$r=1..LR$
Operation	$u=1..LU$
Period	$t=1..LT$
Parameters	
Duration of operation $u$ for job (order) $a$	$t_{a,u}$
If the operation $u_1$ precedes $u_2$ for job (order) $a$ than $kol_{a,u_1,u_2}=1$ otherwise $kol_{a,u_1,u_2}=0$	$kol_{a,u_1,u_2}$
If the operation $u$ uses resource $r$ than $zas_{u,r}=1$ otherwise $zas_{u,r}=0$	$zas_{u,r}$
Number of $r$ resources needed for execution operation $u$	$rg_{u,r}$
The number of available resources $r$ in the period $t$ .	$cp_{r,t}$
The number of resources of the second type (waiters) available during period $g$	$hp_t$
The number of jobs (orders) $a$ at point $s$	$o_{s,a}$
Decision variables	
Calculated number of periods $t$ delivery of all jobs (orders) for point $s$ .	$F_s$
If the execution of operation $u$ for job (order) $a$ for point $s$ uses resource $r$ in period $t$ then $X_{s,a,r,t}=1$ , otherwise $X_{s,a,r,t}=0$	$X_{s,a,r,t}$
If $t$ is the last period in which resource $r$ is used in the execution of operation $u$ for job (order) $a$ for point $s$ then $Y_{s,a,r,t}=1$ , otherwise $Y_{s,a,r,t}=0$	$Y_{s,a,r,t}$
Number of period $t$ in which operation $u$ can be started for job (order) $a$ in point $s$	$B_{s,a,u}$
Number of period $t$ from resource $r$ can be used for operation $o$ of job (order) $a$ in point $s$	$S_{s,a,u,r}$
Makespan	$C_{max}$

### Objective functions.

Minimization of makespan (1a) or minimization of average waiting time at each point  $s$  (1b).

### Constraints.

Constraint (2) determines the order of execution of operations. Constraint (3) determines the start time of the use of the resource  $r$ . Constraint (4) ensures that  $C_{\max}$  is not less than the time of completion of each operation. Execution time for the point  $s$  is greater or equal to the time of execution of each jobs  $a$  at this point (5). Constraint (6) does not allow exceed the available number of resources  $r$  during period  $t$ . Constraint (7) provides resource  $r$  occupancy for the time execution of the operation  $u$ . Operations cannot be interrupted (8). Simultaneous completion of jobs  $a$  from the given point is ensured by constraints (9,10). Constraint (11) blocks resources for execution time. Constraint (12) is responsible for the binarity of selected decision variables.

$$F_{c1} = \min C_{\max} \quad (1a)$$

$$F_{c2} = \min \frac{1}{LS} \sum_{s=1}^{LL} F_s \quad (2b)$$

$$B_{s,a,u_1} + t_{a,u_1} = B_{s,a,u_2} \quad (2)$$

$$\forall s = 1..LS, a = 1..LA, u_1, u_2 = 1..LU, \text{kol}_{a,u_1,u_2} = 1$$

$$S_{s,a,u,r} = B_{s,a,u} \quad \forall s = 1..LS, a = 1..LA, u = 1..LU, \quad (3)$$

$$r = 1..LR: o_{s,a} > 0, \text{zas}_{u,r} > 0$$

$$S_{s,a,u,r} = 0 \quad \forall s = 1..LS, a = 1..LA, u = 1..LU, r = 1..LR$$

$$: o_{s,a} = 0$$

$$S_{s,a,u,r} = 0 \quad \forall s = 1..LS, a = 1..LA, u = 1..LU, r = 1..LR:$$

$$\text{zas}_{u,r} = 0$$

$$C_{\max} \geq F_s \quad \forall s = 1..LS, : q_{s,a} > 0 \quad (4)$$

$$F_s \geq B_{s,a,u} + t_{a,u} \quad \forall a = 1..LS, a = 1..LA, u = 1..LU \quad (5)$$

$$\sum_{s=1}^{LS} \sum_{a=1}^{LA} \sum_{u=1}^{LU} (X_{s,a,u,r,t} \cdot rg_{u,r} \cdot o_{s,a}) \leq cp_{r,t} \quad (6)$$

$$\forall r = 1..LR, t = 1..LT$$

$$\sum_t X_{s,a,u,r,t} = t_{a,u} \quad \forall s = 1..LS, a = 1..LA, u = 1..LU,$$

$$r = 1..LR: o_{s,a} > 0, \text{zas}_{u,r} > 0$$

$$X_{s,a,u,r,t} = 0 \quad \forall s = 1..LS, a = 1..LA, u = 1..LU, r = 1..LR: \quad (7)$$

$$o_{s,a} = 0$$

$$X_{s,a,u,r,t} = 0 \quad \forall s = 1..LS, a = 1..LA, u = 1..LU, r = 1..LR:$$

$$\text{zas}_{u,r} = 0$$

$$X_{s,a,u,r,t-1} - X_{s,a,u,r,t} \leq Y_{s,a,u,r,t-1} \quad \forall s = 1..LS, a = 1..LA, \quad (8)$$

$$u = 1..LU, r = 1..LR, t = 2..LT: o_{s,a} > 0, \text{zas}_{u,r} > 0$$

$$Y_{s,a,u,r,t} = 0 \quad \forall s = 1..LS, a = 1..LA, u = 1..LU,$$

$$r = 1..LR, t = LT$$

$$Y_{s,a,u,r,t} = 0 \quad \forall s = 1..LS, a = 1..LA, u = 1..LU,$$

$$r = 1..LR, t = 1$$

$$\sum_t Y_{s,a,u,r,t} = 1 \quad \forall s = 1..LS, a = 1..LA, u = 1..LU, r = 1..LR \quad (9)$$

$$: o_{s,a} > 0, \text{zas}_{u,r} > 0$$

$$Y_{s,a,u,r,t} = Y_{s,a,u,r,t+1} \quad \forall s = 1..LS, a = 1..LA, u = 1..LU, \quad (10)$$

$$r = 1..LR, t = 1..LT, o_{s,a} > 0, \text{zas}_{u,r} > 0$$

$$X_{s,a,u,r,t} = \begin{cases} 1 & \forall s = 1..LS, a = 1..LA, u = 1..LU, r = 1..LR, \\ & t = 1..LT: t \geq S_{s,a,u,r}, t \leq S_{s,a,u,r} + t_{a,u} \\ 0 & \text{otherwise} \end{cases} \quad (11)$$

$$X_{s,a,u,r,t} = \{0,1\} \quad \forall s = 1..LS, a = 1..LA, u = 1..LU, \quad (12)$$

$$r = 1..LR, t = 1..LT$$

$$Y_{s,a,u,r,t} = \{0,1\} \quad \forall s = 1..LS, a = 1..LA, u = 1..LU,$$

$$r = 1..LR, t = 1..LT$$

### B. Transformation

The transformation of the problem consisted in the transition from the classical representation in the form of operations to the representation in the form of resources. For this purpose, a corresponding CLP predicates were developed, which based on precedence and resource constraints as well as on the duration of particular operations determined the demand times and sizes for each resource. This transformation allows reductions in the size of the problem by the dimension of operation  $u$ . The transformation is performed based on the assumption that all the operations for the job are performed without interruption. Transformation is the key element in the hybrid approach. It allows the reduction in the problem size thus reducing combinatorial search space through the reduction of decision variables and constraints (see Appendix B).

All variables, parameters, auxiliary data etc. (Table II) determined during this process are indicated in the superscript by <sup>CLP</sup>.

The mathematical model has been developed, transformed and linearized for the research problem. The sets, indices, parameters, decision variables are presented in Table I.

### Objective functions after transformation.

Minimization of makespan (1aT) or minimization of average waiting time at each point  $s$  (1bT).

### Constraints after transformation.

Constraint (2T) specifies the moment (period) from which resource  $r$  is needed to execute job (order)  $a$ . Constraint (3T) ensures that the makespan is not less than the completion times of all jobs. Constraint (4T) ensures that the number of available resources  $r$  in period  $t$  is not exceeded. Constraint (5T) provides resource occupancy for the time of the order execution. Resource  $r$  is used without interruption during the execution of job (order)  $a$  from point  $s$  (6T). Constraint (7T) is for determining decision variable  $Y$ . Simultaneous completion of jobs (orders)  $a$  from the given point is ensured by constraint (8T).

To linearize this model, an ancillary variable was used,  $L_{s,t} = \{0,1\}$ , determined according to constraint (9T) (where coefficients/factors  $c^{CLP}_{s,t}$  are determined by the CLP).

TABLE III.  
INDICES, PARAMETERS AND DECISION VARIABLES FOR MATHEMATICAL  
MODEL

<i>Sets</i>	
Set of points (tables)	LS
Set of jobs (orders)	LA
Set of resources	LR
Number of periods	LT
<i>Indices</i>	
Points (tables)	$s=1..LS$
Jobs (Orders)	$a=1..LA$
Resources	$r=1..LR$
Period	$t=1..LT$
<i>Parameters</i>	
Calculated number of period $t$ for the start of demand for resource $r$ and job (order) $a$ (CLP)	$go_{a,r}^{CLP}$
Calculated number of period $t$ for the end of demand for resource $r$ and job (order) $a$ (CLP)	$gk_{a,r}^{CLP}$
Number of $r$ resources needed for execution of job (order) $a$	$gr_{a,r}^{CLP}$
Number used to convert periods to moments (for connecting index $t$ with variable $U_{s,a,r}$ , if $U_{s,a,r}=7$ then index $t=7$ ) (CLP)	$c_t^{CLP}$
The number of available resources $r$ in the period $t$ .	$cp_{r,t}$
The number of resources of the second type (i.e. waiters, packers) available during period $t$	$hp_t$
<i>Inputs</i>	
The number of jobs (orders) $a$ at point $s$	$o_{s,a}$
<i>Decision variables</i>	
Calculated number of periods $t$ (using $c_t^{CLP}$ ) delivery of all jobs (orders) for point $s$ .	$F_s$
The number of period $t$ in which resource $r$ can be used for job (order) $a$ at point $s$	$U_{s,a,r}$
If the execution of job (order) $a$ for point $s$ uses resource $r$ in period $t$ then $X_{s,a,r,t}=1$ , otherwise $X_{s,a,r,t}=0$	$X_{s,a,r,t}$
If $t$ is the last period in which resource $r$ is used in the execution of job(order) $a$ for point $s$ then $Y_{s,a,r,t}=1$ , otherwise $Y_{s,a,r,t}=0$	$Y_{s,a,r,t}$
If $g$ is the last period in which jobs (orders) are executed for point $s$ then $L_{s,t}=1$ , otherwise $L_{s,t}=0$	$L_{s,t}$
makespan	$C_{max}$

Constraints (10T) and (11T) determine the end of the resource  $r$  occupancy. Constraint (11T) is an auxiliary constraint responsible for ending the execution of jobs at point  $s$  but only once. Constraint (12) specifies the number of different type of resources (waiters). Constraint (13) is responsible for the binarity of selected decision variables.

$$F_{c1} = \min C_{max} \quad (1aT)$$

$$F_{c2} = \min \frac{1}{LS} \sum_{i=1}^{LS} F_s \quad (1bT)$$

$$U_{s,a,r} + go_{a,r}^{CLP} = F_s \quad \forall s = 1..LS, a = 1..LA, r = 1..LR:$$

$$o_{s,a} > 0, gr_{a,r}^{CLP} > 0 \quad (2T)$$

$$U_{s,a,r} = 0 \quad \forall s = 1..LS, a = 1..LA; o_{s,a} = 0$$

$$U_{s,a,r} = 0 \quad \forall s = 1..LS, a = 1..LA; gr_{a,r}^{CLP} = 0$$

$$C_{max} \geq F_s \quad \forall s = 1..LS; o_{s,a} > 0 \quad (3T)$$

$$\sum_{s=1}^{LS} \sum_{a=1}^{LA} (X_{s,a,r,t} \cdot gr_{a,r}^{CLP} \cdot o_{s,a}) \leq cp_{r,t} \quad \forall r = 1..LR, t = 1..LT \quad (4T)$$

$$\sum_t^{LT} X_{s,a,r,t} = go_{a,r}^{CLP} - gk_{a,r}^{CLP}$$

$$\forall s = 1..LS, a = 1..LA, r = 1..LR : o_{s,a} > 0, gr_{a,r}^{CLP} > 0$$

$$X_{s,a,r,t} = 0 \quad \forall s = 1..LS, a = 1..LA, r = 1..LR, t = 1..LT \quad (5T)$$

$$: o_{s,a} > 0$$

$$X_{s,a,r,t} = 0 \quad \forall s = 1..LS, a = 1..LA, r = 1..LR, t = 1..LT$$

$$: gr_{a,r}^{CLP} > 0$$

$$X_{s,a,r,t-1} - X_{s,a,r,t} \leq Y_{s,a,r,t-1}$$

$$\forall s = 1..LS, a = 1..LA, r = 1..LR, t = 2..LT$$

$$: o_{s,a} > 0, gr_{a,r}^{CLP} > 0 \quad (6T)$$

$$Y_{s,a,r,t} = 0 \quad s = 1..LS, a = 1..LA, r = 1..LR, t = LG$$

$$Y_{s,a,r,t} = 0 \quad s = 1..LS, a = 1..LA, r = 1..LR, t = 1$$

$$\sum_t^{LT} Y_{s,a,r,t} = 1 \quad (7T)$$

$$\forall s = 1..LS, a = 1..LA, r = 1..LR : o_{s,a} > 0, gr_{a,r}^{CLP} > 0$$

$$Y_{s,a,r1,t} = Y_{s,a,r2,t} \quad \forall s = 1..LS, a = 1..LA, r1, r2 = 1..LR,$$

$$t = 1..LT : o_{s,a} > 0, gr_{a,r}^{CLP} > 0, gk_{a,r1}^{CLP} = 0, gk_{a,r2}^{CLP} = 0, \quad (8T)$$

$$F_s = \sum_{t=1}^{LT} c_t^{CLP} L_{s,t} \quad \forall s = 1..LS \quad (9T)$$

$$Y_{s,a,r,t-gk_{a,r}^{CLP}} = L_{s,t} \quad \forall s = 1..LS, a = 1..LA, r = 1..LR,$$

$$t = gk_{a,r}^{CLP}..LT : o_{s,a} \geq 0, gr_{a,r}^{CLP} \geq 0$$

$$Y_{s,a,r,t} = L_{s,t+gk_{a,r}^{CLP}} \quad \forall s = 1..LS, A = 1..LA, r = 1..LR, \quad (10T)$$

$$t = 1..LT - gk_{a,r}^{CLP} : o_{s,a} \geq 0, gr_{a,r}^{CLP} \geq 0$$

$$\sum_{t=1}^{LT} L_{s,t} \leq 1 \quad \forall s = 1..LS \quad (11T)$$

$$\sum_{s=1}^{LS} L_{s,t} \leq hp_t \quad \forall t = 1..LT \quad (12T)$$

$$\begin{aligned}
&X_{s,a,r,t} = \{0,1\} \\

&Y_{s,a,r,t} = \{0,1\} \\
&\forall s = 1..LS, a = 1..LA, r = 1..LR, t = 1..LT \\
&L_{s,t} = \{0,1\} \forall s = 1..LS, t = 1..LT
\end{aligned} \quad (13T)$$

### C. Heuristic Algorithm

A heuristic algorithm (Figure 4) was developed to enable solving larger-size problems. Its design was based on the

rules of priority and properties. The heuristic algorithm adds consecutive points  $s$  to the schedule starting with those of the highest priority by the set criteria (Table III). If, while adding  $s$  point, the algorithm finds that resource constraint is active, leading to the extension of the schedule length, it moves to another step. This step involves checking whether the adjustment of orders using those resources in a given period can provide a better schedule.

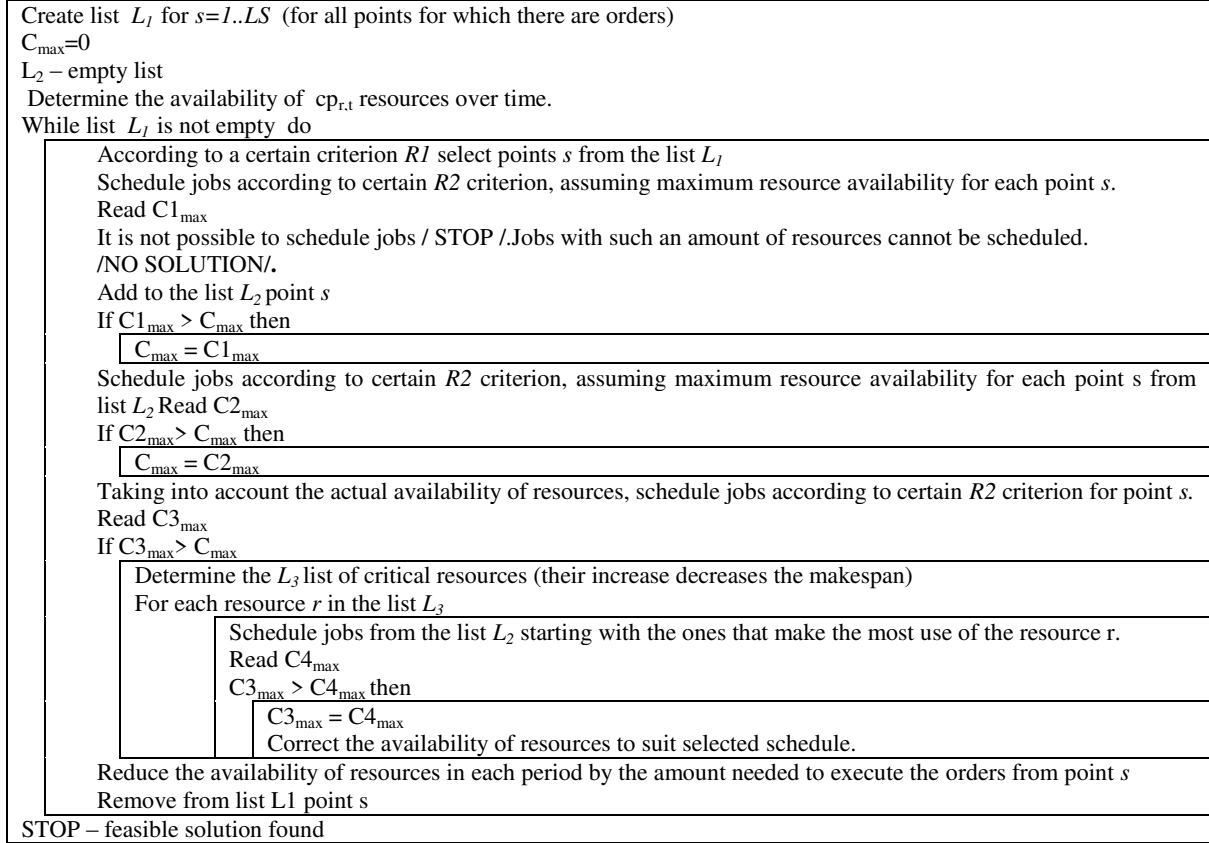

Fig. 4 The heuristic algorithm dedicated to the scheduling group of jobs

TABLE III.  
POSSIBLE VALUES OF CRITERION

Criterion	Description
R1	<ul style="list-style-type: none"> <li>The order that uses the most critical resource</li> <li>The order with the longest execution time</li> </ul>
R2	<u>Queue priority methods known from literature</u> <ul style="list-style-type: none"> <li><u>LPT</u></li> <li><u>SPT</u></li> </ul>

Underlining indicated the criteria chosen for the computational experiments (Section IV).

## IV. NUMERICAL EXPERIMENTS

In order to verify and evaluate the proposed approach and models, many numerical experiments were performed for optimization scheduling groups of jobs. All the experiments relate to the problem with fifty points ( $s=1..50$ ), twenty order types ( $a=1..20$ ), fifty resource types ( $r=1..50$ ), fifteen

operation types ( $u=1..15$ ) and from three to one hundred fifty orders  $o_{s,A}$

The main part of the study was a comparative analysis performed for Fc1 and Fc2 in four environments: mathematical programming (MP), heuristic algorithm, hybrid1 (CLP&MP) and hybrid2 (CLP& heuristic algorithm) hybrid and MP) to evaluate the effectiveness and efficiency of the proposed hybrid approach relative to the classical MP environment and heuristic algorithm. The experiments for examples E1..E7 were conducted for various values of parameters  $LS, N$ . The results are included in Appendix B (Table B1, Table B2). The application of the hybrid approach leads to a substantial reduction in (i) number of decision variables (up to fifteen times), (ii) number of constraints (up to two times) (iii) computing time (more than twenty times faster) for the above examples. For larger numerical examples, such as E3..E7 the MP-based approach cannot be used due to the length of calculations and, most importantly, exceeded size of the problems

accepted by the available MP solvers. Using hybrid approach (hybrid2), it reduces the computation time twice and improves the quality of approximate solutions (0-1% worse from optimal) in relation to the use heuristic algorithm (the quality of approximate solutions are 1-2% worse from optimal).

## V.CONCLUSION

The proposed approach to the modelling and optimization scheduling groups of jobs can be used in many areas. Similar issues exist wherever there are a variety of customer jobs (orders), the handling of which require processes and additionally, both are ordered and executed jointly with a single delivery deadline. In practice, such an approach to group job (order) handling occurs in manufacturing, services, logistics and project management. The presented framework, which is an implementation of the proposed approach, enables effective optimization scheduling groups of jobs. This allows the implementation of optimization models with different objective functions and the introduction of additional constraints to the models already implemented. The illustrative example shows only part of the framework's potential. Significant results are to increase both the speed and the size of the problems solved.

It is foreseen in further research the use of a hybrid approach to (a) modeling and solving scheduling problems in production [16,17], (b) modeling and optimization of IoT

processes [18], and (c) implementation of more complex models, uncertainty, fuzzy logic etc..

## APPENDIX A

TABLE A1.  
DESCRIPTION OF FACTS

Name	Description
points(#S)	A fact that describes the points.
jobs(#A)	A fact that describes the type of jobs (orders).
operations(#U)	A fact that describes the type of operations.
precedens(#A,#U,#U)	A fact that describes the precedence operations in job (order)..
duration(#A,#U,t <sub>A,U</sub> )	A fact that describes execution time for operations in job.
resources(#R,c <sub>R</sub> )	A fact that describes resources (the number of each type)
resource_to_operation(#U,#R,r <sub>gU,R</sub> )	A fact that specifies acceptable allocation of resources to operations.
orders(#S,#A,o <sub>S,A</sub> )	A fact that describes orders at point
resources_to_orders(#A,#R,g <sub>OA,R</sub> , g <sub>kA,R</sub> , g <sub>OA,R</sub> )	A fact determines what resources are needed to complete the order .

**Abstract**—This paper addresses the modeling of modular and reconfigurable transportation systems, aiming at developing tools to support the planning and control. Answer Set Programming (ASP) is employed to formalize rules modeling the characteristic of a transportation system and describing its dynamics. Then, automatic reasoning can be exploited to find solutions in different use cases, including the generation of optimal or alternative paths, the generation and validation of control sequences. The proposed methodology is applied to a reconfigurable industrial transportation system consisting of multiple linear conveyor modules with actuators enabling longitudinal and transversal movements of pallets.

## I. INTRODUCTION

**R**ECONFIGURABLE Manufacturing Systems (RMS) [1], [2] aim at tackling current market challenges such as frequent product changes, product customization, demand variability, rapid changes in technologies and regulations. RMS are conceived as a composition of elements, machines and material handling systems, whose systemic configuration can be easily changed. Reconfigurability should be met at both hardware and software level to reduce reconfiguration time (ramp-up), effort and cost.

Material handling systems (MHS) represent a key component in an RMS, being the pieces of equipment devoted to handling, storing, and controlling materials and parts. When addressing the design of an RMS, the MHS plays a relevant role, since it must support the reconfigurability at system level. A possible solution are Reconfigurable Transportation Systems (RTS), usually based on modular mechatronic transportation units that can be combined to implement a logistic system layout. Carpanzano et al. [3] identified three main challenges to be addressed when designing and implementing RTSs:

- (a) hardware reconfigurability, i.e., the design of transportation systems that meet the physical reconfigurability re-

quirement. Mechanical and mechatronic interfaces are a relevant issue when tackling this matter.

- (b) software development of the control systems, including the appropriate sensing solutions. The suggested architecture is a distributed one, since all the modules should be independent and considered as an autonomous control block.
- (c) real-time management of the production system, considering routings, dispatching policies, planning and scheduling, maintenance.

In this work the main focus will be on (b) and (c). The control problem (b) is particularly relevant when mechatronic systems are involved, due to the difficulty of integrating and managing all the components. The control system of an automated MHS must be able to elaborate plans and instructions considering objectives such as throughput maximization, response time and execution time optimization. Haneyah et al. [4] presented an extensive study of generic planning and control requirements for automated material handling systems. These requirements include starvation, blocking and deadlock avoidance, saturation and buffer balancing, urgencies, disruptions and operational flexibility.

Cataldo and Scattolini [5] presented a methodology to optimize the control of a transportation system where pallets are moved along modular conveyors. The control system was implemented by adopting Model Predictive Control (MPC) with a multi-layer approach. In the low level control (LLC) of the system there are the local Programmable Logic Controllers (PLC) that manage each module sensors and actuators, while at the highest level the MPC controller is implemented and manages the flows of the pallets in real-time providing proper control sequences. The High-Level Control (HLC) System was implemented by representing the transportation system as a directed graph, where nodes are machines and buffer zones, whereas the arcs are the possible movements of the pallet. Based on the graph, a mathematical representation of the system was developed through a Mixed Linear Dynamical (MLD) model and embedded in the MPC controller.

Hegny et al. [6] presented a non-traditional control ap-

This work has been partially funded from the European Union's Horizon 2020 research and innovation programme under grant agreement No. 636966 (Customer-driven design of product-services and production networks to adapt to regional market requirements - ProRegio) and from the Italian research project Smart Manufacturing 2020 within the Cluster Tecnologico Nazionale Fabbrica Intelligente.

proach, implementing a two-levels control architecture based on Multi Agents System (MAS) technology.

In both cases, the need to divide the control system into a low and high level is the solution to the reconfigurability objective. This structure, in fact, allows easier reconfiguration of the software system since the LLC is implemented on each unit and the HLC is designed independently from the physical system. This allows to separate the control of the functioning of the elements composing the system from the high-level control of the system as a whole and from the implementation of planning and routing algorithms.

The planning problem (c) for an automated transportation systems consists in defining routing and dispatching policies regulating the movements of the processed pieces by defining the sequence they visit machines and workstations. Routing and dispatching policies are implemented in the high-level control layer of the control system.

The goal of this paper is the development of an elaboration tool to support the modeling of a transportation system and reasoning on the system dynamics to derive its properties. Possible applications of the tool include:

- (i) the generation of paths and control sequences to implement movements of the objects along the transportation system;
- (ii) the generation of a reachability graph showing how the positions in the transportation system can be connected;
- (iii) validation of the control sequences generated by a planning algorithm;
- (iv) configuration of a transportation system and its devices enabling to meet the required functionalities expressed in terms of movements in the system.

In particular this work will focus on the applications (i) and (ii), with the aim of supporting the following users:

- (1) system designers in the analysis and validation of alternative transportation system configurations;
- (2) control designers addressing an existing hardware design of a transportation system;
- (3) control designers tackling an existing transportation system through the extraction of knowledge, e.g., from the analysis of PLCs, hardware components, etc.

Herein, the elaboration tool is conceived as a logic program that adopts the Answer Set Programming (ASP) language to represent the system in terms of rules and obtain solutions in the form of stable models (i.e. *answer set*). Problems related to the modeling of automation systems to support their control are typically addressed using other techniques like automata, finite state machine and Petri Nets (PN) [7]. In particular, PN is in principle able to support the applications (i)-(iv) previously defined. However, it must be noted that an approach based on PN requires a quite verbose formalism that leads to overly complex models with an explosion in terms of number of *places* and *transitions*. More advanced PN extensions can only partially reduce such complexity. Therefore, even if a PN model can be used to easily derive relevant properties of a system (e.g. reachability, liveness, boundedness,

deadlocks) using general purpose tools, still the generation of the PN model itself is a relevant problem that requires skilled modeling operations and thus represents a bottleneck of the approach. This problem is particularly relevant when dealing with reconfigurable transport systems since a physical reconfiguration demands also a reconfiguration of the model. Even if a modular PN approach can be employed (and it is not immediate in the general case of non-identical transport modules), anyhow it can be cumbersome to identify which are the transitions linking the *places* in different PN sub-graphs.

The proposed ASP-based approach aims first and foremost to support the generation of a formal model for a specific transportation system by taking as input the description of the physical system (*facts*) and the general description of the dynamics and interactions between the basic components of the system (*rules*). Therefore, ASP can be seen as complementary to PN for the generation of the formal model, whereas regarding the reasoning over a formal model of the system there can be an overlapping between ASP and PN, as it will be discussed in the next sections.

The paper is organized as follows. Sect.II will briefly present ASP and some relevant application of this language. Sect.III will introduce the details of the reference transportation problem that is considered in this work. Sect.IV presents the details of the model based on ASP rules. Sect.V shows which type of reasoning can be performed and finally Sect.VI provides an application example.

## II. REASONING WITH ANSWER SET PROGRAMMING

Answer Set Programming [8], [9], [10] is a logic programming language for knowledge representation and reasoning. An ASP program consists of a set of rules of the form:

$$a \leftarrow b_1, \dots, b_m, \text{not } c_1, \dots, \text{not } c_n \quad (1)$$

where  $a, b_i, c_j$  are atoms. The left-hand side of the rule is the *head*, whereas the right-hand side is the *body*. The head is derived to be true if all the literals in the body are true. If a rule has no body, then it is a *fact*. A rule without head is a *constraint*. The symbol *not* in (1) represents a *default negation* (or *weak negation*), that is a key feature of ASP and more generally of non-monotonic reasoning. The solution of an ASP program is an answer set (or stable model), i.e. the smallest set of literals that satisfies the program. An ASP solver can return zero, one or many answer sets.

Another useful feature of the ASP language and its extensions is represented by *cardinality atom*. For instance, the form  $l\{a_1, \dots, a_n\}k$  means that at least  $l$  and at most  $k$  atoms in the set  $\{a_1, \dots, a_n\}$  are true. If  $l$  or  $k$  are missing, then the corresponding side is unbounded.

ASP has been successfully applied in several domains, e.g., product configuration, aerospace, data management, music and planning [10]. ASP is also a declarative language, i.e. a program written in this language does not specify how to search a solution (this is a key difference between ASP and Prolog); indeed, the solution is independently found by the

solver also thanks to the availability of general purpose ASP solvers.

Taking in consideration the scope of automation and control, it is relevant to mention the work of [11] that discussed how ASP can be generically employed to generate plans as alternative stable models. More specifically, [12] addressed how ASP can be applied to support the planning of collaborative robot. [13] proposed an approach to generate paths for robots in a dynamic environment. Similarly, [14] focused on a cost-based robot planning taking by formalizing the rigid knowledge, time-dependent knowledge, action knowledge and incomplete information. However, to the best of our knowledge, this paper represents the first application of ASP in the domain of modular transportation systems.

The relation between ASP and PN has been studied by Anwar et al. [15], [16] and they demonstrated that PN models can be actually encoded in ASP language. Once the model is encoded in ASP, then it is possible to use ASP solvers to analyze typical properties of the system as in the case of a PN (e.g. reachability of a state, basic liveness). Simulations can be run using either a PN or ASP approach, but ASP offers the following advantages:

- ASP may return the enumeration of all possible evolutions of a simulation [15]
- the formal model can be enriched with additional and customized reasoning about the simulations [15]

Therefore, ASP can be used not only to generate a formal model of the system, but also to analyze the system behavior with a reasoning power that is not lower than what can be done with PN. Given a specific transportation system to be analyzed, the advantage of ASP is that it supports both the generation of the formal model and also the reasoning about its properties using the same language and solvers.

### III. PROBLEM STATEMENT

In this work the attention is focused on MHS that consist of conveyors. These transportation systems are bound to specific operational routes and require the installation of fixed tracks. The material is loaded on pallets or specific carriers transported along the conveyors (by means of chains, rollers, belts, etc.). The structure of conveyor systems is usually obtained by combining together standardized modular pieces. Modularity requires considerable design and investment efforts, but it offers the possibility to expand and reconfigure the transportation system according to the variable needs of the plant. Moreover, automation also entails a high level of real-time flexibility, thanks to the possibility of developing complex planning and control software tools. An automated conveyor-based transportation system also contains sensing devices and actuators as well as control tools to manage all these elements. Therefore, the generic transportation system that is taken as a reference is defined as follows:

- the system consists of  $M$  linear conveyor modules;
- pallets are characterized by a rectangular shape and can be moved along the system;

- each module is equipped with 1) sensing elements to detect the presence of a pallet, 2) conveyor belts, or any other similar movement device, 3) stacker cranes for cross movement of the pallet along a direction orthogonal to the movement of the main conveyor belt, 4) blocking actuators to stop the movement of the pallet when it is flowing along the conveyors;
- each module hosts  $N$  discrete positions for pallets, numbered from 1 to  $N$ , discretizing the space available on the module on the basis of the pallet size and shape. Each position can host only one pallet;
- each position is characterized by four sides, numbered from 1 to 4 clock-wise (see Fig.1). Sides are used to describe how positions are connected to each other (see Sect.IV-B);
- the direction of movement of the conveyor belt is *forward* if it causes the pallet to move along a direction with increasing number id of the positions, *backward* in the opposite case;
- the direction of movement of the stacker crane is *left* if it causes the pallet to move on the left when looking from position 1 to  $N$ , *right* in the opposite case;
- the blocking actuators are always coupled with sensing elements. The actuators are designed so that the pallet can move toward a position with an actuator even if it is activated, whereas it can move out of the position only if the actuator is not activated. An actuator can work both when the pallet is moving forward or backward.

The transportation system consists of a set elements connected together to form a complex system characterized by the properties of reconfigurability, scalability and flexibility. Reconfigurability is obtained through varying the arrangement of modules in the plant in order to face changing functional requirements. Similarly, the system is easily scalable by adding or removing modules. Flexibility can be reached by allowing different pallet routings.

Fig. 1. Representation of the sides and feasible movements in a 3-position transportation module with one stacker crane.

### IV. MODELING TRANSPORTATION MODULES USING ASP

This section presents the logic program written in ASP language able to capture the basic characteristics and dynamics of the transportation system and elaborate its evolution in time in terms of the sequence of states reached by the system. The state of the system is defined by the position of the pallets

and the state of actuators and sensors. The dynamic behavior of the system is subject to the following constraints:

- placement of the modules (system physical layout);
- characteristics of the modules in terms of hosted positions and installed actuators;
- characteristics of the modules and cross elements in terms of supported direction of movement.

The addressed problem requires the logic program to be modular, clustering the rules. Each cluster addresses a characteristic of the system or a specific modeling issue and is independent from the others. In general, modularity allows leaner development of the rules and faster maintenance. The main clusters are described in the following subsections: *Input Facts* describing the topological and physical characteristics of the system (Sect.IV-A), the *Rigid Knowledge* defining how the interactions between the system components determine the possible system behavior (Sect.IV-B), and the *Time-dependent Knowledge* defining how the state of the system changes along time because of the control actions (Sect.IV-C).

The clusters of rules are presented by adopting the syntax of `clingo` [17], including its extensions to the basic ASP language. Like in most logic programming languages, the symbol `:-` represents the leftwards arrow that separates the head and body of a rule, as show in (1).

#### A. Input Facts

The physical and geometric characteristics of a specific transportation system are defined in terms of input facts. The following predicates (fluents) need to be properly instantiated:

- `module(M)` defines the transportation module M.
- `pos(Y,M)` defines a position Y on transportation module M.
- `cross(Y,M)` defines the presence of a stacker crane element on position Y of module M.
- `act_stop(Y,M)` defines that there is a blocking actuator on position Y of module M.
- `conn_mod(Y1,M1,S1,Y2,M2,S2)` defines that the side S1 of position Y1 in module M1 is adjacent to the side S2 of position Y2 in module M2.
- `conv(M,D1,D2)` defines the feasible movement directions of the conveyor belt for module M. If the conveyor belt supports both forward and backward direction, then  $D1=f$  and  $D2=b$ , respectively. If the conveyor supports only one movement direction, then corresponding variable is set to 0.
- `cross_conv(Y,M,D1,D2)` defines the feasible directions of movement of a stacker crane that is placed on position Y of module M. If it supports both the left and right directions, then  $D1=l$  and  $D2=r$ , respectively. If the stacker crane supports only one movement direction, then the corresponding variable is set to 0.

#### B. Rigid Knowledge

Rigid knowledge refers to the information that is not subject to change during the execution of the program and its reasoning, i.e. spatial properties of the system, reachable

positions in the system, buffer zones. This knowledge is general purpose because it can be exploited for any specific system characterized by its corresponding *input facts*.

1) *Spatial properties of the system*: The possibility to move a pallet between two adjacent positions must consider the availability of proper actuators. Figure 2 shows some of the types of connections. Specifically, the pallet can be moved from a position to another only if the two positions are adjacent and if the connecting elements are consistent in terms of direction of movement. The feasibility of a transfer between

Fig. 2. Examples of adjacent positions enabling a movement.

two positions is defined by the following predicates:

- `conv_to_conv(Y1,M1,Y2,M2,D1,D2)` between position Y1 of module M1 and position Y2 of module M2 if the conveyor belt of M1 is moving in direction D1 (i.e. f or b) and the conveyor belt of M2 is moving in direction D2 (see cases a. and b. in Fig.2);
- `conv_to_cross(Y1,M1,Y2,M2,D1,D2)` between position Y1 of module M1 and position Y2 of module M2 if the conveyor belt of M1 is moving in direction D1 and the stacker crane on position Y2 is moving in direction D2 (see case c. in Fig.2);
- `cross_to_conv(Y2,M2,Y1,M1,D1,D2)` between position Y1 of module M1 and position Y2 of module M2 if the stacker crane on position Y1 is moving in direction D1 and the conveyor belt of M2 is moving in direction D2 (see case d. in Fig.2);
- `cross_to_cross(Y1,M1,Y2,M2,D1,D2)` between position Y1 of module M1 and position Y2 of module M2 if the stacker crane on position Y1 is moving in direction D1 and the stacker crane on position Y2 is moving in direction D2 (see cases e. and f. in Fig.2).

All the four types of connections can be derived from the input facts. For example rules (2) and (3) defines feasible `conv_to_conv` connections for adjacent positions belonging to the same module (see Fig.2.a). Rule (2) deals with forward movement, whereas rule (3) with backward movement. The underscore symbol in `conv(M, f, _)` and `conv(M, _, b)` is a wildcard standing for any type of movement supported by the conveyor belt for the case of backward and forward movement, respectively.

```
conv_to_conv(Y1,M,Y2,M,f,f) :- Y2=Y1+1,
    pos(Y1,M), pos(Y2,M), conv(M,f,_).
(2)
```

```
conv_to_conv(Y1,M,Y2,M,b,b) :- Y1=Y2+1,
    pos(Y1,M), pos(Y2,M), conv(M,_,b).
(3)
```

If the adjacent positions belong to different modules (see Fig.2.b), then other four rules can be defined to specify the required movements of the two conveyor belts (forward or backward) depending on the relative placement between two position in terms of adjacent sides. For example, rule (4) defines the feasible `conv_to_conv` connection from position Y1 of module M1 to position Y2 of module M2 when the side 2 of Y1 is adjacent to side 4 of Y2. The cardinality atom `1{conn_mod(Y1,M1,S1,Y2,M2,S2); conn_mod(Y2,M2,S2,Y1,M1,S1)}1` takes into account the fact that `conn_mod` is not considering an order between two adjacent positions, i.e. `conn_mod(Y1,M1,S1,Y2,M2,S2)` is equivalent to `conn_mod(Y2,M2,S2,Y1,M1,S1)`.

```
conv_to_conv(Y1,M1,Y2,M2,f,f) :- S1=2,S2=4,
    M1!=M2,pos(Y1,M1),pos(Y2,M2),
    conv(M1,f,_), conv(M2,f,_),
    1{conn_mod(Y1,M1,S1,Y2,M2,S2);
    conn_mod(Y2,M2,S2,Y1,M1,S1)}1.
(4)
```

The movement between not aligned modules is operated by stacker crane actuators. Rules similar to (4) can be defined taking in consideration all the possible couplings (some of which are shown in Fig.2.c-Fig.2.f) to derive the predicates `conv_to_cross`, `cross_to_conv` and `cross_to_cross`. If a connection is not feasible, then the rules are not satisfied and the corresponding predicate is not derived. Due to space limitations, most of these rules are omitted and only rule (5) is shown as an example of `conv_to_cross` connection. In this case the connection from position Y1 of module M1 to position Y2 of module M2 is feasible if the side 2 of Y1 is adjacent to side 3 of Y2

and there is a stacker crane element on the second position (`cross(Y2,M2)`).

```
conv_to_cross(Y1,M1,Y2,M2,f,l) :- S1=2,
    S2=3,M1!=M2,pos(Y1,M1),pos(Y2,M2),
    cross(Y2,M2), conv(M1,f,_),
    cross_conv(Y2,M2,l,_),
    1{conn_mod(Y1,M1,S1,Y2,M2,S2);
    conn_mod(Y2,M2,S2,Y1,M1,S1)}1.
(5)
```

2) *Reachable positions*: Grounding on the previous rules, the predicate `rch(Y1,M1,Y2,M2)` representing the reachability between two positions is derived if position `pos(Y2,M2)` can be reached from position `pos(Y1,M1)` via a feasible connection. Rule (6) shows an example in case of `conv_to_conv` connection. Similar rules can be written for the other possible connections (see Fig.2).

```
rch(Y1,M1,Y2,M2) :- pos(Y1,M1),pos(Y2,M2),
    conv_to_conv(Y1,M1,Y2,M2,_,_).
(6)
```

3) *Buffer zones*: A buffer zone is defined by the predicate `b_zone(Y,M)` if the pallet can be stopped in position Y of module M thanks to the presence of a blocking actuator. The blocking actuator is associated with a sensor able to detect the presence of the pallet and/or the status of the actuator (on/off), hence, a buffer zone is also an observable position. The buffer zones can be derived from rule (7).

```
b_zone(Y,M) :- pos(Y,M),act_stop(Y,M).
(7)
```

### C. Time-dependent Knowledge

The assumption is made that the evolution of the transportation system along time can be represented by defining discrete time intervals ranging from 0 to `max_time`. The following predicates specify the evolution of the system along the time horizon. For sake of simplicity, the case of a single pallet is considered, but the rules can be extended to represent also the general case of multi-pallet systems. The following predicates are used to define the state of the system:

- `p_pos(Y1,M1,T)` defines that the pallet is in position `pos(Y1,M1)` at time T;
- `move(Y1,M1,Y2,M2,T)` defines that at time T the pallet has been moved from `pos(Y1,M1)` to `pos(Y2,M2)`;
- `conv_on(M,D,T)` defines that the conveyor of module M is active at time T and moving in direction D (i.e. f or b);
- `cross_conv_on(Y,M,D,T)` defines that the stacker crane hosted in `pos(Y,M)` is active at time T and moving in direction D (i.e. l or r);
- `stop_on(Y,M,T)` defines that the blocking actuator installed in `pos(Y,M)` is active at time T.

1) *Dynamics*: The following rules generates the sequence of movements of the pallet along the transportation system. Rule (8) states that if a pallet is in a buffer zone, then the following time step it can remain in the same position or move to a reachable position; on the other hand, rule (9) states that if a pallet is in a position that is not a buffer zone, then the following time step it must be moved to a reachable position. Rule (10) makes explicit the movement of a pallet. Rule (11) guarantees that the same pallet cannot be in two different positions at the same time step. Finally, rule (12) is optional and can be enabled if the pallet is forbidden to visit twice the same position within the same control sequence.

```
{p_pos(Y3,M3,T+1) : rch(Y2,M2,Y3,M3);
  p_pos(Y2,M2,T+1)}1 :- p_pos(Y2,M2,T),
  b_zone(Y2,M2), T<=max_time. (8)
```

```
{p_pos(Y3,M3,T+1) : rch(Y2,M2,Y3,M3)}1 :-
  p_pos(Y2,M2,T), not b_zone(Y2,M2),
  T<=max_time. (9)
```

```
move(Y1,M1,Y2,M2,T+1) :-
  p_pos(Y1,M1,T), p_pos(Y2,M2,T+1),
  pos(Y1,M1) != pos(Y2,M2), T<=max_time. (10)
```

```
:- p_pos(Y1,M1,T), p_pos(Y2,M2,T),
  pos(Y1,M1) != pos(Y2,M2), T<=max_time. (11)
```

```
:- move(Y,M,_,_,A), move(Y,M,_,_,B), A!=B. (12)
```

2) *Control Actions*: Given the movements of the pallet, rules can be used for deriving the required sequence of control actions, (e.g. activation of actuators). Rules (13) and (14) derive the activation of the conveyor belt in case of a connection `conv_to_conv`. Other rules are defined (omitted due to space limitations) to derive the activation of the conveyor belt and/or the stacker crane for the other types of connections (`conv_to_cross`, `cross_to_conv` and `cross_to_cross`) as introduced in Sect.IV-B.

```
conv_on(M,D,T) :-
  conv_to_conv(Y,M,Y1,M1,D,D1),
  move(Y,M,Y1,M1,T), T<=max_time. (13)
```

```
conv_on(M1,D1,T) :-
  conv_to_conv(Y,M,Y1,M1,D,D1),
  move(Y,M,Y1,M1,T), T<=max_time. (14)
```

In addition, rules (15)-(17) define if and when the blocking actuator must be activated. Rules (18) and (19) guarantee that

both the conveyor belt and the stacker crane can activate only one direction of movement at the same time.

```
-stop_on(Y,M,T) :- move(Y,M,Y2,M2,T),
  b_zone(Y,M), T<=max_time. (15)
```

```
stop_on(Y2,M2,T) :- move(Y,M,Y2,M2,T),
  b_zone(Y2,M2), T<=max_time. (16)
```

```
stop_on(Y,M,T+1) :- p_pos(Y,M,T),
  b_zone(Y,M), not move(Y,M,_,_,T+1),
  T<=max_time. (17)
```

```
:- conv_on(M,D1,T), conv_on(M,D2,T), D1!=D2. (18)
```

```
:- cross_conv_on(Y,M,D1,T), D1!=D2,
  cross_conv_on(Y,M,D2,T). (19)
```

## V. REASONING

This section shows how the ASP formalization (Sect.IV) can be exploited to perform some reasoning related to:

- possible paths between two positions and generation of the corresponding control actions (Sect.V-A);
- which are the buffer zones that can be directly reached from a given position (Sect.V-B.)

The following predicates are used to characterize the first and last position in a sequence of movements of a pallet:

- `start(Y,M)` defines that the pallet will start from position `pos(Y,M)`;
- `end(Y,M)` defines that the pallet will end at position `pos(Y,M)`;

Given the additional predicates, Rule (20) specifies the starting condition, i.e. the position of the pallet at time 0. Rule (21) is a constraint imposing to reach the end position at any time. Rule (22) terminates the generation of further movements as soon as the pallet reaches the end position.

```
p_pos(Y,M,0) :- start(Y,M). (20)
```

```
:- not p_pos(Y,M,_) , end(Y,M). (21)
```

```
:- p_pos(Y,M,Q), end(Y,M), p_pos(____,Q+1). (22)
```

### A. Path generation

The generation of a path requires as input facts the starting position `start(Y,M)`, the target position `end(Y,M)` and the constant `max_time` as the maximum number of time steps. In this way the ASP solver may potentially generate one or more paths to link the start and end position. Rule (23) can be added to introduce an objective function in the ASP program that will minimize the number of time steps

needed to reach the end position. In this case the ASP solver will return only one feasible path (if existing).

```
#minimize{Q@1: p_pos(Y,M,Q),end(Y,M)}.
```

(23)

### B. Graph generation

A directed graph (or reachability graph) can be used to represent the feasible transitions of a pallet between two adjacent buffer zones, as presented in [5]. The arcs can be generated by solving the ASP program consisting of the rules in Sect.IV together with rules (24)-(27). The number of arcs coming out of the buffer zones will be equal to the number of stable models generated by the ASP solver. Rules (24) and (25) impose the start and end position to be in a buffer zone, respectively. Rule (26) guarantees that the start and end positions are different, whereas rule (27) sets the end position as soon as the pallet visits a position corresponding to a buffer zone.

```
1{start(Y,M): b_zone(Y,M)}1.
```

(24)

```
1{end(Y,M): b_zone(Y,M)}1.
```

(25)

```
:- end(Y,M), start(Y,M).
```

(26)

```
end(Y,M) :- p_pos(Y,M,T),b_zone(Y,M),
            T>0,T<=max_time.
```

(27)

## VI. EXPERIMENTS

This sections demonstrates how the reasoning capabilities presented in Sect.V can be exploited when addressing a realistic modular transportation system. The ASP solver *clingo* was used to run the experiments.

### A. Path generation

The generation of a path and the corresponding control sequence (cf. Sect.V-A) is tested taking in consideration the transportation system represented in Fig.3 that consists of two identical modules (Module 1 and Module 2) with three positions each, a stacker crane and blocking actuators in the first and last positions. The conveyor belt and the stacker cranes allow both directions of movement.

The input facts representing the system characteristics are:

```
module(1). module(2). pos((1;2;3),1).
pos((1;2;3),2). cross((1;3),1).
cross((1;3),2). act_stop((1;3),1).
act_stop((1;3),2). conn_mod(1,1,3,3,2,3).
conn_mod(2,1,3,2,2,3).
conn_mod(3,1,3,1,2,3).
conv(1,f,b). conv(2,f,b).
cross_conv(1,1,1,r). cross_conv(3,1,1,r).
cross_conv(1,2,1,r). cross_conv(3,2,1,r).
#const max_time=5.
```

The rules elaborating the layout derive the following feasible connections:

Fig. 3. Test case 1.

```
rch(1,1,2,1) rch(2,1,3,1) rch(1,2,2,2)
rch(2,2,3,2) rch(2,1,1,1) rch(3,1,2,1)
rch(2,2,1,2) rch(3,2,2,2) rch(1,1,3,2)
rch(3,1,1,2) rch(3,2,1,1) rch(1,2,3,1)
```

If the rule (23) is disabled and the start and end positions are defined as `start(1,1)` and `end(3,2)`, then the program generates six stable models:

```
Answer: 1
p_pos(1,1,0) p_pos(3,2,1) move(1,1,3,2,1)
cross_conv_on(1,1,r,1)
cross_conv_on(3,2,1,1)
Answer: 2
p_pos(1,1,0) p_pos(1,1,1) p_pos(3,2,2)
move(1,1,3,2,2) cross_conv_on(1,1,r,2)
cross_conv_on(3,2,1,2)
Answer: 3
p_pos(1,1,0) p_pos(1,1,1) p_pos(1,1,2)
p_pos(3,2,3) move(1,1,3,2,3)
cross_conv_on(1,1,r,3)
cross_conv_on(3,2,1,3)
Answer: 4
p_pos(1,1,0) p_pos(1,1,1) p_pos(1,1,2)
p_pos(1,1,3) p_pos(3,2,4)
move(1,1,3,2,4) cross_conv_on(1,1,r,4)
cross_conv_on(3,2,1,4)
Answer: 5
p_pos(1,1,0) p_pos(1,1,1) p_pos(1,1,2)
p_pos(1,1,3) p_pos(1,1,4) p_pos(3,2,5)
move(1,1,3,2,5) cross_conv_on(1,1,r,5)
cross_conv_on(3,2,1,5)
Answer: 6
p_pos(1,1,0) p_pos(2,1,1) p_pos(3,1,2)
p_pos(1,2,3) p_pos(2,2,4) p_pos(3,2,5)
move(1,1,2,1,1) move(2,1,3,1,2)
move(3,1,1,2,3) move(1,2,2,2,4)
```

```

move(2,2,3,2,5)
conv_on(1,f,1) conv_on(1,f,2)
cross_conv_on(3,1,r,3)
cross_conv_on(1,2,1,3)
conv_on(2,f,4) conv_on(2,f,5)
SATISFIABLE Models: 6, Time: 0.115s

```

Answer 1 and Answer 6 are the relevant solutions and are graphically represented in Fig.4 with a dashed line and a continuous line, respectively. Indeed, Answer 2-Answer 5 are equivalent to Answer 1 with a delay in the starting position. If the minimization objective in rule (23) is enabled, then the program returns Answer 1 as the best solution.

It can be noticed that the solutions define how and when the actuators must be activated. For instance, Answer 1 requires only `cross(1,1)` and `cross(3,2)` to be activated at time 1 moving in direction `r` and `l`, respectively.

Fig. 4. Test case 1 and possible paths.

```

cross_conv(2,3,1,r).
module(4).pos((1;2;3),4).cross((1;3),4).
cross_conv(1,4,1,r).cross_conv(3,4,1,r).
act_stop((1;3),4).conv(4,f,b).
module(5).pos((1;2;3),5).cross((1;3),5).
act_stop((1;3),5).conv(5,f,b).
cross_conv(1,5,1,r).cross_conv(3,5,1,r).
conn_mod(2,1,2,1,2,4).
conn_mod(2,3,2,2,2,3).
conn_mod(1,4,1,1,1,3).
conn_mod(1,4,3,3,5,3).
conn_mod(2,4,1,2,1,3).
conn_mod(2,4,3,2,5,3).
conn_mod(3,4,1,1,2,3).
conn_mod(3,4,2,2,3,1).
conn_mod(3,4,3,1,5,3).
conn_mod(1,5,4,1,3,1).

```

Fig. 5. Test case 2.

### B. Graph generation

The generation of a graph to represent the feasible transitions of a pallet between two adjacent buffer zones (cf. Sect.V-B) is tested taking in consideration the transportation system represented in Fig.5 that consists of five different modules with two or three positions each. Given the position of the blocking actuators and the the stacker cranes, the buffer zones consist in the positions `pos(2,1)`, `pos(2,2)`, `pos(3,2)`, `pos(1,4)`, `pos(3,4)`, `pos(2,3)`, `pos(3,5)`, `pos(1,5)`, `pos(1,3)`.

The input facts representing the system characteristics are:

```

module(1).pos((1;2),1).act_stop(2,1).
conv(1,f,0).
module(2).pos((1;2;3),2).act_stop(2,2).
act_stop(3,2).cross(2,2).conv(2,f,0).
cross_conv(2,2,1,r).
module(3).pos((1;2),3).act_stop((1;2),3).
cross(2,3).conv(3,f,b).

```

The graph can be generated if a program with the rules presented in Sect.V-B is run:

```

Answer: 1
start(2,3) end(1,3)
Answer: 2
start(2,3) end(3,4)
Answer: 3
start(1,5) end(3,4)
Answer: 4
start(2,2) end(3,2)
Answer: 5
start(3,4) end(2,3)
Answer: 6
start(1,3) end(2,3)

Since 16 stable models are obtained, it means that 16 directed arcs must be added to the reachability graph representing the considered transportation system, as shown in Fig.6. For instance, since the position `pos(2,2)` can be reached from the position `pos(2,1)`, then an arc from node `pos(2,1)` to node `pos(2,2)` is added to the graph.

Fig. 6. Reachability graph of Test case 2.

## VII. CONCLUSIONS

This paper presented an initial study showing the use of ASP to enable automatic generation of a formal model representing a modular and reconfigurable transportation systems. In addition, the reasoning capabilities of ASP can be exploited to derive system properties and control sequences. Further developments will address:

- an extension to the multi-pallet case. This will require to modify and the rules in Sect.IV-C to specify the position of each pallet. Moreover, it will be needed to constrain that in a position there can only one pallet.
- the addition of rules to support the applications (iii) and (iv) defined in Sect.I

- testing the programs on problems of larger size. The rules have already been tested on the plant presented in [18] showing an acceptable performance.
- the integration with a semantic representation of the system for an automatic generation of the input facts and the results of the reasoning to better support the interoperability with other tools [19], [20].
- a more extended comparison between ASP and Petri Nets. Moreover, given the input facts characterizing a system (cf. Sect.IV-A), then the rigid knowledge (cf. Sect.IV-B) with additional rules can be actually used to automatically generate a formal model of the system as a Petri Net. This would be the reciprocal of what developed by Anwar et al. [15] and would pave the way to a synergistic use of ASP and Petri Nets.

## ACKNOWLEDGMENT

The authors thank Dr. Andrea Cataldo for his support in the definition of the problem statement and the formalization and analysis of the case studies.

# 10<sup>th</sup> International Symposium on Multimedia Applications and Processing

## BACKGROUND AND GOALS

**M**ULTIMEDIA information has become ubiquitous on the web, creating new challenges for indexing, access, search and retrieval. Recent advances in pervasive computers, networks, telecommunications, and information technology, along with the proliferation of multimedia mobile devices—such as laptops, iPods, personal digital assistants (PDA), and cellular telephones—have stimulated the development of intelligent pervasive multimedia applications. These key technologies are creating a multimedia revolution that will have significant impact across a wide spectrum of consumer, business, healthcare, educational and governmental domains. Yet many challenges remain, especially when it comes to efficiently indexing, mining, querying, searching, retrieving, displaying and interacting with multimedia data.

The Multimedia—Processing and Applications 2017 (MMAP 2017) Symposium addresses several themes related to theory and practice within multimedia domain. The enormous interest in multimedia from many activity areas (medicine, entertainment, education) led researchers and industry to make a continuous effort to create new, innovative multimedia algorithms and applications.

As a result the conference goal is to bring together researchers, engineers, developers and practitioners in order to communicate their newest and original contributions. The key objective of the MMAP conference is to gather results from academia and industry partners working in all subfields of multimedia: content design, development, authoring and evaluation, systems/tools oriented research and development. We are also interested in looking at service architectures, protocols, and standards for multimedia communications—including middleware—along with the related security issues, such as secure multimedia information sharing. Finally, we encourage submissions describing work on novel applications that exploit the unique set of advantages offered by multimedia computing techniques, including home-networked entertainment and games. However, innovative contributions that don't exactly fit into these areas will also be considered because they might be of benefit to conference attendees.

## CALL FOR PAPERS

MMAP 2017 is a major forum for researchers and practitioners from academia, industry, and government to present, discuss, and exchange ideas that address real-world problems with real-world solutions.

The MMAP 2016 Symposium welcomes submissions of original papers concerning all aspects of multimedia do-

main ranging from concepts and theoretical developments to advanced technologies and innovative applications. MMAP 2016 invites original previously unpublished contributions that are not submitted concurrently to a journal or another conference. Papers acceptance and publication will be judged based on their relevance to the symposium theme, clarity of presentation, originality and accuracy of results and proposed solutions.

## TOPICS

- Audio, Image and Video Processing
- Animation, Virtual Reality, 3D and Stereo Imaging
- Big Data Science and Multimedia Systems
- Cloud Computing and Multimedia Applications
- Machine Learning, Data Mining, Information Retrieval in Multimedia Applications
- Multimedia File Systems and Databases: Indexing, Recognition and Retrieval
- Multimedia in Internet and Web Based Systems
- E-Learning, E-Commerce and E-Society Applications
- Human Computer Interaction and Interfaces in Multimedia Applications
- Multimedia in Medical Applications
- Entertainment and games
- Security in Multimedia Applications: Authentication and Watermarking
- Distributed Multimedia Systems
- Network and Operating System Support for Multimedia
- Mobile Network Architecture
- Intelligent Multimedia Network Applications
- Future Trends in Computing System Technologies and Applications

## BEST PAPER AWARD

A best paper award will be made for work of high quality presented at the MMAP Symposium. The technical committee in conjunction with the organizing/steering committee will decide on the qualifying papers. Award comprises a certificate for the authors and will be announced on time of conference.

## STEERING COMMITTEE

- **Amy Neustein**, Boston University, USA, Editor of Speech Technology
- **Lakhmi C. Jain**, University of South Australia and University of Canberra, Australia
- **Ioannis Pitas**, University of Thessaloniki5, Greece
- **Costin Badica**, University of Craiova, Romania

# Preface to the 10<sup>th</sup> International Symposium on Multimedia Applications and Processing

Dumitru Dan Burdescu

**T**HE 10<sup>th</sup> International Symposium on Multimedia Applications and Processing (MMAP'17) within the framework Federated Conference on Computer Science and Information Systems (FedCSIS)—<https://fedcsis.org/2017/mmap> addressed several themes related to theory and practice within multimedia domain. The enormous interest in multimedia from many activity areas (medicine, digital government, e-commerce, public safety, entertainment, education, advertising etc.) led researchers and industry to make a continuous effort to create new, innovative multimedia algorithms and applications.

The concept of multimedia from the traditional idea of 'multi-mediums' such as text, photographs, slides, video and audio tapes (analogue) is being redefined by the use of new computer concepts to integrate the digitized information to include text, graphics, sound, animation and full-motion. The dreams of multimedia technologists have come true and today we are able to store, transport, access and manipulate digitized multimedia information by simple drag and drop actions or export/import information to and from distant locations. The proliferation of image capturing devices and their diverse applications have enabled multimedia technology to contribute in the advancement of almost every aspect of human life. Multimedia research has evolved at tremendous speed in the last few decades to capitalize on the breadth of such applications, ranging from image/video coding and processing to multimedia communications to the analysis of human behavior to medical diagnostics. Most of these topics involve techniques from artificial intelligence, computer vision, and multimedia, but also human computer interaction, educational science, and psychology.

Multimedia technologies have achieved impressive results in the last years and they may be the key for a revolution in the cultural heritage area. These new technologies in fact can now make available for the public huge amounts of heterogeneous data creating unbelievable opportunities of study and capitalization of the cultural items.

Early information presentation applications of pervasive displays were largely focused on supporting the workplace. More recently, news and advertising information have become commonplace. However, with the trend toward situated displays, and a wide user base, new applications have started to emerge. Perhaps the most common of these are applications for behavior change in which visualization of previously unseen data is used to try and encourage viewers to modify their current behavior—often for health or sustainability reasons.

Although the potential for behavior change applications is clear, there remains a question as to the long-term effectiveness of such interventions.

Multimedia is increasingly becoming the “biggest big data” as the most important and valuable source for insights and information. It covers from everyone's experiences to everything happening in the world. There will be lots of multimedia big data—surveillance video, entertainment and social media, medical images, consumer images, voice and video, to name a few, only if their volumes grow to the extent that the traditional multimedia processing and analysis systems cannot handle effectively. Consequently, multimedia big data is spurring on tremendous amounts of research and development of related technologies and applications. As an active and interdisciplinary research field, multimedia big data also presents a great opportunity for multimedia computing in the big data era. The challenges and opportunities highlighted in this field will foster some interesting future developments in the multimedia research and applications.

Recent advances in computing, networking, storage, and information technology have enabled the collection and distribution of vast amounts of multimedia data in a variety of applications such as entertainment, education, environmental protection, e-commerce, public safety, digital government, homeland security, and manufacturing. Today, there are lots of heterogeneous and homogeneous media data from multiple sources, such as news media websites, micro-blog, mobile phone, social networking websites, and photo/video sharing websites. Integrated together, these media data represent different aspects of the real-world and help document the evolution of the world. Consequently, it is impossible to correctly conceive and to appropriately understand the world without exploiting the data available on these different sources of rich multimedia content simultaneously and synergistically.

Based on the articles, we can conclude that providing the right form of authoring tools for non-professionals is still a non-trivial task. We hope these papers are a valuable resource for scholars and practitioners who want to better understand the state of the art and the upcoming challenges in this fascinating field.

Quality of experiences and user experience are important aspects of future multimedia services. The perceptual quality of a multimedia system with multiple quality metrics is the combined quality perceived by subjects when using the system's user interface. There have been several previous studies on developing a general method for optimizing the

perceptual quality of multimedia systems. Researchers conducted studies to combine existing quality metrics with metric selection using offline psychophysical measurements or using a heuristic method, such as evolutionary algorithms. However, these approaches are limited in that they depend on existing

quality metrics and just provide a framework for combining them. There have also been approaches that use a black-box method to optimize multimedia systems without well-modeled metrics.

# Available Bandwidth Estimation in Smart VPN Bonding Technique based on a NARX Neural Network

**Abstract**—Today many applications require a high Quality of Service (QoS) to the network, especially for real time applications like VoIP services, video/audio conferences, video surveillance, high definition video transmission, etc. Besides, there are many application scenarios for which it is essential to guarantee high QoS in high speed mobility context using an Internet Mobile access. However, internet mobile networks are not designed to support the real-time data traffic due to many factors such as resource sharing, traffic congestion, radio link, coverage, etc., which affect the Quality of Experience (QoE). In order to improve the QoS in mobility scenarios, the authors propose a new technique named “Smart VPN Bonding” which is based on aggregation of two or more internet mobile accesses and is able to provide a higher end-to-end available bandwidth due to an adaptive load balancing algorithm. In this paper, in order to dynamically establish the correct load balancing weights of the smart VPN bonder, a neural network approach to predict the main Key Performance Indicators (KPIs) values in a determinate geographical point is proposed.

**Index Terms**—Smart VPN Bonding, bandwidth prediction, QoS improvement, Neural Network Introduction.

## I. INTRODUCTION

NOWADAYS the use of mobile Internet services, namely the use of Internet services through the data access offered by different cellular providers has experienced a significant increase. This increase is certainly due to the growing demanding needs of users to be connected anywhere and anytime, but also to the possibility of providing a connection in areas beyond reach over wired infrastructure.

There are numerous application scenarios, and others are currently under development, for the situations in which it is essential to have a stable Internet access and high performance even in the conditions of mobility:

- Wi-Fi on public transport,
- Connection between moving units and central station (e.g. Rescue units),

- Video surveillance of means of transport (e.g. Transport values),
- Telemedicine in mobility (e.g. Ambulances for first aid).

In addition, real time services like audio and video transmission (VoIP, audio/video conference, remote video surveillance, etc.) and services that require high Quality of Service (QoS) are currently having an exponential growth of usage.

A possible approach to improve network performance is based on the possibility to use a technique called VPN Bonding capable of aggregating the available Internet access (Ethernet, 3G, 4G, WiFi, etc.) with the ultimate goal to noticeably improve performance in terms of bandwidth, thus reaching ideal broadband speeds equal to the sum of the available bandwidths. In addition obviously obtaining a high fault tolerance in case of inefficiency. This is possible thanks to load balancing mechanism which acts at the level 2 capable of sorting packages on various available connections.

The basic idea involves the use of different mobile operators in order to compensate possible deficiencies of an operator, sorting the load mainly toward the available connections from other operators who at that moment and at that point offer greater performance.

Empirical studies show that in order to obtain an excellent result tending to the ideal solution, namely that of using a bandwidth equal exactly to the sum of the bandwidths offered by each access, it is essential that traffic can be balanced in a manner proportional to the performance offered by each Internet connection or improved methods [14].

Obviously, if we focus on mobility contexts in which one has to use the cellular network, it must be emphasized that the QoS (Quality of Service) offered by each access is definitely subject to greater variability when compared [21], for example, to the QoS offered by a classic ADSL. This is

because additional factors that can affect the quality of the connection are involved in the Mobile Internet scenario: propagation conditions, interference levels, dependence on activities of other users as a shared communication channel, saturation of the cell to which it is hooked, but especially the concept of mobility, which can lead the user to move from a good coverage area to a poor radio signal coverage areas thus ensuring that the performance of the data connection may be affected.

As mentioned above, in order to cope with the variability of access conditions there should be a real-time evaluation of the QoS offered by each single data access, so as to vary in an adaptive way the weights to be assigned to the load balancing mechanism and thus try to always balance the load in an optimal manner.

It is therefore essential to identify the techniques to make an accurate QoS estimation and simultaneously have low times of convergence in highly dynamic environment.

Section II outlines the state-of-the-art bandwidth prediction techniques that use a dataset of past collected information, according to a certain point in the territory. Section III discusses in brief the Smart VPN Bonding technique [1] [2], providing an overview of the techniques so far adopted for the estimate of the QoS, in particular the available bandwidth, highlighting problems and introducing benefits that an approach through a predictive neural network could offer.

## II. RELATED WORKS

In literature we can find different application contexts in which it is useful to perform certain actions on the basis of predictions based on the analysis of historical events. In particular, this approach is used in many contexts to ensure high QoS for network applications.

This approach, for example, can be used to improve the performance of routing algorithms, whereas the additional parameters are essential in the choice of the optimal route, such as prediction of the available bandwidth and the delay. By estimating these parameters following the values they had in the past the routing algorithm is able to select the most satisfactory path in terms of the bandwidth and the delay [4].

A similar approach could be useful to improve performance in the algorithms used in the handover mechanisms. In [5] a handover mechanism is proposed using a predictive method based on fuzzy logic, while in [6] a vertical handover algorithm is suggested based on the prediction of RSSI so as to be able to make an intelligent and flexible passage of information through different 4G wireless communication systems, reducing the switching delay in comparison with the classical algorithms of vertical handover.

In [7] and [8] the idea of building the "bandwidth map" is put forward to enhance the QoS in highly mobile environments [22]. Through the use of these maps, based on information collected in the past, one can expect the available bandwidth in a given geographical point, calculated as an average historical value, and as a consequence dynamically determine the most suitable bit rate for encoding video streaming.

In some real applications it is very useful to predict some parameters by a limited data subset. In particular some studies are concerned about the relation between packet delay and other parameters. For instance, in [9] a relation between Round Trip Time (RTT) and other geographic and network properties is investigated.

Finally, to improve prediction and reduce the error rate different approaches based on the use of Neural Networks have been studied, in particular for the purpose of the Radio Frequency (RF) power prediction [10], [11] and for the bandwidth estimation [12], [13].

## III. SMART VPN BONDING

### A. Architecture

As discussed in previous sections, the Smart VPN Bonding technique allows aggregating the resources offered by two or more mobile radio data accesses obtaining a remarkable increase in performance in terms of bandwidth. Fig. 1 indicates the proposed architecture of the Smart VPN Bonding [1], [2].

Fig. 1. Smart VPN Bonding architecture [2]

The scope is to create a VPN tunnel between each access mobile radio and the end point of the communication, i.e. the remote server. After creating the VPN tunnels they can be aggregated into a single interface with the aim to establish a broadband connection between the source and the destination. This is possible since a load balancing mechanism capable of sorting the frames into various VPN tunnels aggregated in the "Bond" interface is adopted. Obviously the performance can be boosted in terms of bandwidth if traffic is balanced in proportion to the available bandwidth provided by each access or more efficient sort [14].

Considering the contexts in mobility, where the QoS is subjected to high variability, it has been necessary to combine this technique with an adaptive load balancing mechanism able to vary dynamically the load in a manner proportional to the estimated available bandwidth on each data access.

To measure the available bandwidth, estimation tools based on non-intrusive technique such as Self Loading of Periodic

**Fig. 2.** Prototype employed during test campaign [2]

Stream (SLoPS) techniques have been adopted [15], [16], [17].

Thanks to the adoption of these techniques a fairly accurate estimate of the available bandwidth was made, but unfortunately these techniques have relatively long convergence time, which could prove to be inadequate in high mobility contexts where the access conditions may change rapidly.

In the following subsection the performance, advantages and issues of Smart VPN Bonding technique are presented.

### B. Performance evaluation

In order to evaluate the performance of Smart VPN bonding technique we report the results of a test campaign [1], [2].

The tests were carried out using a prototype based on ALIX2D2 board, a system board optimized for routing and network applications; two USB Internet Keys equipped with two SIMs of different mobile network operators (called Operator 1 and Operator 2) to provide cellular connectivity; ZeroShell and OpenVPN has been used as operative systems and VPN manager respectively; finally a proprietary script has been realized by using *bash* and *python* language to evaluate the end-to-end available bandwidth and, consequently, to establish the weights to assign to load balancing mechanism. The experimental prototype is shown in Fig. 2, while the Smart VPN Bonding behavior is depicted in Fig. 3.

The performances are obtained in terms of throughput measured using some FTP sessions over the two Internet accesses in 15 different geographic test points. In this scenario the QoS offered by Operator 1 is comparable to Operator 2. The Fig. 4 shown the average values obtained. In this case both operators provide a high QoS, so a static approach based on round robin strategy applied to load balancing mechanism represents a good solution, increasing performance by more than 50% if compared to the best mobile operator.

**Fig. 3.** Throughput measured in good network conditions for the Operator 1, Operator 2 and bonding interface

**Fig. 4.** Average throughput comparison

The performance delivered by the VPN bonding coupled with the static load balancing between the two available Internet accesses is satisfactory in the above mentioned scenarios. However, this technique has some disadvantages when the bandwidth offered by two operators is not similar.

Fig. 5 shows a particular case in which the available bandwidth provided by Operator 1 is affected by a considerable degradation due to a poor radio coverage. In this case a static weights assignment to load balancing mechanism don't represent the best approach (Fig. 5a). Indeed, the bonding interface behavior is similar to the worst mobile operator, so the VPN bonding technique does not offer any performance improvement because of the incorrect weights assignment. Instead, using an adaptive weights assignment in order to counteract the drawbacks related to the variability of the end-to-end bandwidth offered by each radio operator along the path the performance in terms of throughput is considerably enhanced (Fig. 5b). The scenarios above mentioned highlight the advantages and bandwidth improvement provided by Smart VPN Bonding. However, a limit of this technique is represented by high response time to react rapidly to changing network conditions due to bandwidth estimation tool. Fig. 6 shows the performance of Smart VPN Bonding technique transmitting a large file during a change of location site, from a good to poor radio coverage areas for one of two mobile operators.

Fig. 5. Operator 1 bandwidth degradation: (a) static weights, (b) adaptive weights

Fig. 6. Smart VPN Bonding time response

After the change of location site the throughput measured on bonding interface is considerably lower caused by incorrect load balancing. From the example illustrative in Fig. 6, the system has required about 18 seconds to estimate the available bandwidth offered by both internet accesses, to recognize the changing network conditions and modify the weights assignment to load balancing mechanism. In fact, as soon as the change of weights has occurred, the throughput on bonding interface increases.

This high response time has encouraged the authors to investigate the relation between RTT and available bandwidth in a specific geographic location, in order to obtain an accurate bandwidth estimation in a very short time. Indeed, the RTT measurement is very easy and much faster than available bandwidth estimation, and even more suitable in high mobility context.

In order to verify and analyze this relation a Neural Network approach was adopted.

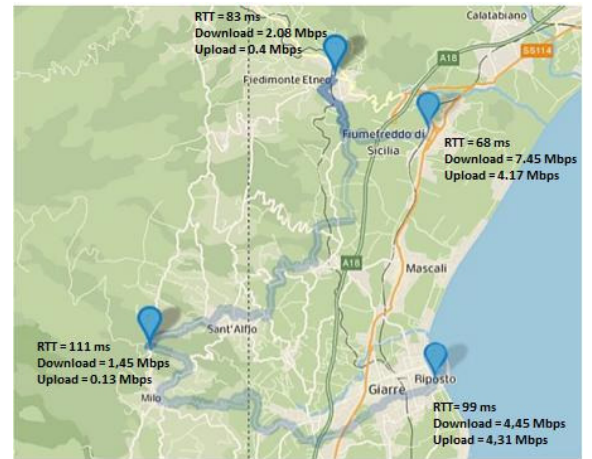

Fig. 7. Testbed Scenario

The dataset for the Neural Network training includes values of RTT, download end-to-end available bandwidth and upload end-to-end available bandwidth calculated every 5 minutes. To filter out any episodic RTT effects, each RTT measurement was calculated as the median value of 5 individual samples spaced 2 seconds apart. The available end-to-end bandwidth measurements were carried out using *Pathchirp* tool.

#### IV. DATASET

The dataset for Neural Network training includes the data collected in an urban scenario, as shown in Fig. 7. Along the path shown in Fig. 7, the test points have been selected to

Fig. 8. The RNN used for the prediction of the upload and download rates.

Fig. 9. Learning curves of the Recurrent Neural Network.

measure RTT, end-to-end upload and download bandwidth. In Fig. 7 are reported just some examples of measuring points.

As mentioned in Section III, the end-to-end available bandwidth estimation tools have long convergence time, inadequate for high mobility contexts, so the relationship between available bandwidth values and RTT is analyzed, in order to adopt RTT measurement to predict the available bandwidth values. For each test point, 60 values of RTT, end-to-end upload and download available bandwidth have been collected for the training of the Neural Network. In Section V the results and the performance for one test point are reported. These results can be extended to other test points thanks to the generalization ability of the Neural Network.

#### V. NEURAL NETWORK PERFORMANCE

Different topologies of Neural Network were experimented in

order to gain some insight into the most appropriate network architecture [18], [19], [20], [21].

The best conducted experiments in terms of MSE, no-overfitting and generalization were obtained using a real-time Recurrent Neural Network (RNN) as depicted in Fig. 8. The RNN is composed by an input layer, an output layer and two hidden layers: the four neurons of the first hidden layer and the eight neurons of the second hidden layer have radial basis transfer function. While for the two neurons of the output layer has been used a linear transfer function. The RTT time series is used as input vector while the upload and download rate time series are used as output vectors. The input vector is delayed with zero step delay and one step delay while the output vectors are delayed with one step delay and two step delay. So the RNN predicts the values of upload and download rates at time  $t_0 + I$  based on the value of the RTT at time  $t_0$  and

$t_0-1$ . The time step in this paper is one minute. The learning curves, shown in Fig. 9, pointed out the good performance of the RNN reached after 100000 epochs with a mean squared error of  $6.6e-05$  and an excellent generalization due to the fact that the test curve is always very close to the training curve.

## VI. CONCLUSIONS

In this paper we have investigated the relation between the Round Trip Time (RTT) and the end-to-end available bandwidth (upload and download) in order to simplify and speed up the estimation bandwidth process.

The results highlight that it is possible to estimate the available bandwidth based on the knowledge of the past values of the RTT obtaining a low MSE. Thanks to this information it is possible to apply a fast reconfiguration of weights of the load balancing mechanism adopted in VPN bonding technique to guarantee a higher end-to-end available bandwidth than a static approach (e.g. round robin strategy). This approach is very useful to improve the VPN bonding performance, but can be used in several other application scenarios for the important adaptation of available bandwidth (e.g. video transmission frame rate).

**Abstract**—High Efficiency Video Coding (HEVC), a modern video compression standard, exceeds the predecessor H.264 in efficiency by 50%, but with cost of increased complexity. It is one of main research topics for FPGA engineers working on image compression algorithms. On the other hand high-level synthesis tools after few years of lower interest from the industry and academic research, started to gain more of it recently. This paper presents FPGA implementation of HEVC 2D Inverse DCT transform implemented on Xilinx Virtex-6 using Impulse C high level language. Achieved results exceed 1080p@30fps with relatively high FPGA clock frequency and moderate resource usage.

## I. INTRODUCTION

H.265 is the most recent video coding algorithm released by joint collaboration between ITU and ISO organizations [1], and also described in details in [2]. It is claimed that this compression is 50% better than its predecessor, H.264. Both mentioned video coding standards use finite precision approximation of Discrete Coding Transform to change from the spatial domain to frequency, however H.264 uses only transform block sizes 4x4 and 8x8. HEVC uses various, so called Transform Unit (TU) sizes, ranging from 4x4 to 32x32 pixels.

High level synthesis languages have gained focus in recent years both in academic and industry research. During last years, few such types of commercial and academic tools have been developed. Impulse C is one of languages which can be translated to HDL, and further synthesized. It allows also to partition the solution, to run it in the mixed software/hardware environment. HLS usage can significantly shorten development cycle, but with cost of FPGA resources and lower clock frequency achieved.

Most of important scientific journals published special issue editions focused entirely on H.265 implementations, both hardware and software, to mention [3] and [4]. The majority of those articles are dealing with encoding challenges. Some of them like [5] exploits Graphics Processing Units (GPUs) to accelerate the intra decoding procedure in HEVC decoder. Hardware partial implementations of H.265 in HLS are presented e.g., in [6] and [7] dealing with only part of the standard, which may imply overall challenges in implementing the entire HEVC encoding/decoding in FPGA.

In general, number of published hardware implementations of HEVC decoder in FPGA (full or partial) is relatively large, but there is very small number of publications on H.265 decoders using high level languages. In this paper, authors would like to reference publication related to HEVC IDCT implementation using Xilinx Vivado HLS and compared with few other implementations [8].

This paper presents first known to authors, H.265 Inverse Discrete Cosine/Sine Transform hardware implementation in Impulse C language [9], and achieved results in terms of clock frequency, frame rate and resource usage in comparison with [10]. Solution was verified on hardware platform PICO M503 [11], equipped with Virtex-6 FPGA family. This paper consist of few sections. In the following subsection, Impulse C features have been very briefly described, and their influence on the resulting implementation performance have been discussed in later section. Next section presents basic informations about 2D IDCT. Later proposed hardware architecture is depicted, following with achieved results in comparison with other solutions. Conclusions are closing this paper.

### A. Impulse C - high level language

High level synthesis is a set of tools able to translate algorithm description written in a high level language (mostly C/C++-based), to industry standard hardware description languages (HDL), like Verilog or VHDL, which then can be synthesized for the desired FPGA family. They provide also tools to analyse the parallelism of the generated code. HLS needs to also provide capabilities for the high-speed communication and synchronization between processing elements, to allow for the efficient algorithm decomposition into execution units running in parallel manner. One of the language from this group is Impulse C [9]. As the name suggests, it is ANSI C-based language, supporting almost all of its syntax, with addition of some library functions used for communication. Algorithm described in Impulse C can be decomposed into parallel processing units called processes. They can exchange data or/and synchronize between each other using few mechanisms, like streams, which allow for fast data exchange in FIFO-like manner. Signals allow to achieve synchronization between processes and pass single

32-bit data, similar to *rendez-vous* mechanism in real-time systems programming. Remaining synchronization methods are semaphores and shared memory. Impulse C compiler analyses the data dependency, and splits the processing into stages. In each stage all instructions without data dependency are scheduled to execute. This implies state machine implementation in generated HDL. Programmer has some influence on parallelization, using specific keywords, called pragmas, in the source code, that can, e.g. pipeline the execution of the loop, or unroll all instructions inside the loop, under some conditions. In Impulse C, developer can partition the project to split the execution between software and hardware. For some of FPGA development boards, Impulse C IDE provides also libraries and drivers, called Platform Support Package (PSP), which allow to build and run complete project in real hardware/software co-environment. Libraries provide communication mechanism, especially stream data flow, between software and hardware. In this way programmable devices can be used as a coprocessor, also this approach fits in the idea of FPGA-as-a-Service (FaaS), and latest Amazon AWS EC2 cloud [12] solution.

### B. HEVC 2D transform description

HEVC defines finite precision approximation of 2-dimensional discrete cosine transform for Transform Unit sizes from 4x4 to 32x32 pixels [1] [2]. In addition, it specifies 4x4 Discrete Sine Transform approximation for use in intra-frame solutions. Similar approach was introduced in H.264. In earlier video coding standards, mathematical formula for calculating cosine transform was used, leading to different implementations, which resulted in mismatch between different codecs. Because of this reason, in newer coding standards, like H.264, VC-1, HEVC, a core, integer transform has been defined, suitable for fixed-point and hardware implementations. Scaling and inverse transform processes are specified in the normalization document, while the TU size and quantization factor are chosen by the encoder. The main purpose of the transform is to de-correlate input data, which in most cases are residual data calculated based on prediction. Inverse DCT coefficients were carefully investigated and analysed by working group defining the H.265 standard. It was decided to represent each matrix coefficient with 8-bit. To perform integer transform, scaling factor is used at the end of the process, which is a power of 2, to easily implement it as a right shift. DCT has several properties very useful in terms of usage in video coding algorithms, particularly:

- Orthogonality, which allows transform coefficient to be uncorrelated,
- Good energy compaction,
- Smaller IDCT size matrix, is a sub-sample of the higher TU size,
- All rows have equal norm.

Formula for calculating 2D IDCT is as follows:

$$Y = XA A^T \quad (1)$$

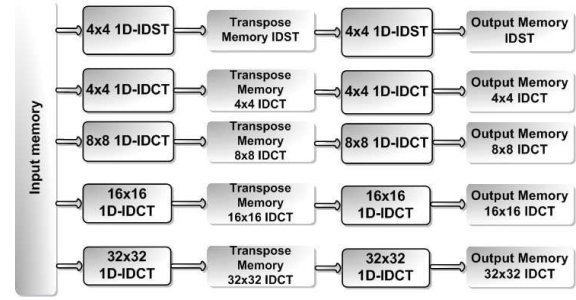

Fig. 1. HEVC 2D-IDCT proposed architecture.

It is known that 2D transform can be calculated in two 1D steps, with intermediate transpose memory. This decomposition is not standardized, but it is widely adopted in both software and hardware implementations to optimize calculations. This part of the decoding process is one of the most computationally expensive. Because of that, it is beneficial to realize it in the dedicated and optimized co-processor. Today's FPGAs are well positioned to serve such role.

## II. IMPLEMENTATION

### A. HEVC 2D IDCT Impulse C hardware implementation

In the presented Impulse C implementation of HEVC 2D IDCT/IDST, transform split into two 1D calculations with transpose memory was adopted, to pipeline the entire architecture. The implementation is based on HEVC reference software version HM-16.14 [13]. Figure 1 depicts proposed architecture. There is one single input memory for all transform sizes. All blocks performing 1D-IDCT/IDST reads from the same memory. Transpose memory has been split into 5 different memory blocks with size appropriate for the TU size. Split has been used to minimize critical path length. The same approach has been used for the output memory of the second stage of transform.

Figure 2 presents proposed architecture, while fig. 3 the actual source code for the 4x4 1D-IDCT module. Input memory has been split into 32 separate BRAM memories, each representing single row of 2D coefficient, to read the entire column simultaneously, and then copied into several sets of register arrays for multiple read in the same cycle later on. Similar approach has been applied to the transpose memory. Transform results are clipped to the range <-32767, 32768>, before written to the either Transpose Memory or Output Memory. All complex mathematical operations have been decomposed into simpler ones, to minimize critical path in resulting implementation. Presented solution has been split into software processes and hardware processing elements. Three software processes have been defined: *Producer*, which reads the input data from the file and sends it to the FPGA over PCIe bus. *Consumer* receives the result of inverse transform from the PICO M503 board, and stores the received data in the file for further verification/processing. *Stats* process receives data with processing duration (in clock cycles) of important hardware modules for every Transform Unit to

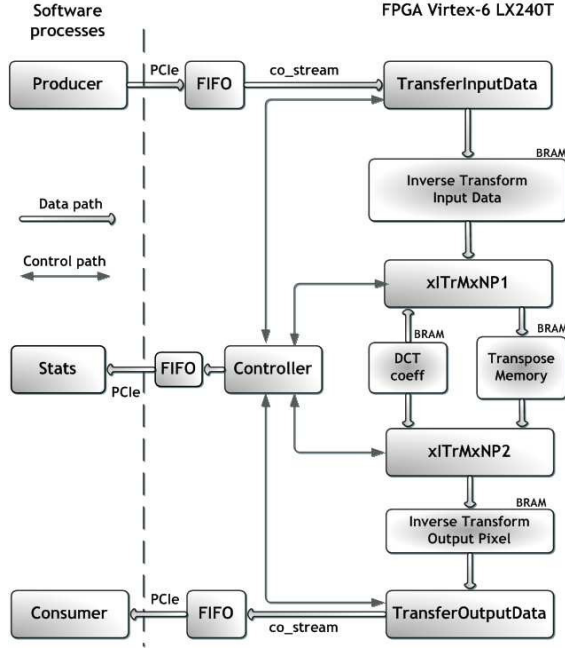

Fig. 2. HEVC Inverse Transform hardware/software architecture.

prove real-time performance of the implemented solution. On the FPGA side, five important processing elements (PEs) can be seen. *xITrMxNP1* and *xITrMxNP2* perform the actual 1D inverse transform in the pipeline manner. There are also modules to receive/send the data from/to the PCIe bus. Data between hardware processes are exchanged using BRAM memory. In  $n$ -th iteration one process (e.g. *xITrMxNP1*) writes the data to the one half of the memory, while the other (e.g. *xITrMxNP2*) reads from the other half. Controller process is responsible for all PEs synchronization, as well as collecting duration data and sending it over PCIe to the *Stats* software process. Presented solution is hardware/software co-design, but in FPGA only inverse transform is calculated. Software processes are responsible for data transfers.

### B. Implementation improvement techniques

Regular C++ H.265 reference software [13] inverse transform implementation, can not be directly compiled using Impulse C, also achieving 30fps frame rate requirement is not guaranteed. In order to meet real-time requirements for the video decoder, several changes and improvements have been introduced into the code. They include:

- Code changes - pointer arithmetic, dynamic allocations, and C++ specific features removal,
- Impulse C specific pragmas,
- Code refactoring - assignment simplification, arrays split or/and duplication, loop unrolling and pipelining, additional function(s) and process(es) extraction, explicit clock boundaries.

In this paper some of Impulse C features, like loop unrolling and pipelining used in the presented implementation, will be

```
void partialButterflyInverse4Phase1(co_uint1 aMemoryIndex, co_int8 shift)
{
    #pragma CO PRIMITIVE
    (... variable declarations ...)

8x8 2D-IDCT	197	31.3
16x16 2D-IDCT	812	30.4
32x32 2D-IDCT	2541	38.6

described in more detail.

1) *Loop unrolling*: This technique is commonly used in FPGA development. It results in speedup of the loop calculation in cost of area. In Impulse C it can be forced using dedicated pragma (*#pragma CO UNROLL*). In order to benefit from it, data array must be scalarizable, which is possible under few conditions:

- Array scalarization option is enabled in the compiler,
- Array cannot be initialized where declared,
- Array elements are accessed with constant indexes,
- Array elements cannot be read and written in single C statement,
- Loop index must be of type *int*.

In the provided code snippet in fig.3, for 4x4 1D-IDCT butterfly calculation, loop unrolling was applied. This allows to save at least 16 clock cycles per each TU (4 iterations of the inner loop \* 4 iterations of the outer loop) in comparison with the implementation without it. The purpose of the outer loop is to duplicate input data, in order to access them in parallel for the transform calculation, and minimize the fanout from the *tempCoeff* array in the resulting netlist.

2) *Loop pipelining*: Pipelined architecture is often very effective, however not all types of algorithms can be executed in such way efficiently. Inverse transform definition fits into this architecture. In impulse C loop pipelining must be called explicitly with the special C pragma (*#pragma CO PIPELINE*). Once compiled, it can be verified with Stage Master Explorer, what is the rate and the latency of the pipeline. *Rate* equals number of cycles required to complete single loop iteration, also determines how often pipeline can consume input data. So the goal is to reach rate equal 1. *Latency* is the number of cycles required for an input data to reach its output, it is also the pipeline length. The goal here is to have it as smallest as possible, especially for loops with small number of iterations. Pragma *CO SET stageDelay*, defines maximum number of combinatorial gate delays for single stage, and it is roughly equal to the gate delay in the target hardware. To achieve rate

optimal value, input data array for 1D-IDCT has been split into arrays representing each row. This allows to access the entire column of TU simultaneously. Also intermediate data arrays have been implemented and used in a way to scalarize them by the compiler, as described previously. Additional intermediate arrays have also been defined to break the critical path, however with cost of higher latency. Also each call to Clip3 method inferred separate logic in order to make those calculations simultaneous.

### C. Results and comparison with other implementations

Results of the proposed implementation written in Impulse C have been compared with results presented in [10], especially for Vivado HLS implementation which seems to be the most comparable. Presented solution uses multipliers realized in DSP blocks with exception to multiplication by 64, which is replaced by left shift operation. Table I contains comparison results.

Full HD fps has been approximated based on input data containing 58k TUs, calculated by the reference encoder [13], for the 3840x2160 frame resolution. So for the purpose of results comparison, estimated number of Transform Units in Full HD frame equals 14.5k. Based on processing time gathered in runtime, average inverse transform duration for the first 14.5k TUs equals  $T_{avg} = 357$  [clock cycles]. Achieved results are comparable to the Vivado HLS solution in terms of clock frequency, number of Slices and flip-flops used. Proposed solution uses 50% LUTs than HLS implementation presented in [10]. However the frame rate is significantly lower, but still exceeds 1080p@30fps resolution. In the currently discussed architecture, mechanism to gather duration data of all important PEs has been implemented. Complete data contains Table II. It can be seen that the most time consuming is 32x32 TU size, which is intuitive. On the other hand frame rate achieved with only this type of TUs is the highest one, as the number of such units within the video frame is smaller.

## III. CONCLUSIONS

In this paper, first known to authors, 2D-IDCT HEVC hardware implementation using Impulse C has been presented, with additional software processes for data transfer and profiling. Achieved results are compared with Vivado HLS solution proposed in [10], and are better in terms of resources used, but worse in terms of frame rate. Using HLS tools can greatly speedup implementation process, minimizing number of errors, as the same C testbench can be used later in HDL simulation and hardware functional verification. Future work can include critical path minimization or/and area optimization of the implementation to achieve better frame rate, even 4K real-time requirements, however this may require newer FPGA family, e.g. Xilinx UltraScale/UltraScale+ with higher speed grade. The other direction could be to include all intra-decoder parts as either software or hardware processes, and gradually move them to the FPGA.

## ACKNOWLEDGMENT

Authors would like to thank Impulse Accelerated Technologies (<http://www.impulseaccelerated.com>) for providing software license for the CoDeveloper Integrated Development Environment.

The work was supported by the AGH-UST grant 11.11.120.612.

**Abstract**—The image retrieval from multimedia databases is a very challenging problem nowadays. Not only it requires the proper query form, but also efficient methods of data storage. The problem is important, because nowadays there are many different systems which needs image retrieval. As an example web searching engines may be given, which had to store a very huge amount of images and needs fast image retrieval of chosen ones. Also social media portals increasingly face the same requirements. This paper presents a new Content Based Image Retrieval database. It is based on new object representation which is based on approximation of objects by a set of shapes. The structure of the database is designed in order to reduce the number of comparisons using a tree structure. The main advantages of the proposed solution are: easy queries for users, faster image retrieval and ability to parallelize queries.

## I. INTRODUCTION

THE image retrieval from multimedia databases is a very challenging problem nowadays. Not only it requires the proper query form, but also efficient methods of data storage. The problem is important, because nowadays there are many different systems which needs image retrieval. As an example web searching engines may be given, which had to store a very huge amount of images and needs fast image retrieval of chosen ones by users. Also social media portals increasingly face the same requirements. Other examples may be monitoring systems which have to detect objects and then find them in the database in order to e.g. check if they are undesirable and additional actions have to be performed. Also number plate or face recognition systems have to perform database queries based on the data present in the image. There are also some attempts of sketch-based CBIR usage in conjunction with gesture recognition [1].

This paper presents a new Content Based Image Retrieval database which is based on our previous researches [2], [3], [4], [5]. The main idea of the Query by Approximate Shapes algorithm is based on a new object representation which consists of approximation of objects by a set of shapes. There are six base shapes defined [2], called primitives. Each primitive may contain not only information about its type, but also parameters which describes each single shape occurrence (e.g. a slope for lines or an angle for arches) and relations to other shapes. In order to store all information about the object, a graph of shapes is proposed. The structure of the database which stores such graphs in order to be efficient, have

to reduce the number of comparisons, thus a tree structure is proposed. We defined two types of tree nodes:

- common nodes which are used to organize the data
- data nodes which only stores graphs

The main advantages of proposed solution are: easy queries for users (both images and graphs drawn by a human are accepted), faster retrieval of results thanks to the hierarchical structure and storing similar graphs in congruent nodes, ability to parallelize operations during query process and possibility to use different implementations of the database on the lower level (e.g. using NoSQL data stores, relational databases or containers).

The paper is organized as follows: the Section II presents related works in the area of Image Retrieval and database structures. The Section III contains our motivation and assumptions which are made for the system. The Section IV describes the object representation used in the database. The Section V is dedicated to the database structure and contains descriptions of inner structure, operations on nodes and queries. The Section VI shows initial experimental results. The Section VII presents the plans for the future works and conclusions. The last section contains bibliography.

## II. RELATED WORKS

The multimedia database Image Retrieval algorithms may be assigned to three types of algorithms:

- based on textual descriptions, most often keywords - Keywords Based Image Retrieval (KBIR) algorithms
- based on semantic information extracted from the image - Semantic Based Image Retrieval (SBIR) algorithms
- based on information which is present in the image - Content Based Image Retrieval (CBIR) algorithms

The Keyword Based Image Retrieval algorithms use textual annotations in order to describe the whole image or their parts. Most often descriptions are made by humans and the precision of keywords is limited to the knowledge and perception of a person [3]. For objects which are well known it is easy to represent them by annotations and the results of retrieval are very satisfactory. For example a car object may be named very precisely by the brand, model name, version, production year and color. When the object is not well known or it is not easy to describe it precisely by keywords, the results

may be imprecise. This is due to the fact that annotations are very subjective and different person may use different words as keywords for the same objects [6], [7]. For example a landscape with trees and water may be annotated by one person as a forest and a river, but by another one as trees and a lake. The third person contrary may use the name of place where the photo was taken. In this situation the results of a query may be imprecise and unsatisfactory for the user. Another disadvantage of the KBIR approach is that it is hard to automatically add keywords without human interaction.

The Semantic Based Image Retrieval algorithms are similar to Keyword Based Image Retrieval algorithms because they use also words to perform queries. However, contrary to them, they allows users to write queries as phrases which are more natural form for them. Such different query interface is used in order to overcome the so called 'semantic gap' which is a difference between what a human could describe and what is present in the image [7], [8]. After defining by an user, the phrases are mapped onto so called semantic features which are correlated with the content of the image [9]. The use of semantic based textual approach is more comfortable and easy for users but still if they does not have the full knowledge about searched images the results may be insufficient. There are also approaches which uses graphical queries which are then transformed into textual description. One of the most interesting research is [10] which uses a sketch as a query, then extracts textual annotations - semantic features and then finds 3D models of objects which are described by similar or the same set of features.

The Content Based Image Retrieval algorithms use information present in the image to perform queries [3]. In this area two types of algorithms could be distinguished: low-level and high-level [2]. The first type of algorithms are based on extraction of features for the whole image. There may be statistical image features used, e.g. a normalized color histogram [11]. Another methods may be a difference moment and entropy [12], a spatial domain image representation [13] or a bag of words histogram [14]. There are also approaches which use different MPEG-7 descriptors, e.g. shape and texture descriptors [15]. Since the features describes the whole image, the low-level CBIR algorithms provide very satisfactory results when a query is performed in order to find similar images. However, when an user would like to obtain images with the same object but with different backgrounds, the low level algorithms are not efficient and the results may be insufficient. The high-level CBIR algorithms are more suitable for that situations. Their main idea is to separate objects from the background and other parts of the image. Most often the region extraction method is used [2] which is based on gathering similar groups of pixels into uniform areas which are then transformed into a graph, storing the mutual relations between nodes. In order to extract regions, methods based on e.g. color thresholds, moment-based local operators [16] or fuzzy patterns recognition [17] may be used. The query process is strictly based on searching subgraphs between a graph which was extracted from the stored image and a graphs

stored in the database. The main disadvantage of the region-based algorithms is the need of query image which have to store many details. If an user does not have a proper one, it must be prepared which may require drawing skills.

There are also CBIR algorithms which allows performing queries without having the full knowledge about the searched objects. There are algorithms which are low-level e.g. [18]. The approach presented by authors is based on human drawn sketches which are then transformed into lower resolution images and compared with sketches in the database using edge detection techniques. The method provides good results, but is oriented on finding similar paintings, which is not sufficient for querying by objects. [19]. Other researches uses global contour map and salient contour map in order to extract objects and compare them with images in the database. There are also researches which use additionally relevant feedback (e.g. SIFT algorithm) an re-ranking to improve the results precision [20]. In our previous researches [4], [2], [5], [3] we proposed a high level algorithm which is based on decomposing object into its approximated by predefined shapes representation (Query by Approximate Shape). The shapes are used for creating a graph which is then compared with other graphs stored in the database. In this paper we describe the database structure based on the Query by Approximate Shape method.

All images or objects representations have to be stored in an efficient way. Most often a structure based on cells or trees are used [21]. One of the most interesting approaches is [22] which is based on a tree storing cells. The similar images are stored in the same cells, but when the similarity between images is below the determined threshold, another cell is created (a process in the paper called a mitosis). In [4] we proposed the first attempts for the database structure for our object representation which was based on Scalable Distributed Two-Layer Data Structures. The approach provided good results but was prone to rapid tree height increase. Moreover we would like to prepare the database structure which would be more universal and allow to use different data structures types in the lower implementation level (e.g. SD2DS, but also data containers or relational databases). This would increase the number of possible applications e.g. to use our database on devices with very small resources. Our database structure in some parts is based on the same ideas as [22] (e.g. storing similar data in the same part of the tree), but we use different inner structure and different methods of object representation and querying.

### III. MOTIVATION

The multimedia database structure as well as performing queries is a very broad problem. Not only querying by images may be complicated, but also storing a very huge amount of data, because images and their representation used for comparisons had to be kept. Some attempts for the database structure were presented in [4], but we would like to obtain more universal structure which could be used with different implementations for specific cases. This would allow implementing the Query by Approximate Shape database using for

Fig. 1. The primitives used to describe objects [2].

Fig. 2. The attributes used for line segments (a) and arches (b).

example Scalable Distibuted Two-Layer Data Structures for data servers, relational databases (e.g. MySQL) for desktops and containers like vectors or lists for tablets. As a result of our research we would like to obtain the system which fulfill the following requirements:

- ability to perform queries using graphs extracted from a query image or graphs drawn by a human (without need of drawing skills)
- easy addition of a new object without rebuilding or training the whole structure
- fast access to the data
- the database structure which allows parallelization in order to improve the efficiency of queries (and for example use different machines to process searching in different subtrees)
- the ability to set the minimum similarity between objects which is needed to add them to the result set
- higher level of database structure, which allows different implementations e.g. using NoSQL data stores, relational databases, containers etc.

#### IV. OBJECT GRAPH

The main idea of our algorithm is based on representing objects by shapes. Each object can be described using approximation by a set of geometrical shapes. The example representation was shown in a Fig. 3. In our previous research [2] we proposed to use following shapes, called primitives: line segments, polylines, polygons, arches, polyarches and arc-sided polygons (polygons constructed from arches) (Fig. 1). Each shape is defined by its type and its attributes:

- line segments are defined by the angle of its slope and optionally by their length (Fig. 2 a)
- polylines and polygons are defined by the number of line segments from which they are built and attributes of each of them
- arches are defined by the angle of the arc and optionally by its radius or diameter (Fig. 2 b)
- polyarches and arc-sided polygons are defined similarly like polylines and polygons by the number of arches from which they are built and attributes of each of them

The proposed object representation allows using two types of queries: a manually hand drawn sketches (e.g. using predefined

Fig. 3. The example sailboat object representation: a) an image, b) an object drawn with lines (black color) and arches (red color).

shapes, like in vector graphics) or to automatically extract shapes from the query image. Thanks to that, the database human interface may be more universal and more suitable for people without drawing skills. Moreover automatically generated queries by e.g. by monitoring systems would be also easily performed. The manually drawn sketches may be prepared using a set of predefined shapes and they may be very schematic without many details. Due to that fact they may be prepared fastly and easilty without high drawing skills. The automatically extraction of shapes from images is based on line segments and arches detection e.g. using Line Segment Detector algorithm and Circular Hough Transform[2]. Firstly all lines and arches are detected and then if it is possible, they are joined constructing more complex shapes like polylines, polygons, poly-arches and arc-sided polygons. The extraction procedure is described with more details in [2].

When representing an objects by set of shapes, there may be also needed an information how they are positioned to each others or which of them are connected. In order to store such an information a graph may be used [2].

Each graph may contain not also a description used to comparisons with other graphs, but also some metadata which is useful when returning results. For example metadata may contain the image name, its description and image file path or image binary pixels data.

In order to compare graphs with each others, a coefficient called *similarity* is used which describes how similar two graphs are. The values of *similarity* are between 0 and 1. The value 1 means that the graphs are the same, 0 that they are completely different. When generating a results set, some minimal threshold should be used to mark which graphs are similar and should be taken into account.

#### V. THE DATABASE STRUCTURE

The database structure is based on a tree which is build from different types of nodes. There are two types of elements:

- common (graphs) nodes which are used to organize the data
- data nodes which only stores graphs

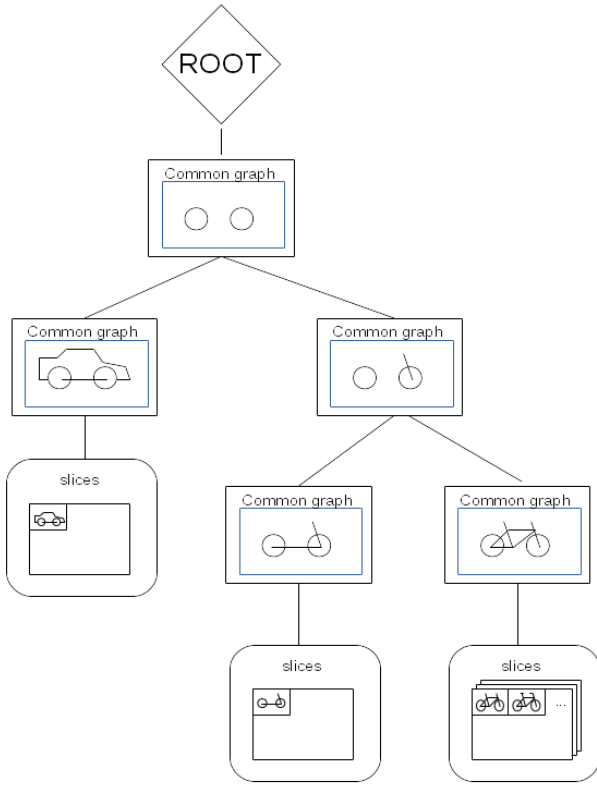

Fig. 4. The overview of the tree database structure

The database structure is partially based on our previous research [4]. In order to improve the time of comparisons, similar graphs are grouped into the same node or nodes, called data nodes. Moreover this could reduce greatly the height of the tree which was a problem in [4].

The root node is used as an entry point to the tree and does not contain a graph thus when compared with the query graph, it always returns the highest similarity. It may contain many children which are then compared on the next level of query.

The common graphs nodes are gathering similar parts of their children nodes as a graph. Therefore when the query graph is compared and does not have enough similarity, there is no need to compare other levels of tree and the whole subtree can be abandoned, which highly decrease the time of the query.

The data nodes does not have any children but contains one or more object graphs (which are correlated to images using metadata). They are used to gather similar graphs in the same node of the tree. Graphs are stored in a so called slice which is strictly a vector of graphs. The first vector element is the most similar graph to the common graph stored in the parent common node. Next graphs stored in the vector are compared to the first element and sorted from the most similar to the least. In order to improve the query time and to allow using parallelism or different machines to store some parts of graphs

**Algorithm 1** Splitting a vector of graphs when the maximum size is reached

---

**Ensure:**  $T_s$  - maximum number of graphs in the slice;  $dh$  - data node,  $vec$  - vector with graphs  
 $vSize \leftarrow size(vec)$ ;  
2: **if**  $vSize > T_s$  **then**  
    create new vector  $vec2$ ;  
4:   copy into  $vec2$  graphs from  $vec[T_s]$  to  $vec[vSize]$ ;  
    remove  $vec[T_s]$  to  $vec[vSize]$ ;  
6:   add  $vec2$  to  $dh$ ;  
**end if**

---

and images, there may be more than one slices of graphs stored in a one data node. Therefore, the first slice should store the most similar graph to the parent common graph and when a desired maximum number of graphs in a vector is achieved, the next vector slice is created (Alg. 1).

#### A. Inserting new graphs

Inserting a graph into the database is similar to the approach presented in [4]. Firstly the tree root is reached and then comparisons with all its children's graphs are performed. Comparisons are performed in order to find the best match between children's graphs nodes and the inserted graph (Fig. 5). When computing the similarity we divide the sum of found similarities between matched nodes by the minimum number of nodes in both graphs (Fig. 5 e) in order to avoid the situation when for the same matching, different similarity values are obtained (Fig. 5 c, d). If the similarity is high enough then its children are tested. If comparisons with two or more nodes returns high similarity, the node with the highest similarity value is used as a direction of the tree traversal. The new graph and common graphs comparisons are performed until the data node is reached. Then the graph insertion is performed, as described previously. Firstly the comparison of the first graph in the first slice is performed and then, based on the similarity result, the graph is put into the graphs vector in the position which is correlated with the *sim* value. If the maximum number of graphs in the vector is reached, the split operation is performed (Alg. 1). If during the tree traversal the comparison with the node's graph does not give enough similarity value, then a pair of new common and data nodes have to be created. The creation process is as follows: firstly a new graph which contains only common parts of the inserted graph and nodes's graph is being created and stored as a new common node. Next a new data node is created and the new graph is inserted into its data vector. Finally, the new common node is used as a parent for the node graph and new data node. The whole process is shown in the Fig. 6.

The graph insertion algorithm is presented in Alg. 2.

#### B. Querying the database

The database querying by a graph is much easier and faster with the proposed structure. Firstly, comparisons with all root children are performed. If similarity with one or more of

**Ensure:**  $g$  - the graph which has to be inserted;  $T_{sim}$  - minimal similarity of graphs  
 $node \leftarrow root$ ;

2: **while**  $node$  is not NULL **do**  
      $traverse \leftarrow true$ ;

4:   **if**  $node$  is a data node **then**  
     compare  $g$  with first graph in first slice of  $node$   
     [compare graphs using Alg. 3];

6:   insert  $g$  into  $node$  in the position related to the similarity;  
     **exit**

8:   **end if**

10:   **if**  $node$  is not a root **then**  
      $sim \leftarrow compareCommon(g, node - commonGraph)$  [compare graphs using Alg. 3];  
     **if**  $sim < T_{sim}$  **then**  
          $traverse \leftarrow false$ ;

12:    **end if**

14:   **end if**

16:   **if**  $traverse$  **then**  
     compare all  $node$ 's children common graphs with  $g$ , choose maximum similarity as  $sim$  [compare graphs using Alg. 3];  
     **if**  $sim < T_{sim}$  **then**  
          $traverse \leftarrow false$ ;

18:    **else**  
      $node \leftarrow$  child with max  $sim$ ;  
     **continue**;

20:    **end if**

22:   **end if**

24:   **if**  $!traverse$  **then**  
      $commGraph \leftarrow$  common part of  $g$  and  $node$ 's  $commonGraph$ ;  
     create new common node  $th$   
     insert  $commGraph$  into  $th$   
     create new data node  $dh$  and add as child to  $th$   
     insert  $g$  into  $dh$   
     add  $node$  as child to  $th$   
     **exit**

30:    **end if**

32:   **end if**

**end while**

---

them is high enough, each of them is tested until a common node with unsatisfactory similarity or a data node is reached. When a tree with not enough similarity is reached, the rest of the subtree is not tested. When a data node is reached, the comparisons within slices are performed. Firstly the similarity with the first and last graphs in slices are computed. If both are high enough, all graphs from slices are returned, if not, the proper range is specified using Algorithm 6.

The example querying process is shown in the the Fig. 7. The graph used for query is shown in Fig. 7 a). Firstly, the graph is compared with the root's child (id=2) which

  for each  $node_{g_i}$  in  $g_i$  do
20:   choose the match with nodes in  $g_{db}$  with highest  $sim_{g_i, g_{db}}$  value and add to  $sim$  ;
  end for
22:  $sim \leftarrow sim \div \min(\text{number of nodes in } g_i, \text{number of nodes in } g_{db})$ ;
  return  $sim$ ;

```

---

gives the *similarity* ( $sim$ ) value equal 1 - all nodes between graphs were matched. Then the minimal similarity threshold ( $T_{sim}$ ) is checked. The test was passed, the children nodes (id=3, id=4) are checked. The similarity result with the first node (id=3) does not passed the minimal similarity threshold test - the computed  $sim$  was equal 0.5 which is lower than  $T_{sim}$  value (0.8). These resulted in abandoning this tree path (consequently its child- id=5 is not tested). The comparison with the second id=2 child (id=4) returned *similarity* equal to one, which is higher than  $T_{sim}$  value. Therefore, its children are tested - id=6 and id=7. The *similarity* with id=6 node is equal 0.75 which is fairly high, but lower than  $T_{sim}$  and this path is also abandoned. Next, the id=7 is tested, the similarity is equal to 1, then its child (id=9) is tested. Since id=9 is a data node, other types of tests are performed. Firstly, the *similarity* with the first element in the first slice is computed.

---

**Algorithm 4** Comparing graphs nodes between each others. As a result the similarity coefficient is returned (values: <0,1>).

---

**Ensure:**  $pa$ ,  $pb$  - primitives to compare;

```

if nodes types are different then
2:   return 0
end if
4: if nodes types are line segments then
    $diff \leftarrow |angle\ slope\ of\ pa - angle\ slope\ of\ pb|$ 
6:   return  $sim \leftarrow 1 - diff$ 
end if
8: if nodes types are arches then
    $diff \leftarrow |angle\ of\ pa - angle\ of\ pb|$ 
10:  return  $sim \leftarrow 1 - diff$ 
end if
12: if nodes types are polylines, polygons, polyarches or arc-sided polygons then
    $diff \leftarrow |number\ of\ segments\ in\ pa - number\ of\ segments\ in\ pb|$ 
14:  try to match all segments between  $pa$  and  $pb$ , choosing the smallest difference of their attributes, sum all corresponding differences and add to  $diff$ 
    $sim \leftarrow (1 + \text{minimum number of segments}(pa, pb)) - diff$ 
16:  if  $sim > 1$  then
     $sim \leftarrow 1$ 
18:  return  $sim$ 
  end if
20: end if

```

---

Next the *similarity* with the last element in the first slice is computed. In this example both values are higher or equal to  $T_{sim}$  so the whole slice is returned as a result of the query.

Because each subtree is tested independently, the querying algorithm could be easily paralleled. The querying algorithm without parallelism is shown in Alg. 5.

### C. Deleting nodes

Deleting a graph from the database may be performed as follows: firstly if a graph is not the only one element in the slice, it may be removed from the vector without performing additional operations. If after removing a graph the slice does not contain any elements, the data node and its parent should be removed from the tree.

### D. Query parallelization possibilities

The proposed database structure allows parallelization of a query process. Since testing each tree node is independent from others, it may be executed in different threads or machine nodes. If a data node stores many slices, they may be also checked independently. Gathering the results may need some synchronization if all results have to be sent at the same time. However, this process could be also implemented as asynchronous, sending partial results to the client when they are obtained.

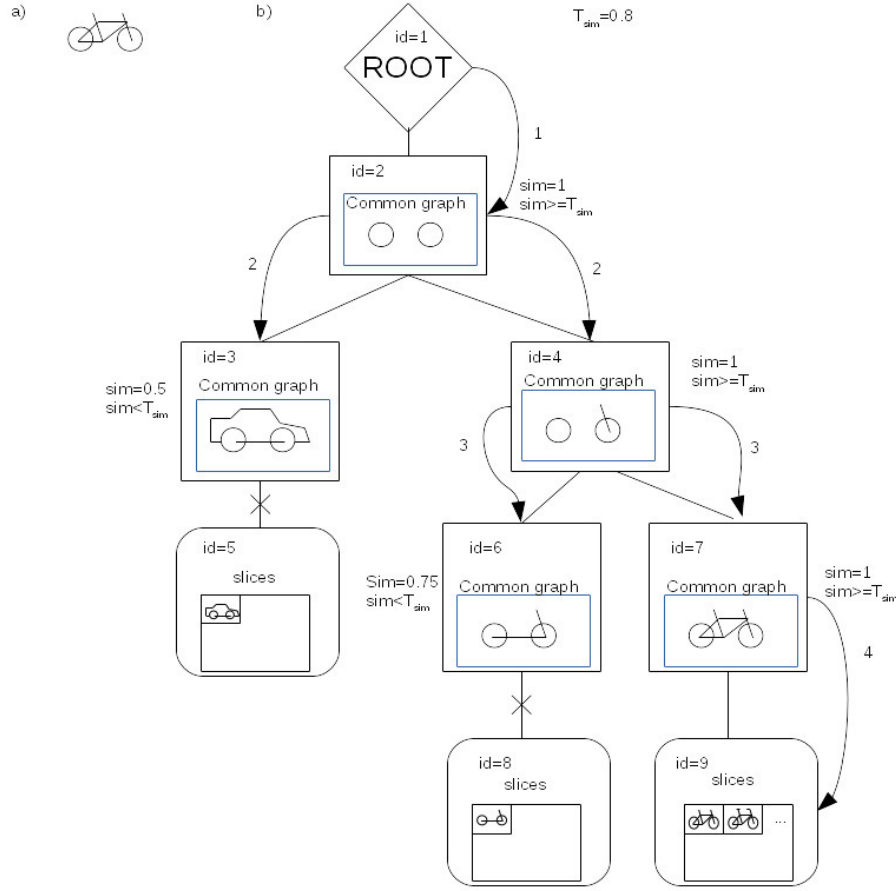

Fig. 7. The example query tree traversal: a) the query object graph, b) the query

**Algorithm 5** Querying the database

---

**Ensure:**  $g$  - the query graph;  $T_{sim}$  - minimal similarity of graphs;  $stack$  - a stack which is used to store nodes to check;

put  $root$  into the  $stack$ ;

2: **while**  $stack$  is not empty **do**

$node \leftarrow$  pop element from  $stack$

4: **if**  $node$  is a data node **then**

choose all graphs from  $node$  slices using Alg. 6;

6: **continue**;

**end if**

8: **if**  $node$  is not a root **then**

$sim \leftarrow$  similarity of  $g$  and common graph in  $node$  [compare graphs using Alg. 3];

10: **if**  $sim \geq T_{sim}$  **then**

put all  $node$  children to the  $stack$ ;

12: **end if**

**else**

14: put all  $node$  children to the  $stack$ ;

**end if**

16: **end while**

---

## VI. EXPERIMENTAL RESULTS

The proposed approach was initially tested using prototype database structure implementation written in C++ and database of cars, motorbikes, bicycles and scooters containing 111 images. In order to test the precision two coefficients were used:

$$precision = \frac{\text{number of relevant results images}}{\text{total number of results images}} \quad (1)$$

$$recall = \frac{\text{number of relevant results images}}{\text{total number of relevant images in the database}} \quad (2)$$

The test results for the chosen 6 objects are presented in the Table I. It may be observed that the precision of the results is high for bicycles, motorbikes and cars objects, but for scooter it is much lower. This was caused by the high similarity of scooter graphs to bicycles and motorbikes objects. However the recall values are much lower than precision. This is caused by usage of real life images which contained different variations of objects. As a feature research direction we would to increase this coefficient values.

Additionally some initial tests for comparisons between linear and tree database structure were performed in order to

**Algorithm 6** Querying the slice in data node

---

**Ensure:**  $g$  - the query graph;  $slices[1..n][1..m]$  - the  $n$  slices which stores vectors of  $m$  graphs;  $T_{sim}$  - minimal similarity of graphs;

**for each**  $slice$  in  $slices$  **do**

2:  $L \leftarrow slice[1];$   
 $R \leftarrow slice[m];$

4: **while**  $l \leq r$  **do**  
 $sim_L \leftarrow$  similarity of  $g$  and first graph in  $slice[L]$   
[compare graphs using Alg. 3];

6:  $sim_R \leftarrow$  similarity of  $g$  and last graph in  $slice[R]$   
[compare graphs using Alg. 3];

**if**  $sim_L \geq T_{sim}$  and  $sim_R \geq T_{sim}$  **then**

8: add all graphs from slice between  $L$  and  $R$  indexes into the result set;  
break while loop;

10: **else**  
**if**  $sim_L \geq T_{sim}$  **then**

12:  $L \leftarrow L + 1;$   
**end if**

14: **if**  $sim_R \geq T_{sim}$  **then**  
 $R \leftarrow R - 1;$

16: **end if**  
**end if**

18: **end while**  
**end for**

---

TABLE I  
THE PRECISION AND RECALL RESULTS FOR CHOSEN TEST OBJECTS

object	Query by Shape	
	precision	recall
bicycle	0.93	0.37
bicycle (a sketch)	1.0	0.60
scooter	0.67	1.0
motorbike	0.86	0.40
car (Fiat 500)	0.89	0.33
car (Mercedes Benz)	0.79	0.73

observe how efficient is proposed structure. The results are presented in the Table II. The tests for two different number of elements were performed. It could be seen that for the smaller number of graphs (23) the query time is similar for both structures. When the number of graphs was increased (to 68) the tree structure returned results about two times faster than linear structure, which was expected. As our future research we would like to perform more similar tests with much higher number of graphs.

## VII. CONCLUSION AND FUTURE WORKS

This paper presents a new Content Based Image Retrieval database structure. The main idea of the proposed approach is based on object representation proposed in [2]. Each object can be represented as a set of predefined shapes: a line segment, a polygon, a polyline, an arc, a polyarc and an arc-sided polygon. All shapes are connected into a graph, in order to store the mutual relations between them. The object

TABLE II  
THE COMPARISON OF QUERY EXECUTION TIMES FOR LINEAR AND TREE DATA STRUCTURE.

structure	query time in microseconds	
	23 graphs	68 graphs
linear	62	114
tree	58	63

representation allows users to use as a query images or simple sketches which does not need drawing skills. The proposed database structure is based on a tree with two types of nodes - common nodes which are used to organize the data and data nodes which stores similar graphs. This structure allow faster retrieval of results, because during the first query steps almost all not similar graphs are omitted. Moreover the query could be parallelized very easily in order to increase the performance. The proposed database structure is also more universal than our first approach presented in [4] because it is designed in order to allow different implementations suited for specific applications (e.g using SD2DS for servers or simple containers for mobile devices).

The future research includes testing the database structure with higher number of elements and comparisons with linear structure. Moreover the *recall* coefficient should be improved. Another direction would be implementing the parallelized queries in order to test their efficiency. Another set of tests should be performed in order to evaluate different lower database level implementations, using e.g. SD2DS data structures or MySQL. Moreover different graphs comparisons algorithms may be tested, e.g. using optimization methods with constraints [23].

**Abstract—** Older adults are the fastest growing segment of the population worldwide. This paper presents a evaluation of the user experience of two online web-banking sites from an older user's point of view. We therefore conducted a usability testing employing 12 older participants, in order to analyze the needs and issues faced by this user group when performing real-world tasks. The study involved six tasks which users were required to complete within a specific time. Most of the participants were interested in learning to use online banking. Our results show that older persons do not find web-banking sites easy or user-friendly. Our qualitative findings revealed that both of the web-banking sites we examined presented problems. Implications for the future include the need to redesign bank websites so as to include guidelines and other suggestions made in this study.

### I. INTRODUCTION

**P**OPULATION aging is a worldwide phenomenon. At the present time, the older section of the population lives surrounded by technology, internet- and mobile-based, most of which is, however, not adapted to their needs. However, this increase worldwide in numbers of the aged means that the need for online and mobile technology services will only increase. By 2020, it is anticipated that there will be more than a billion older adults, making it essential that websites be designed for easy use by the elderly [1].

Online banking is an exchange that employs laptops or other mobile devices, such as smart phones and tablets. Through online banking, the user can transfer and receive money, pay bills, initiate fixed deposits and perform transactions and other tasks. At the time when research for this paper began, little attention had been paid to the concerns of older adults and their ability to access online banking systems. According to a recent Federal Reserve Board report, only 18% of people over the age of 60 use mobile banking [2].

Providing online banking resources, however, does not guarantee that older adults will be successful at accessing the system or understanding how to complete their tasks. Banking institutions have been creating websites for many years now, although these cannot be said to be user-friendly for older users, in that they create barriers that tend to

prevent such users from using their mobile devices to access and use banking services [3].

It is clearly necessary to adapt applications and services both to the needs and preferences of this increasing number of older users and to the requirements of new economic contexts [4]. Older users encounter numerous barriers that arise from aging when they interact with computer technology and particularly when they attempt online banking [5].

The purpose of our study was to explore the experiences of "seniors" (persons aged 65 and over) in relation to online banking websites. More particularly, this study attempts to explore the experiences of seniors using two popular online web banking sites, that is, those belonging to two Greek banks, Alpha Bank and Piraeus Bank. The study offers an empirical evaluation of how far online banking interfaces meet the needs of older users and how such persons perceive their online-banking experiences.

We start our paper with a review of the literature, which establishes the theoretical background to our study. We then describe the research methodology employed, discuss the results and offer informal recommendations before the conclusions.

### II. BACKGROUND

#### A. Defining "Seniors"

There is no exact point in a person's life at which they become a "senior". However, due to an obvious need for such a definition, various classifications of "seniors" or "older adults" do exist. Nielsen defines "seniors" as users aged 65 years or older, without giving an upper limit. He notes that users aged 65 and older are 43% slower at using websites than users aged 21–55. This represents an advance over results given in earlier studies, but designs should clearly be modified still more, to accommodate the needs of aging users even further. Nielsen points out that the success rate for completing online tasks is typically a third less for those over 65 years of age than for those under 55 years old [6]. Website tasks take seniors on average 7:43 minutes to complete, whilst younger users complete their tasks in 5:28 minutes [6]. Nielsen uses a simple definition. For him, "Seniors" are simply users aged 65 years or older. Nielsen also reports that "Between the ages of 25 and 60, the time

users need to complete website tasks increases by 0.8% per year” [7].

B. Ageing

The aging population in the Europe is already large and is growing. It enjoys considerable social and economic power. Furthermore, people are now living longer. Nearly 80% of the population now survives beyond the age of 65. In 2010, older workers accounted for 17% - 31% of the population of the European Union, while it is forecast that by 2050 these rates will have more than doubled [8]. Intimately related to issues involved in the design of new websites or applications for seniors is the importance of understanding the highly complex process of human ageing as cognitive, perceptual and motor abilities decline with age and thus render more difficult many tasks, including basic pointing and selecting, that are commonly used in interaction with a device [9], [10], [11], [12].

C. Online Banking

Online banking makes use of electronic payment processes that allow both customers and financial institutions to perform a wide range of banking transactions through their website. Some online banks are traditional banks which also offer online banking, while others exist only in cyberspace and have no physical presence. Online Banking is changing the way customers interact with the banks [13]. Seniors, however, are not accustomed to computers and are more unfamiliar with the functional use of information technology based services than are middle-aged adults and the young [14].

D. User Experience

User experience (UX) is a concept widely used in human-computer interaction (HCI), both in research and practice. As devices and applications become increasingly ubiquitous, it becomes ever more important to improve and facilitate UX. The International Organization for Standardization (ISO) defines user experience as “a person's perceptions and responses that result from the use or anticipated use of a product, system or service” [15]. User experience is thus subjective and focuses on use. In regard to user performance when using a device, previous studies have shown that novice users usually face greater difficulties than the experienced do in handling computer devices or in acquiring computer skills [16],[17]. In Buxton’s [18] view, user experience consists of a combination of visual and experiential aesthetics and usability. The experience of online banking on the part of seniors is a mix of positive and negative. A minority of older people use Internet banking and appreciate its convenience. The most important barriers to utilizing online banking lay in the fact that would-be users did not know how to get started and that they found existing online banking confusing. The quality of User Experience is what dictates whether seniors adopt the system or not. Getting the design right improves user experience and may attract new customers [19].

III. RESEARCH METHODOLOGY

To examine how seniors conceptualize online banking, participants were invited to participate in a usability testing involving interaction with two of the most popular web banking sites in Greece, namely , the Alpha Bank site (B1) and the Piraeus Bank site. (B2) (Fig.1, Fig.2).

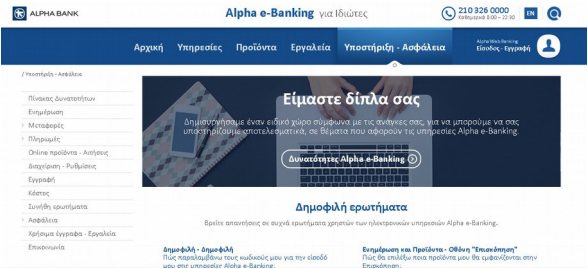

Fig.1 Screen capture Alpha Bank (B1)

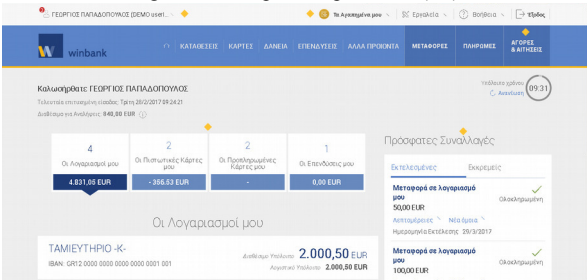

Fig.2 Bank Screen capture Piraeus Bank (B2)

A. Participants

Twelve participants in their 60s and 70s (7 females and 5 males) were contacted and selected through verbal contact.

TABLE I  
PARTICIPANTS’ AGE, GENDER

Alpha Bank (B1)						
ID	P1	P2	P3	P4	P5	P6
Age	62	74	65	72	63	79
Gender	F	F	M	F	F	M
Mean age = 69.2				SD= 6.3		
Piraeus Bank (B2)						
ID	P7	P8	P9	P10	P11	P12
Age	67	73	66	67	78	63
Gender	M	M	F	F	F	M
Mean age = 69.0				SD= 5.0		

For this recruitment procedure, we applied the following three criteria:

1. that the seniors wished to use online banking,
2. that they had no previous experience of these two sites
3. that they had at least some experience of the internet.

The participants are educated, reasonably healthy, active and motivated older users and as mentioned above, have basic computer skills. Given the evidence from our previous studies, the number of people in this experiment was sufficient to provide satisfactory evidence and depth of

knowledge. The age and gender of the participants and their assignment to either bank site, which was performed randomly, are shown in Table I. All participants gave their written, informed consent to participate.

#### B. Procedure

Our study evaluated two simulated bank websites, Alpha (B1) and Piraeus (B2). A digital camera was used to create a complete record of all user interactions with the website. After being welcomed by the experimenters, participants were told that they were to take part in a user experience test. Participants thereupon completed a pre-questionnaire regarding demographics and computer technology use. Test sessions started with a brief introduction, in which the purpose of the study was explained. To ensure the privacy of participants and reproduce a realistic environment, two prototypes were developed that simulated the behavior of the two bank websites through the use of prototyping software. Participants were then shown the home page of the bank website assigned to them and asked various questions about it. Participants were then asked to complete a series of tasks related to each of the two sites.

Overall, the two sets of tasks were similar, but differed in detail, given that the content and the options varied between the two sites. During the test session, a digital camera was used to create a complete record of all user interactions with the interface. The users' voices were recorded and their activity on the website was also recorded by means of screen-capture software. During each session, two experimenters were present, one primarily to engage with the participants, and the other to take notes. User performance was recorded in terms of the effectiveness, efficiency and ease of use of bank websites.

#### C. User Tasks

For the usability test, the participants were required to complete the six tasks given in Table II. The tasks were chosen as being representative of online banking activities. Participants were allowed up to four minutes to complete each task.

TABLE II  
PARTICIPANTS' TASKS

<b>Task 1</b>	Turn on device and select the bank site
<b>Task 2</b>	Understanding the home page
<b>Task 3</b>	Login to your account
<b>Task 4</b>	Navigating through the bank site
<b>Task 5</b>	Make a transaction (money transfer)
<b>Task 6</b>	Print the receipt of this transaction

### IV. RESULTS AND DISCUSSION

Overall, participants found the websites functional, but frustrating. The results obtained were used to compare our two bank websites in terms of efficiency, effectiveness and ease of use. "Effectiveness" refers to how "well" a system does what it supposed to do. To evaluate task effectiveness,

we measured the percentage of steps successfully negotiated within the time limit (5 min).

"Efficiency" refers to how quickly a system supports the user in what he wishes to do. To evaluate efficiency, we recorded the time required to process the task. "Satisfaction" and "ease of use" refer to the subjective view of the system on the part of the user [20],[21],[22]. Qualitative and quantitative data were collected from each participant. Qualitative data included the participants' verbal protocol as recorded in video recordings and discussion with each participant after the test.

#### A. Efficiency-Task completion Time

Efficiency is a measure that is highly dependent on the amount of time spent completing the task. We recorded the total amount of time required to complete each task on each of the bank websites. Table III shows information on the mean time spent by the participants. Some tasks were more difficult to complete than others and this is reflected by the average time spent on the task. The results indicate that participants spent more time (Average time) on task completion when interacting with website B2.

#### B. Effectiveness

The percentage of users that manage to complete a task successfully is the "success rate". This thus becomes a measure of the effectiveness of the design. Our results are shown in Table III.

TABLE III  
TASK COMPLETION TIME & SUCCESS RATE

Tasks	Average Time for Completion in seconds		Standard deviation		Success Rate (percentage)	
	B1	B2	B1	B2	B1	B2
<b>Task 1</b>	124	141	36.9	82.8	100%	100%
<b>Task 2</b>	94	96	26.8	19.5	83%	67%
<b>Task 3</b>	126	166	40.7	58.3	67%	67%
<b>Task 4</b>	169	250	33.8	73.5	67%	50%
<b>Task 5</b>	234	282	61.4	70.9	67%	50%
<b>Task 6</b>	171	200	28.2	58.0	83%	67%

#### C. Post- test Questionnaire

User satisfaction may be an important factor in motivating people to use a web site, an application or a product and may affect user performance. After completing the tasks, therefore, participants were asked follow-up questions regarding their experiences with the website. The post questionnaire results show that:

- The bank sites were easy to access (B1 (83%), B2 (50%)) and very easy (B2 (17%)) (**Task 1**)
- Participants understood the home page B1 (67%) and B2 (50%)(**Task 2**)
- When participants were asked about the simulation task that involved logging in to their account, they found it neutral (B1(67%), B2(50%))(**Task 3**).

- As regards navigation through the two sites, one third of participants found this task difficult, one third found it neutral and one third found it easy. Difficulties arose in identifying the correct button for the action they wanted to complete (**Task 4**).
- Most participants found the task involving a transaction difficult (B1 (67%), B2 (67%)) (**Task 5**).
- Participants were very clearly unable to find the icon for printing the transaction receipt. In particular, this task at site B2 was found difficult (83%) to very difficult (17%), due to the small size of the icon involved (**Task 6**).

Participants commented on their frustration when using their website. In particular, Participant 2 commented “*Some tasks were very frustrating*”, Participant 8 complained that “*I can’t find my way back to the previous page, when I try to fill in my account number in Task 5*”.

We observed several other sources of confusion and frustration for the participants, including not understanding “*where they were*” in the case of both sites. This arose because of the low contrast between the button they had selected and the background. Participant 11 claimed that he was unable to find the “*print button*” in site B2 to print his transaction. The closer the visual representation is to the intended meaning, the shorter the articulatory distance becomes [23]. In addition, participants commented that “*There is too much to read*” and they had to scroll down the page. Several participants did not know how to use cues on web pages (e.g. page titles, menu highlighting) to keep track of where they were on the website and so felt lost.

#### D. Overall user experience

Several participants mentioned that they were excited to learn about computers and online banking, because this would enable them to save time and money, although they did not have anyone to teach them. Some of them used our study as a learning opportunity, and paid close attention after a task had been completed, in order to learn more about online banking and the correct way to complete tasks.

Although many of the seniors showed interest in using online banking, many voiced concerns regarding usability that arose from confusing navigation and layout, small text, inadequately contrasting colours, very small icons and a lack of comprehension of web terminology.

Regarding interface options and selections, seniors preferred fewer options. Seniors want to learn to use online banking, but are sometimes intimidated. This was apparent to us in discussion subsequent to the post test questionnaire. Some of the critical barriers to seniors adopting online banking include:

- small fonts and very small abstract icons and symbols,
- poor text legibility, due to the use of capitals letters for selection sections (B2),
- difficulties in accessing content indicated by poorly contrasting colours,
- the need for excessive scrolling, in which participants need to scroll the page to read important information,

- small buttons, functions that are difficult to manipulate, such as scrolling a menu (B2) and unnecessarily complicated interfaces,
- difficulty in finding one’s location in the site and
- cluttered interfaces

Fig.3 Task difficulty in percentage for B1 bank website

Fig.4 Task difficulty in percentage for B2 bank website

#### E. Design recommendations

In view of our usability test results and our analysis of our post questionnaire results, we make the following recommendations in the hope of making improvements in the areas in which participants experienced problems, confusion and frustration.

- Inserting more space between sections, employing larger fonts for headers and using more deeply contrasting colors would improve perceptions of hierarchy and help direct seniors to the sections to which they wish to navigate.
  - Scrolling menus shouldn’t be used, as seniors dislike them.
  - A clear distinction should be made between clickable buttons and non-clickable features.
  - There should be provision of clear feedback on actions.
- Johnson and Finn argue that, if one keeps in mind the usability issues experienced by seniors when one designs

interfaces, one can improve the user experience for many people, rather than just the elderly [24].

#### D. Limitations

Given the small sample size ( $n = 12$ ), the results of our study cannot claim to offer a comprehensive picture of seniors' interaction with online banking systems. Another important factor limiting the applicability of our results lies in the fact that participants used simulated, rather than real, websites. Furthermore, although participants had to log in to our simulated sites, they were not required to wait for a response from the bank.

This is of importance, as it has been reported in the literature that most senior users abandon their efforts in a few seconds, if they face difficulties during login.

#### V. CONCLUSION

The aim of our study was to explore seniors' experience of online banking. We used twelve participants and two Greek websites, that of Alpha bank and that of Piraeus Bank to test our experimental methodology. Six of the participants were randomly assigned to one website and six to the other. Because of the small size of the sample ( $n=12$ ), we evaluated our data on the basis of descriptive statistics. We elicited user experience by means of six tasks.

Several seniors indeed wish to use online banking and the majority of those whom we surveyed are interested in using internet banking, because they understand its benefits. The results of the study show that both in terms of usability and overall impression our participants found the websites to be functional, but felt that they require considerable improvement to ensure a user-friendly experience. Design considerations should include the suggestions made by seniors, such as the use of larger font, the use of highly contrasting colours in selections, the reduction of features and the use of an intuitive interface and of a structure offering easier navigation. Furthermore, some abstract icons, such as that for the 'print' function, may need to be redesigned, so that older adults understand their function more easily.

In view of the lack of studies on the experience of seniors with banking websites, it is our hope that this study has contributed to the literature, in that it offers findings that will improve the usability for seniors of online banking sites.

**Abstract**—In this paper the problem of corneal endothelium image segmentation is considered. Particularly, a fully automatic approach for delineating contours of corneal endothelial cells is proposed. The approach produces one pixel width outline of cells. It bases on a simple feedforward neural network trained to recognize pixels which belong to the cell borders. The edge probability (edginess) map output by the network is next analysed row by row and column by column in order to find local peaks of the network response. These peaks are considered as cell border candidates and in the last step of the method via binary morphological processing are linked to create continuous outlines of cells. The results of applying the proposed approach to publicly available data set of corneal endothelium images as well as the assessment of the method against ground truth segmentation are presented and discussed. Obtained results show, that the proposed approach performs very well. The resulting mean absolute error of cell number determination is around 5% while the average DICE measure reaches 0.83 which is a good result, especially when one pixel width objects are compared.

**Index Terms**—corneal endothelium, cell segmentation, feedforward neural network, peaks detection

## I. INTRODUCTION

THE corneal endothelium i.e. the inner layer of the cornea, is of great interest for ophthalmologists. This layer is formed by closely packed, predominantly hexagonal cells whose shape and structure can provide important diagnostic information about the cornea health status or indicate some corneal diseases [1], [2]. Particularly, the quantification of corneal health status is usually performed based on endothelial image by means of corneal endothelial cell density. Additional measures like cell size distribution or cells hexagonality are also useful to evaluate the health status of the corneal tissue. However, the usage of the latter measures is not common in everyday clinical routine. It is because performing this kind of assessment requires segmentation of all cells present in the endothelial image. Having in mind that in the healthy cornea there are up to 3000 endothelial cells per square millimetre, their manual segmentation is very tedious and very time consuming activity. The reason is that it requires manual delineation of cell borders. Since no commercial software is available for corneal endothelial cell segmentation, the development of the dedicated image processing and analysis algorithms for computer aided diagnosis of corneal diseases still remains a vital problem [3].

Segmentation of corneal endothelial cells is a difficult and sometimes very challenging task. The problems arise mainly due to inhomogeneous background illumination in specular microscopy corneal endothelium images. This factor reduces contrast in some regions of an image and makes cell borders difficult to recognize even by an expert.

Several semi-automatic or fully automatic solutions for segmentation of endothelial image have already been introduced. Their aim is to delineate cell borders using such techniques as: local greyscale thresholding followed by scissoring and morphological thinning [4], [5], scale-space filtering followed by binarization and morphological processing [6] or hexagon detection using shape dependent filters [7], [8], [9]. More sophisticated methods include application of watersheds [10], [11], [12], [13], [14], active contours [15], [16], genetic algorithms [17] or analysis of local pixel levels aimed at finding intensity valleys corresponding to borders between cells [18]. Several machine learning approaches have also been proposed by the team of Ruggeri, including: neural network [19], [20], Bayesian framework [21], support vector machines classifier [22] and genetic algorithm [23]. However, up to this point none of the existing techniques allows to achieve perfect segmentation of endothelial cells. The results

Fig. 1. A sample pair of images from the Alizarine dataset; a) original corneal endothelium image  $I_{RGB}$ ; b) the corresponding ground truth  $G$ .

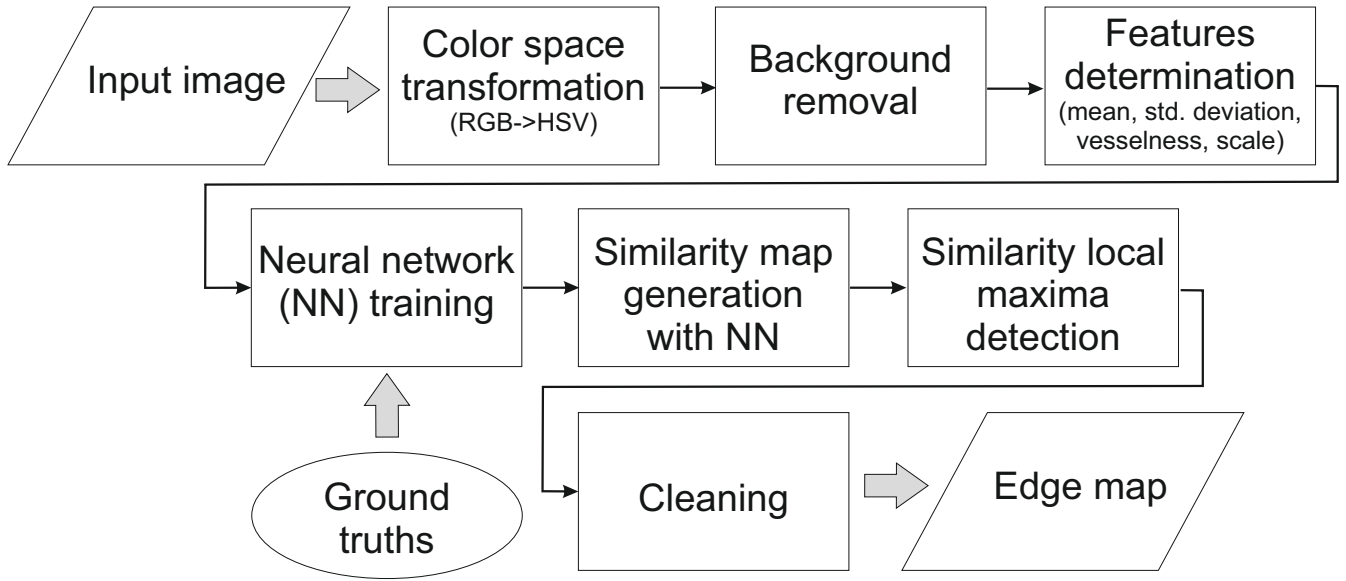

Fig. 2. The general work-flow of the proposed approach for corneal endothelium image segmentation.

still require manual editing, since undetected or false cell boundaries often appear in the resulting image.

Having in mind above limitations, this paper proposes an alternative solution to automatic segmentation of endothelial cells from microscopic images of corneal endothelium. The proposed approach is based on a simple feedforward neural network which is thought to recognize pixels located at the borders between cells and thus segment their contours. The edge probability map output by the network is next subjected to further processing in order to produce one pixel width boundaries of cells. Particularly, local peaks of edge probability map are considered as cell border pixels and linked to create continuous outlines of cells.

The following part of this paper is organised as follows. Firstly, in Section II the description of the dataset used in this study is given. The proposed approach is described in details in Section III and followed by evaluation of the results and discussion in Section IV. Finally, Section V concludes the paper.

## II. INPUT DATA

In this work corneal endothelium image *Alizarine* data set was used [20]. The dataset (which can be downloaded from [24]) contains 30 images of corneal endothelium, each stored as JPEG compressed file of the resolution 576×768 pixels. The images were acquired from 30 porcine eyes stained with alizarine red using inverse phase contrast microscope (CK 40, Olympus) at 200×magnification and analogue camera (SSC-DC50AP, Sony).

In the dataset for each image the corresponding manually created ground truth is provided. The ground truth images delineate borders between single cells within selected regions of each image. On average the area of  $0.54 \pm 0.07 \text{ mm}^2$  per cornea was assessed, ranging from 0.31 to 0.64  $\text{mm}^2$ .

A sample corneal endothelium image from the considered dataset is shown in Figure 1a, while the corresponding ground truth is presented in Figure 1b. From the figure it can be seen that cells manifest themselves as uniformly sized hexagonal regions separated by visibly darker borders. Due to the acquisition protocol and uneven illumination in some regions of the image the contrast between cell boundaries and background is low. Additionally, intensity inhomogeneity within the background can be observed. These factors significantly hinder cell segmentation.

## III. THE PROPOSED APPROACH

The aim of the proposed approach is to obtain a binary representation  $\mathcal{M}(x, y) : \Omega \subset \mathbb{R}^2 \rightarrow \{0, 1\}$  of endothelial cell borders in corneal endothelium image  $\mathcal{I}_{RGB}(x, y)$ . Particularly, the output of the proposed approach is binary image  $\mathcal{M}$  in which 1 (i.e. white pixels) correspond with cell borders and 0 (i.e. black pixels) correspond with cell bodies. This is obtained by following the procedure summarised in Figure 2.

The main idea behind the introduced approach is to use ground truth images provided in *Alizarine* dataset to train a simple feedforward neural network to recognize borders between cells. The trained network is next used to perform edge based segmentation of endothelial cells in new images. The details of this procedure are given in the following subsections.

### A. Colour space transformation and colour component selection

In the input corneal endothelial images  $\mathcal{I}_{RGB}$  each pixel  $(x, y)$  stores red, green and blue colour component, i.e.  $\mathcal{I}_{RGB}(x, y) = [r(x, y), g(x, y), b(x, y)]$ . Prior to the main processing the transformation  $F : \mathcal{I}_{RGB} \rightarrow \mathcal{I}_{HSV}$  into the HSV colour space is applied, where  $\mathcal{I}_{HSV}(x, y) =$

$[h(x, y), s(x, y), v(x, y)]$  and colour components represent hue, saturation and value respectively. Further processing is performed with respect to  $v$  colour component, since other colour components do not carry significant information related to cell borders. This is illustrated in Figure 3 which presents sample corneal endothelium image and the corresponding  $h, s, v$  colour components.

Fig. 3. A corneal endothelium image HSV colour components; a) original image  $I_{RGB}$ ; b) hue colour component  $h$ ; c) saturation colour component  $s$ ; d) value colour component  $v$ .

### B. Background removal

In the next step image  $v$  is enhanced in order to compensate for non-uniform intensity distribution within background and thus to highlight image information at the cell borders. This is obtained via background  $v_{bkg}$  subtraction performed in accordance with the following equation:

$$\hat{v} = v - v_{bkg} \quad (1)$$

where image of background is a result of greyscale morphological opening of image  $v$  with a big structural element  $s_{el}$  (see Eqn. 2).

$$v_{bkg} = (v \ominus s_{el}) \oplus s_{el} \quad (2)$$

where  $\ominus$  denotes erosion and  $\oplus$  denotes dilation.

The element  $s_{el}$  should be big enough to remove cell borders. In this study  $s_{el}$  was selected to be a disk of a radius 15 pixels. Shape of the structural element was set experimentally. Disk shape was used due to similarity to cells shape.

### C. Features determination

In features determination stage the following features are determined for each pixel  $(x, y)$  of an image  $v$ :

- average value of intensity  $\bar{v}$  in the neighbourhood of  $5 \times 5$  pixels;
- standard deviation of intensity  $\sigma_v$  in the neighbourhood of  $5 \times 5$  pixels;
- vesselness  $\mathcal{V}$  determined from image  $v$  using Frangi's approach with default settings [25];
- scale  $\mathcal{V}_\sigma$  used for vesselness determination [25].

The images representing considered features obtained for a sample image are presented in Figure 4. It can be seen, that vesselness (Fig. 4e), scale (Fig. 4f) and partially standard deviation (Fig. 4d) give visibly distinguished responses at the edges of cells, while intensity information may be helpful in distinguishing cells bodies.

The experiments considering selection of some of the above features were also performed, however using all of these five features yielded the best results in terms of cell detection accuracy.

### D. Neural network training

Features determined as described above are next composed into a feature vector  $F = [v, \bar{v}, \sigma_v, \mathcal{V}, \mathcal{V}_\sigma]$  and assigned to the corresponding pixel  $(x, y)$ . The feature vectors together with the corresponding ground truths segmentations are used to train a neural network  $\mathcal{T}$  such that  $\mathcal{T} : F(x, y) \rightarrow \{\mathcal{O}(x, y) : \mathcal{O}(x, y) \in [0, 1]\}$  and value of 0 corresponds with a cell body while value of 1 denotes a cell boundary.

In the study a simple feedforward neural network of architecture presented in Figure 5 was used. Particularly, the network consists of one hidden layer (with tan-sigmoid transfer function) followed by output layer (with linear transfer function). The hidden layer consists of 10 neurons. Both the number of hidden layers as well as the number of hidden neurons within the layer were adjusted in a trial, balancing between the time required for training and the accuracy of cell borders detection. For training the Levenberg-Marquardt backpropagation approach [26] was used since for the considered problem it provided the best regression between network outputs and network targets. Initial weights and biases were set randomly.

### E. Peaks Detection

The response of a neural network  $\mathcal{O}(x, y)$  (i.e. edginess or edge probability map) contains values between 0 and 1 and visibly highlights image information at the borders of cells. However, the response is not everywhere uniform and some weaker boundaries are less highlighted. Additionally, the highlighted edges are few pixels width, thus borders detection can not be accurately performed via image thresholding. Therefore, in order to precisely define border location analysis of local network response maxima is performed via peaks detection. Particularly, the network response image  $\mathcal{O}$  is processed independently row by row and column by column. Each row  $r_j$  such that  $\mathcal{O} = [r_j]_{W \times 1}$ ,  $j \in \{1, \dots, H\}$  and each column  $c_i$  such that  $\mathcal{O} = [c_i]_{1 \times H}$ ,  $i \in \{1, \dots, W\}$  (where  $W$ ,  $H$  denote image width and height respectively) is processed separately. The values contained in each column  $c_i$  and each

Fig. 5. The structure of a feedforward neural network used in this research.

row  $r_j$  are treated as a signal in which local peaks indicate edges. A local peak is a data sample that is larger than its nearest neighbouring samples. If a peak is flat, only the point with the lowest index is considered. In order to diminish the number of local maxima around the cell boundaries only peaks higher than some threshold  $T_{PeakHeight}$  are considered. The idea of peaks detection is sketched in Figure 6 which shows the distribution of neural network response over a sample row. Peaks of the accepted height are marked with red circles. The pseudocode of the complete procedure of cell edge candidate detection is shown in Algorithm 1.

#### F. Cleaning

Together with real boundary segments, the cell edge candidate detection procedure produces also some small isolated groups of pixels which do not belong to the cell boundaries. In the in the last step of the proposed approach these regions are removed.

The cleaning procedure incorporates a sequence of the following morphological operations performed on a binary image:

- *removal of isolated pixels*
- *dilation with a small structural element*  
the aim of this step is to close small gaps in the cell boundaries and thus make boundaries continuous; in this

Fig. 6. The idea of local peaks detection. Peaks of the accepted prominence are marked with red circles.

---

study a square structural element of a size 5×5 pixels was used;

- *skeletonization*

for this purpose the iterative thinning is used; the aim of this step is to provide one-pixel-width boundaries of endothelial cells;

- *pruning*

aiming at removal of spurious branches of skeleton which mostly include fragments of discontinuous boundaries.

The results of the consecutive steps of the proposed approach applied to a sample endothelial image are shown in Figure 7. In particular Figure 7a shows value colour component  $v$  of a sample input image. This is followed by image  $\hat{v}$  after background removal shown in Figure 7b. The output  $\mathcal{O}$  of a feedforward neural network is presented in Figure 7c and

followed in Figure 7d by the map of network response local maxima. The map after cleaning  $\mathcal{M}$  is presented in Figure 7e and overlaid on the original image in Figure 7f.

#### IV. RESULTS AND DISCUSSION

For verification purposes the endothelial cell Alizarine data set was divided into two equal subsets (i.e. containing 15 images each). First, images denoted by even numbers were used to train the neural network  $\mathcal{T}$  (a training set). Next, images denoted by odd numbers were used as a testing set. Particularly, the proposed cell edges detection procedure was applied to each image within the testing set. The network training took about 10 minutes while segmentation of a single image lasted for about 2 seconds (PC computer, 24 GB RAM, Intel Core i7, 3.2 GHz).

The accuracy of the proposed approach on testing set was assessed twofold. First, the alignment between the ground truths and segmentation results was investigated. Particularly, the results  $\mathcal{M}$  of cell segmentation were compared with the ground truth results  $\mathcal{G}$  by means of mean square error (MSE), correlation (COR) and DICE measure (DIC) given by Equations 3-5. During the assessment, edge pixels were considered as object. Since in the ground truths  $\mathcal{G}$  the edges were few pixels width, they were skeletonized (by thinning) prior to comparison. The results of the above comparison are summarized in Table I with image ID given in the first column and the mean values given in the last row. In the comparison, only the regions with known ground truth borders were considered.

$$MSE = \frac{1}{K} \sum_x \sum_y (\mathcal{M}(x, y) - \mathcal{G}(x, y))^2 \quad (3)$$

where  $K$  denotes a number of pixels in a considered image region.

$$COR = \frac{\sum_x \sum_y (\mathcal{M}(x, y) - \bar{\mathcal{M}})(\mathcal{G}(x, y) - \bar{\mathcal{G}})}{\sqrt{(\sum_x \sum_y (\mathcal{M}(x, y) - \bar{\mathcal{M}})^2)(\sum_x \sum_y (\mathcal{G}(x, y) - \bar{\mathcal{G}})^2)}} \quad (4)$$

$$DIC = \frac{2|\mathcal{M} \cap \mathcal{G}|}{|\mathcal{M}| + |\mathcal{G}|} \quad (5)$$

Fig. 7. Consecutive steps of the proposed approach; a) original image  $\mathcal{I}_{RGB}$ ; b) value colour component  $v$ ; c) output of the neural network  $\mathcal{O}$ ; d) results of local peaks detection; e) final result  $\mathcal{M}$  - cleaned and pruned map of local peaks; f) final result overlaid on the original image.

Additionally, the comparison was made between the number  $N$  of cells in the segmentation result and in the ground truth image  $N_{GT}$  as well as the corresponding average cell sizes  $\bar{S}$  and  $\bar{S}_{GT}$ . Cell sizes were measured in pixels. Additionally, the absolute error  $\delta N$  of the determined cell number and the absolute error  $\delta \bar{S}$  of the average cell size were calculated according to Equations 6 and 7 respectively.

The results of this comparison were summarised in the Table I with image ID given in the first column and the mean values of errors given in the last row. Again, in the assessment, only the regions with known ground truth borders were considered.

$$\delta N = \frac{N - n_{GT}}{n_{GT}} \times 100\% \quad (6)$$

$$\delta \bar{S} = \frac{\bar{S} - \bar{S}_{GT}}{\bar{S}_{GT}} \times 100\% \quad (7)$$

The numerical assessment is supplemented by visual results in Figure 8. In the upper panel original images are presented. In the middle panel the cell edges produced by the proposed approach are overlaid on the original images. Finally, in the bottom panel results are compared with the corresponding ground truths. Particularly, white colour indicates regions where both results overlay. Green colour corresponds to false

edges introduced by the proposed approach while the missing edges are shown in magenta. For presentation purposes the best result (case 19, Fig. 8a), the worst result (case 29, Fig. 8b) and the "average" result (case 13, Fig. 8c) were selected.

Based on both the numerical and the visual results it can be concluded, that the proposed approach performs reasonably well. The visual results in Figure 8 clearly show, that the borders produced by the proposed approach and the ground truth are well aligned. This is confirmed by the average values of correlation and DICE equal to 0.817 and 0.826 respectively (see Tab. I). These measures should be considered high, especially having in mind that edges considered here as object are one pixel width and even slight displacement of the edge may decrease these measures, not necessarily meaning that the cell segmentation failed. This effect also can be observed in Figure 8. Additionally, both correlation and DICE measure would have been higher, if the edge pruning hadn't been performed in order to obtain closed borders only. High accuracy of the results is also confirmed with very low MSE on average equal to 0.017 (ranging from 0.013 to 0.029).

From Table II it can be seen, that the proposed method slightly underestimates the number  $N$  of the detected cells. This in turn increases the average cell size and will increase the determined cell densities. The corresponding, average error  $\delta N$  of the determined cell number equals to -5.2% (ranging from -2.6% to -9.0%) while the resulting cell size determination error is on the average equal to 4.5% (ranging from 2.6% to 9.3%). In the case of the considered study it corresponded on average to 18 cells which were joined with

their neighbours (ranging from 7 cells in the case 19 to 40 cells in the case 29). However, this can be fast corrected by manual editing which in the worst case considered in this study requires drawing c.a. 20 lines and takes definitely less time, than manual segmentation.

## V. CONCLUSIONS

The proposed approach for endothelial image segmentation provides promising results without user intervention. Additionally, the results are provided in a reasonable time. Although the architecture of a neural network incorporated in the approach was simple, it was capable of delineating accurately most of endothelial cell borders. The results seem even more promising, when one notices that the training dataset contained only several images. It should be also highlighted, that in the ground truth images used for neural network training, only well defined borders were marked. Unsharp and blurry borders were not highlighted and thus it was not possible to train the neural network to recognize this kind of borders. Therefore, the future work will be concentrated on extending the training dataset by corneal endothelium images of low quality in order to make the proposed method capable of segmenting low contrast borders.

## ACKNOWLEDGMENT

This work was co-financed by the Lodz University of Technology, Faculty of Electrical, Electronic, Computer and Control Engineering as a part of a statutory project.

I would also like to acknowledge Dr hab. Adam Piórkowski from AGH University of Science and Technology in Poland for inspiring the research described in this paper.

**Abstract**—In this paper, we discuss the generation of symbols (and alphabets) based on specific user requirements (medium, priorities, type of information that needs to be conveyed). A framework for the generation of alphabets is proposed, and its use for the generation of a shorthand writing system is explored. We discuss the possible use of machine learning and genetic algorithms to gather inputs for generation of such alphabets and for optimization of already generated ones. The alphabets generated using such methods may be used in very different fields, from the creation of synthetic languages and constructed scripts to the creation of sensible commands for multimodal interaction through Human-Computer Interfaces, such as mouse gestures, touchpads, body gestures, eye-tracking cameras, and brain-computing Interfaces, especially in applications for elderly care and people with disabilities.

## I. INTRODUCTION

THE NEED to create writing systems has been with humankind since the dawn of time, and they always evolved based on the concrete challenges the writers faced. For example, the angular shapes of the runes are very convenient to be carved in wood or stone [1]. The rapid increase of available mediums in the recent decades determined the need for many more alphabets, for very different use cases, such as controlling computers using touchpads, mouse gestures or eye tracking cameras. It is especially important for elderly care applications [2] on the basis of the newly available information and communication technologies based on multimodal interaction through human-computer interfaces like wearable computing, augmented reality, brain-computing interfaces [3], etc.

Many approaches for the manual creation of alphabets have been used, but we are not familiar with a formalized system for their generation. Manually created alphabets are usually suboptimal. For example, it might be argued that the Latin alphabet favours the writer more than the reader, since it evolved under the constraints of pen and paper, and those constraints are much less relevant in the computer age. Fonts which try to overcome this limitation exist [4]. In a similar fashion, many systems do not use the possibilities given by the medium or context, electing to base themselves on already existing (familiar to the user, but suboptimal context-wise) symbols. A formalized framework capable of gathering requirements, generating symbols, grading them on a set of criteria and mapping them to meanings may be able to overcome many of those limitations.

The main aim of this paper is to propose a formalized framework capable of gathering requirements, generating symbols, grading them on a set of criteria and mapping them

to meanings, which potentially may overcome many of these limitations. The section II. *Characteristics of a Rational Alphabet* contains the short characterization of basic terms and parameters of alphabets. The section III. *Requirements for the needed alphabet* includes an example description of the requirements posed for alphabets used for shorthand systems. The section IV. *Generation of Glyphs* proposes a method for the generation of glyphs with examples. The section V. *Evaluation of Glyphs and Alphabets* contains discussion of fitness of glyphs/alphabets in relation to machine learning methods. The section VI. *Discussion and future work* dedicated to discussion of the results obtained and lessons learned.

## II. CHARACTERISTICS OF A RATIONAL ALPHABET

"Glyph" is defined as unique mark/symbol in a given medium. "Symbol" is defined as a glyph with a meaning attached to it. "Alphabet" is defined as a system of such symbols, including possible modifiers and conventions.

Glyphs are generated and rated first, and meanings are assigned later; the alphabet as a whole is rated at the very end. This two-step process design choice is based on performance reasons (mutating individual glyphs and their meanings at the same time is too complex for any reasonably-sized alphabet) and is meant as a starting point for further research and adaptation.

The following characteristics should generalize well for almost any alphabet, independently from the medium, dimensionality, and purpose. The vocabulary related to writing 2D characters with a pen or stylus is used, but this can be replaced with any other device.

### A. Writing comfort and ergonomics

For our purposes, we define comfort as "how easy and enjoyable is to use the alphabet".

- How much mental effort does the recall of the symbols require (ease of recall)
  - How familiar are the symbols to the user at the moment he is writing.
    - \* Similarity to already known stimuli
    - \* Availability of a mnemonic system
- Fluency/flow, both for individual letters and their usual combinations.
- Physical limitations. For example, some strokes might be easier to write if someone is right-handed, or holds his pen in a certain way.

We suggest the following metrics as starting points for future research and discussion:

1) *Mental effort*: We think that this would be best measured via existing methods and some new methods of fatigue estimation on the basis of machine learning methods [5]. Changes in pupil size might be an especially interesting avenue in this aspect [6], as something objective and easy to measure.

If memory is more an issue than cognitive load, than generating the alphabet in such a way so that the glyphs can be "calculated" at writing time might help; as a very example of this, when we were manually creating our shorthand system, we decided to encode time, modality, and person via a single glyph consisting of three parts.

2) *Fluency*: Possible metrics for fluency could be:

- Number of shap angles per glyph.
- Curvature per glyph. Both can be defined as sum the sum of absolute changes in direction per unit of distance.
- Ratio of strokes that mean something semantically, as opposed to "connecting one glyph with another", to the entire number.
- Number of easily connectable glyphs following each other in an average text, so that as little unnecessary movements are made. For example, given a representative source text,

$$c = \sum_{i=1}^n \sum_{j=1}^n E(g_i, g_j) P(g_i, g_j)$$

, where  $n$  is the number of existing glyphs,  $E(g_i, g_j)$  is how "easy" are the two glyph to connect,  $P(g_i, g_j)$  is how the probability  $g_i$  will be directly before  $g_j$ .

### B. Writing speed

Defined not as "how fast the pen moves", but rather "how much time is needed to convey the needed information".

- How fast are individual glyphs to write. This intersects heavily with "Fluency".
  - Fluency from the subsection above.
  - How much the pen needs to travel to form the glyph.
- How much "meaning" can be encoded in one glyph. This is directly related to redundancy and entropy, discussed in the following sections.
- The more simple glyphs should be mapped to the most common symbols.

A potentially interesting experiment would be timing people using the system, and dividing the amount of information written by the time taken; but this would raise questions about the input information. Accurately calculating the entropy of the conveyed information for this purpose would be practical only for alphabets used in very narrow and formalized contexts.

### C. Ease of recognition

- How different are the glyphs between each other
- how much are distortions likely to worsen the recognition of the glyphs.

Additionally, here various memory biases and characteristics of human memory will be at play (see, for example, the Von Restorff effect [7]).

### D. Universality

Ideally, the glyphs should generalize well. That means that once learned for styluses, the same alphabet shouldn't be too hard to port to other mediums without losing many of the above mentioned characteristics. Excepting changes of dimensionality (3D-gestures might be hard to port to a 2D-stylus), this is probably the hardest to quantify and account for.

## III. REQUIREMENTS FOR THE NEEDED ALPHABET

Most writing systems have been heavily influenced by the constraints inherent in their area of use — purpose, characteristics of the information they needed to convey, materials. Even naturally evolving systems tend to converge towards local optima rather than a global optimum. Requirements and use patterns may gradually change, while the systems may be stuck in a state that is not optimal anymore. Therefore, a very careful analysis of the requirements and limitations is needed.

As example of applying our requirements above to our case of shorthand system, we can consider the following:

1) On a purely symbolic level:

a) Writing letters

- i) number of strokes needed to encode individual letters
- ii) complexity of the resulting glyph

b) Writing words

- i) connections between individual letters (glyphs)
- ii) how likely are letters that are easy to connect to each to be represented by easily connectable glyphs
- iii) if all existing glyphs are not identical in complexity, what is the ratio of easy-to-write glyphs to the complex ones in a typical text (the bigger the ratio, the better)

2) Writing sentences:

- a) are there any often-repeating words or groups of words which, when replaced by a shorter, even if complex, symbol, would lead to a gain in time? ("The" as a typical example).

3) On a semantic level: Are there any grammatical categories or modalities that are represented in natural text with many letters, that when replaced by a single glyph or a modifier, would lead to a gain in time? (tenses, number, gender, hypotheticals, ...). The above mentioned symbol encoding time, modality, and person, to shorten words like "they would have been able to", happened at this level of abstraction.

4) On an information theoretical level: How much redundancy is needed? How many errors in transcription can happen before the message becomes either unreadable or its meaning is distorted? (Natural languages are redundant via multiple mechanisms, notably via agreement in person, gender, case... Errors or interferences will still allow to understand what's being said, up to a certain

Fig. 1. Example of generated glyph with low fitness

Fig. 2. Glyph with higher fitness

point. This may not be the case for constructed writing systems, if they are built with low redundancy.) [8]

One way to quantify some of the above would be analyzing source texts. At the end, at least the following information should be available:

- frequencies of individual letters  $p_i$
- most-needed connections  $c_{ij}$

As example of how the information can be used, let's consider again our hypothetical shorthand system. Each of the generated glyphs can have three possible starting and ending strokes, represented by integers, and positioned at different heights.  $I_s, I_e = \{0, 1, 2\}$  Glyphs  $i, j$  where  $i_e = j_s$  are considered easily connectable. Using this information, later we can map the glyphs to meanings in such a way, that the letters that are most likely to follow each other are more likely to be represented by easily connectable glyphs. The problem would be trivially solvable by having all glyphs start and end at the same point, but this would make it harder to differentiate the individual glyphs.

#### IV. GENERATION OF THE GLYPHS

The second part of the proposed framework is the generation of possible glyphs. In this paper, Bezier curves have been used to generate the glyphs and calculate some of the needed metrics. During the generation of the example glyphs, we made the following assumptions about the alphabet for which the glyphs are generated:

- 1) The glyphs have a definite starting and ending point; the number of such points is limited, to facilitate connecting the symbols to each other.
- 2) The stroke width does not vary (as, for example, in the case of Pitman shorthand), because of the low availability of pens able to convey even two levels of thickness and of low average penmanship skill in most people. (Though using it as a third or fourth dimension would certainly be possible.)
- 3) The symbols will fit into a square bounding box.

The generation of glyphs starts by fixing a definite starting and ending point and then adding a semi-random number of control points. Figures 1-3 are examples of glyphs generated using the above rules.

#### V. EVALUATION OF GLYPHS AND ALPHABETS

In this stage, the fitness of each glyph is determined. Many approaches are possible, and they heavily depend on the context and the medium for which the generation is being done. For our shorthand system, the main criteria were length and simplicity. The number of control points has been used as a proxy of fitness and has been partly accounted for in the generation phase (empirically, the more control points the more chaotic the glyph is). The second metric is complexity, which may be loosely defined as "how hard it would be to write this symbol using a pen". For our purposes, complexity is defined as  $\frac{c}{l}$ , where  $c$  is the sum of the angles in the polygonal representation of the curve (informally, how curved the glyph is; the more curves there are and the sharper the individual curves are, the bigger the value is), and  $l$  is the length of the curve (a certain amount of curves on a large glyph should not be penalized as much as the same amount on a smaller one).  $C$  is calculated by converting the curve between the first adjoining control points to a polygon, summing the absolute value of the angles between all adjoining lines, and repeating the process for all the successive control points.  $c = \sum_{i=1}^n \sum_{j=2}^p L_n(j_i, j_i - 1)$ , where  $n$  is the number of control points,  $p$  is the number of lines used to approximate the curve,  $L$  is the angle between two lines, and  $j_i$  is the line after the control point  $i$ .

The reasons for defining  $c$  as we did are manifold, one of them being that a very similar metric is used for evaluating

Fig. 3. The simpler a glyph is, the higher fitness it has

the similarity of the two glyphs to each other. Much better metrics are possible.

The subjective reactions to signs might vary between people, differences due to age, cultural and/or language background are probable. This might be a promising area to study with the help of machine learning. Data like "Symbols similar to X perform poorly with demographic Y" would be valuable for creating alphabets when something about the probable users is known.

Additionally, machine learning would open the doors for custom-tailored systems, where users rate some symbols and based on their feedback predictions are made about what other symbols they might like, remember and use. The first mapping of the generated glyphs, before its fitness is rated, is necessarily very tentative. In this paper we have not touched grammatical modalities and ways to shorten them in great detail, as they would merit quite a lot more research and space (and, probably, their own paper); regardless, they would have their place at this step of the framework. For an alphabet, our goals could be the following:

- 1) As much high-fitness letters as possible
- 2) Letters which are found the most often should have the highest fitness (that is, be as simple as possible).
- 3) The letters should be unlike to each other
- 4) The letters should be easily connectable

The most important requirement is for the letters to be unlike each other. This is needed both for the resulting text to be readable (the existence of a 1-to-1 mapping between a text written in shorthand and a normal text, or at least for the resulting text being readable using contextual clues) and for improving the memorization of the glyphs (memorizing many similar stimuli is much harder than many different ones, unless a good framework for memorization is given, such as dividing symbols in parts).

For our purposes histogram comparison was the most straight-forward to implement. The data for the histogram is provided by the angles computed at the previous step. Basic shapes and turns would be recognizable, and the difference between the two makeshift histograms would approximate the difference between the glyphs. Here,  $D_{ij}$  is the difference between glyphs  $i, j$ .

Therefore, one formula for the fitness could be:

$$f = \sum_{i=1}^n f_i + \sum_{i=1}^n \sum_{j=1}^n D_{ij} + \sum_{i=1}^n f_i p_i$$

and the glyphs are picked so that the above formula is maximized. (The formula above does not include connections.)

A genetic algorithm at this point would attempt adding/removing/moving control points, switching glyphs between letters, introducing mirror-distortions etc. etc.

## VI. DISCUSSION AND FUTURE WORK

The basic ideas of this framework can be applied for the generation of any alphabet used in the real world. For touchpads, for example, connections may be built not using

three possible endings, but 2D-points on the screen instead, and multitouch and weight-sensitivity may be included in the generation. By adding dimensions, 3D-gestures alphabets may be created. Much better heuristics for fitness may be created by more precise algorithms, machine learning and use of biology and cognitive science. The approaches demonstrated here are general enough to allow an enormous amount of flexibility in the kind of alphabets they may be used to create. One of the more interesting avenues of further research would be creating algorithms for mapping glyphs to semantics, both to letters and to more complex grammar categories or structures. Finding (with AI?) the categories which could be shortened to one or two symbols is challenging by itself, but not all of the possible patterns found by an AI would be intuitive enough for a person to use or even to understand.

**Abstract**—Recently, there has been an increasing number of attempts to analyze sport activities through the combination of sports science and ICT technology. In the case of soccer, several leading companies have already developed tracking techniques for players to automatically acquire sports analysis data. However, the automatic extraction of event data for analyzing the sports games is limited to the level of academic research, and the field still depends on the manual work of professional analysts. This paper proposes a soccer event recognition technology based on pattern matching. As can be seen from the experimental results, it is possible to recognize various events much more accurately than the event recognition technology at academic research level.

## I. INTRODUCTION

**R**ECENTLY, a case attempting to analyze sports activity through sports science and ICT technology combines increased. In particular, in the case of soccer and baseball games, as shown in Table I, several leading international companies have already developed tracking techniques for players and balls to automatically acquire sports analysis data [1]. However, the automatic extraction of event data for analyzing the contents of sports games is a mere academic research level. Especially, in the case of soccer games, it is still dependent on the manual work of professional recorders and analysts.

TABLE I  
MAJOR COMMERCIAL SPORTS ANALYSIS SYSTEM

Products	Sports	Special features
TRACAB	Soccer	Video-based real-time 3D player tracking technique created using rocket tracking technology
Viper	Soccer	Sensor-based technology to measure player's speed, acceleration, maximum speed and heart rate during sports game
Prozone	Soccer	Player tracking and real-time game analysis based on big data
Club Portal	Soccer	Real-time player tracking and handwriting input based event extraction
Hawk-Eye	Soccer Tennis	Goal line out detection based on high-speed multi cameras
SportVision	Baseball	Player/Ball recognition and tracking in MLB by using the composition of radar and video-based tracking technology
FreeD	Baseball	3D play motion reconstruction by using high-speed multi cameras

In this paper, we propose a soccer event recognition technique based on pattern matching that can solve the problems of existing academic research and apply it to real field of soccer event recognition technique.

The composition of this paper is as follows. In Sec. II, we describe the existing researches. In Sec. III, we propose automatic pattern matching based soccer event recognition. Sec. IV shows the experimental results of the proposed method. Finally, Sec. V discusses the conclusions and future research directions.

## II. PREVIOUS WORKS

The existing event recognition techniques using soccer video are largely based on video-shot and voice based. First, in the case of video-shot based event recognition, the sequence of the method of shooting the game for each event in the soccer broadcast video is defined in advance for recognizing the goal, shooting, corner kick, free kick, penalty kick and foul [2], [3]. That is, firstly, the given soccer broadcast video is classified into a close-up view, a short view, a long view, and a crowd view, and then a pattern of each view is displayed for each event. On the other hand, in the case of voice-based event recognition, a method of recognizing the occurrence of important events by recognizing the referee whistle sound and the voice loudness and style of the commentator and spectators was used [4].

The above conventional methods are not based on the action of the object such as the player/referee who perform the actual game, but rather recognize audio/video clues in broadcast soccer video and recognize main event based on it. Therefore, it has a limitation that it can not sufficiently reflect the change of the shooting technique or the reaction pattern of the spectator and the commentator which is different from the predefined pattern. In addition, the existing technique can not recognize the event itself because it does not accurately understand the movement and motion of the player/referee. Therefore, rather than classifying and analyzing each event accurately, it has a limitation that it focuses more on producing highlight video by grouping the recognized points on the assumption that the main event will exist at the recognized point in time.

Taking all the above into consideration, we need a way to accurately identify soccer events through the position and

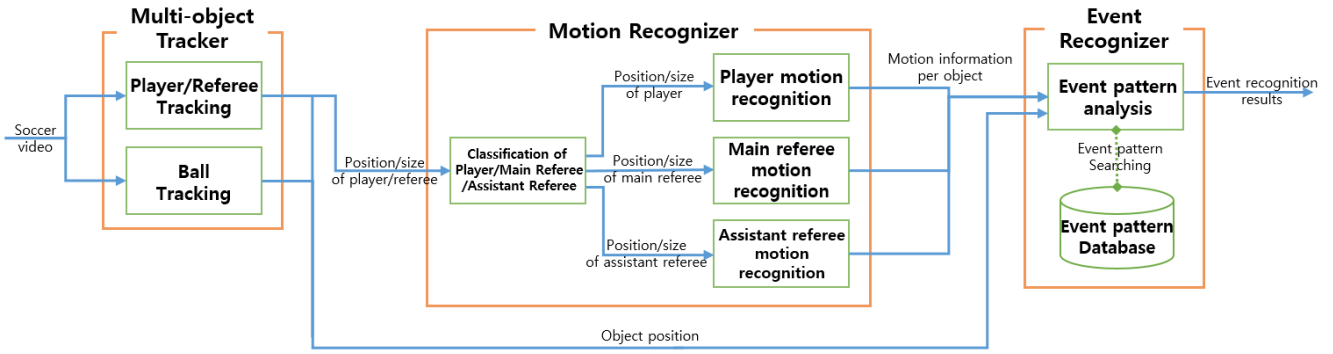

Fig. 1. Block diagram for soccer event recognition system

motion information of the objects directly related to the game, such as the players/referees/ball, not the indirect clues related to the game, such as the camera movement and the response of the spectators/commentators.

### III. PROPOSED METHOD

The proposed event recognition system is shown in Fig. 1. As can be seen in the figure, the proposed soccer event recognition system comprises multi-object tracking unit for recognizing the position and size of the players/referees/ball from the given video, a motion recognition unit for classifying each tracked object, and an event recognition unit for recognizing the event on the basis of the recognized per-object motion and position information. That is, in order to recognize the event in the soccer game by using the proposed method, techniques development for multi-object tracking and motion recognition should be preceded.

The multi-object tracking unit receives the soccer video as input and extracts the position and size information of the players/referees/ball in the game and delivers it to the next stage. Here, the tracker for the players/referees and the tracker for the balls are classified into two modules because they should be developed on the basis of different algorithms based on the characteristics of the objects.

The motion recognition unit receives the tracking information of the players/referees as an input, first classifies

TABLE III  
EXAMPLES OF EVENT RECOGNITION PATTERN

Event	Examples of recognition pattern
Shooting	The player had a ball → The player made a kick motion → The ball moved in the direction of the goalpost
Pass	The player had a ball → The player made a kick motion → The ball moved to the same team player
Tackle	The player made a walking or running motion → The player made a lying down motion → The opponent with a similar position
Corner kick	The positions of player and ball are similar and near the corner kick position → The player made a kick motion → The ball moved (to anywhere)
Free kick	The main referee made a pointing with one arm motion → The positions of player and ball are similar → The player made a kick motion → The ball moved (to anywhere)
Penalty kick	The main referee made a pointing with one arm motion → The positions of player and ball are similar and near the penalty kick spot → The player made a kick motion → The ball moved in the direction of the goalpost
Offside	The assistant referee made a lifting the flag over the head motion → The assistant referee made a lifting the flag to the chest height motion
Foul	The main referee made a pointing with one arm motion
Card	The main referee made a lifting yellow or red card motion
Assist	Recognizing the pass event → Recognizing the shooting event → The position of ball is inside the goal line
Player substitution	The main referee made a pointing with one arm motion → One player leaves the field → Another player from the same team enters the field

TABLE II  
MOTION LIST FOR EACH OBJECT CLASSIFIER

Main referee	Assistant referee	Field player
Walking without hand gestures	Walking without flag gestures	Walking
Running without hand gestures	Running without flag gestures	Running
Pointing with one arm	Walking sideways without flag gestures	Corner Kick Free Kick
Lifting yellow card	Lifting the flag over the head	Kick with wielding arm
Lifting red card	Lifting the flag to the chest height	Throw in
	Pointing with the flag	Lying down

each object by the players/main referee/assistant referees, and performs motion recognition for each classification. Table II shows the motion list for each object classifier that will be recognized by the motion recognition unit in order to finally aim at event recognition.

The event recognizing unit finds the sequence of motion and position information of objects which is similar to a predefined event pattern inside the event pattern database through a pattern matching technique and outputs it as a recognized

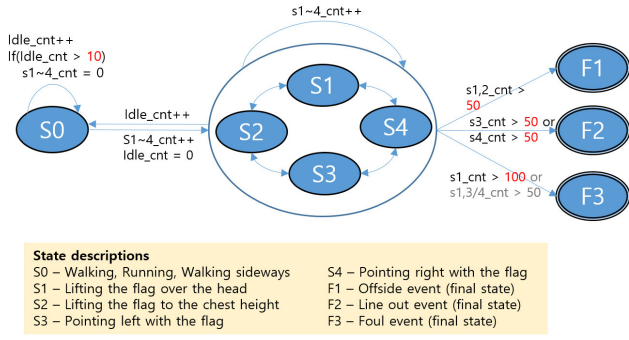

Fig. 2. Derived assistant referee DFA for soccer event recognition

soccer event. Here, the events to be recognized in this paper are the 11 major soccer events being defined and used by the Korea Professional Soccer Federation. Table III shows some examples of patterns for each event included in the event pattern database [5].

If we look at the characteristics of the pattern defined in this table, it can be seen that an arbitrary state can be expressed by integrating the position and motion information of the object. Then, if the state moves from one state to the next state and reaches the final state, it can be seen that the pattern is defined so that the event can be recognized. Through this consideration, we derived a deterministic finite automata (DFA) consisting of states and transitions from event patterns to implement a pattern-based event recognizer. An example of the derived event DFA is shown in Fig. 2.

#### IV. EXPERIMENTAL RESULTS

In order to develop the proposed soccer event recognition technique and to test its performance, it is necessary to develop a multi-object tracker and a motion recognizer. For this purpose, we implemented the multi-object tracking technique proposed by Kim *et al.* [6] and the deep learning based soccer object motion recognizer proposed by Lee *et al.* [7]

As videos for this experiment, we selected 3 games of the K League Challenge 2016 and conducted the experiment. The game was taken at 4K 30fps, and the camera was installed in a fixed form and the entire area of the stadium was recorded with one camera. Snapshot samples of the captured video are shown in Fig. 3.

In the DFA configuration for event recognition, ownership of the ball was the most important issue. In the paper, the simplest assumption is that the corresponding object has a ball whose distance between the ball and the object is below the threshold. If there are more than two objects below the threshold, it is assumed that the closer object has the ball. The threshold setting for the experiment was set to 0.5 meters.

The finally derived DFAs are three, and the key object of each DFA is main referee, assistant referee, and ball respectively. The main referee DFA was designed to recognize foul and card events, and the assistant referee DFA was designed to recognize offside and foul events. In the case

Fig. 3. Snapshot samples of the K League challenge 2016 for the experiments

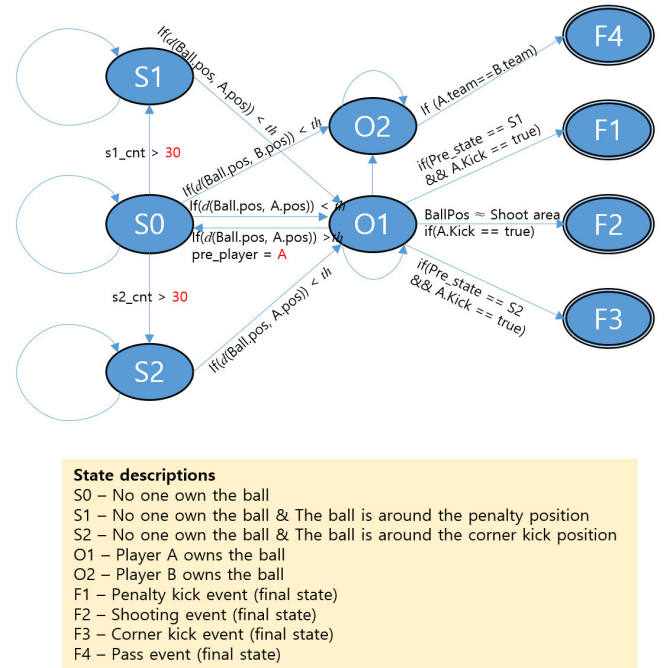

Fig. 4. Derived ball DFA for soccer event recognition

of ball DFA, it was designed to recognize shooting, pass, corner kick, penalty kick, and assist events. In the case of tackle and player substitution events, it is difficult to define the relationship among multiple objects. Thus, we excluded those events recognition attempt in this paper. The derived assistant referee DFA is shown in Fig. 2, and the ball DFA is shown in Fig. 4. In the case of the referee DFA, the complexity is very simple so it is not included in this paper.

TABLE IV  
RESULTS OF PROPOSED SOCCER EVENT RECOGNIZER

Events	The number of occurrences	The number of recognitions	Recognition rate
Shooting	14	7	50%
Pass	35	21	60%
Corner kick	18	11	61.1%
Free kick	10	4	40%
Penalty kick	3	3	100%
Offside	15	14	93.3%
Foul	17	10	58.8%
Card	5	4	80%
Assist	3	1	33.3%

(a) Offside event recognition by assistant referee DFA (before, after, result)

(b) Corner kick event recognition by ball DFA (before, after, result)

(c) Shooting event recognition by ball DFA (before, after, result)

Fig. 5. Example of soccer event recognition result based on pattern matching

Table IV and Fig. 5 show the results of the soccer event recognition experiment through the assistant referee and Ball DFAs. The table shows that the simpler the object motion and the fewer the related objects, the higher the accuracy of event recognition. Also, as shown in the figure, the proposed event recognizer accurately reports detailed information such as the start/end points of the event and the related object position, unlike the level of existing academic researches, when the event recognition is successful.

However, the proposed technique does not have enough event recognition accuracy. This is mainly due to the performance problems of multi-object tracker and motion recognizer, and the lack of available event patterns. In order to recognize the accurate event, the position of the objects obtained through the multi-object tracker must be precise, and then the motions of the recognized object must be accurately recognized through the motion recognizer. However, the tracking accuracy of the current tracker is about 90% for the player/referee and about 70% for the ball, and the recognition accuracy of the motion recognizer is about 85% for the recognized tracking result. Therefore, the cumulative errors in these two

parts will inevitably affect the accuracy of event recognizer. In addition, there are cases in which the recognition pattern of each soccer event has not been enough so that the event occurrence situation is not recognized. These problems are expected to gradually improve over time.

## V. CONCLUSION AND FUTURE DIRECTIONS

Along with the trend to integrate ICT technology into the sports area, it is also attempting to understand the game clearly by extracting low level statistics in the soccer game. Of course, attempts to automate high-level event recognition through ICT technology are ongoing, but it is still in the hands of skilled professionals.

In this paper, we propose a method to recognize specific event type, occurrence timing, and generated object by using event pattern matching technique based on multi-object positions and motion information from soccer game video. Therefore, it is possible to recognize more specific events than conventional techniques that recognize only main events using shooting pattern or audio information for event recognition.

In the future, we will further refine the proposed technique and try to recognize a higher level of soccer game strategy that can be composed of a set of position/motion/event. In addition, if the original idea of the proposed technology is appropriately used, it will be very useful not only in the soccer game, but also in the video understanding application such as the analysis of other sport fields and CCTV based human behavior analysis in which similar patterns of events occur.

**Abstract**—We consider a digital watermarking system intended for an embedding of additional information into audio (typically musical) files that should be resistant against a removal attack. The proposed embedding procedure is based on a reverberation and extraction procedure executing a cepstral transform. A removal attack based on blind dereverberation is investigated both theoretically and experimentally. In order to prevent such an attack, a slight modification of the embedding procedure is also proposed. Further experiments show that the proposed watermarking system provides both a good quality of the cover audio-signal and a sufficiently large embedding rate.

**Index Terms**—Audio watermarking, blind dereverberation, cepstrum, reverberation

## I. INTRODUCTION

IT is well known that the technology of digital watermarking (WM) is the most effective approach to provide copyright protection for digital media products. Examples of such products are the digital audio and video works. In the current paper we consider audio works (first of all musical files presented as digital signals in format *wav*). Such objects in which it is necessary to embed an additional information will be called in the sequel *cover objects* (CO). Dishonest users (pirates indeed) may try to remove the embedded WM without remarkable corruption of the CO hoping to illegally redistribute them to other users. They may accomplish the desired result after some processing of the watermarked objects in such a way that the legal users were unable to extract WM correctly from the redistributed copies and consequently they will be unable to perform a forensic consideration against pirates.

On the contrary, the owners of the products may try to embed into the CO a WM that cannot be removed without significant corruption at the CO. A significant corruption of CO results in their lower values at the market and a redistribution occurs useless.

Several embedding WM techniques for audio-signals are well known and they have been extensively used, e. g. *phase-shift-keying* (PSK) modulation [1] or WM system based on *echo hiding* (EH) [2]. But as it was shown [2], [3] that within both PSK and EH WM systems the embedded WM can be easily removed without significant degradation of the CO.

The use of spread spectrum signals in the embedding procedures that are controlled by a secret *stegokey* seems to

be very attractive. But a more careful consideration [4] shows that such signals are vulnerable to desynchronization attacks.

At a single glance, the use of a reverberation procedure with a secure pulse response of the reverberation filter, controlled by a stegokey, is the best approach. In fact, on the one hand the use of a reverberation with filter pulse response close to a *room pulse response filter* provides a good quality of audio CO [5]. On the other hand, the use of complex pulse response forms prevents a compensation of reverberation (making a dereverberation – in other words) that could be allow to remove the embedding.

But unfortunately, a changing of pulse response form on every bit interval results (as our experiments showed) in a significant corruption of CO. Therefore we propose some “intermediate” approach that is presented in Section II. But without some additional transforms, described in Section IV, the WM system presented in Sections II and III will be yet vulnerable to the blind dereverberation attack described in those sections also. The proposed modified WM system is presented in Section IV. Section V concludes the paper and presents some open problems for the future work.

## II. ATTACK ON A WM SYSTEM THAT IS BASED ON THE EMBEDDING WITH A REVERBERATION USAGE

Let us assume that a given WM system uses some fixed (but sufficiently complex) reverberation *filter pulse response*  $(h_b(n))_{n=1}^N$  for all watermarking session, where  $N$  is the number of samples on every bit interval. In order to embed bits  $b = 0$  or  $b = 1$  it is used only fixed but different time delays with each filter corresponding to additional information. Then the digital WM-ed signal  $(Z(n))_{n=1}^N$  on each bit interval can be presented as follows:

$$\forall n = 1, \dots, N : Z(n) = S(n) * h_b(n) , \quad b \in \{0, 1\} \quad (1)$$

where  $(S(n))_{n=1}^N$  is the input audio signal (CO),  $(h_b(n))_{n=1}^N$  is the filter pulse response depending on the embedding bit  $b$ ,  $*$  is the operation of convolution, and  $N$  is the number of samples on each symbol interval. By applying the cepstrum transform to both sides of (1) we get [6]:

$$\forall n = 1, \dots, N : \tilde{Z}(n) = \tilde{S}(n) + \tilde{h}_b(n) , \quad b \in \{0, 1\} \quad (2)$$

where  $\sim$  denotes the *cepstrum transform*:

$$C(x)(n) = \frac{1}{N} \sum_{k=0}^{N-1} e^{\frac{2\pi}{N} \iota n k} (\iota \Theta(k) + \log x'(k)) = \tilde{x}(n) \quad (3)$$

with

$$\forall k = 1, \dots, N : x'(k) = \sum_{m=0}^{N-1} e^{-\frac{2\pi}{N} \iota m k} x(m),$$

$(x'(k))_{k=1}^N$  is the signal amplitude,  $(\Theta(k))_{k=1}^N$  is the signal phase and  $\iota = \sqrt{-1}$ .

In reality, relation (2) is only an approximation of a finite signal. The accuracy of expression (2) depends on the number of zeros added to the finite signal. If the number of added zeros is sufficiently large, then relation (2) holds with small errors. The advantage of (2) compared with expression (1) consists in the easiness of the cepstrum transform to apply well known algorithms for optimal receivers [7] if the interference  $(S'(n))_{n=1}^N$  can be approximated by white Gaussian noise.

The extraction algorithm for such a WM system is the well known *correlation receiver*:

$$b = \text{Arg max}_{b \in \{0,1\}} \sum_{n=1}^N \tilde{Z}(n) \tilde{h}_b(n). \quad (4)$$

Let us assume that an attacker that trying to remove the WM is able to estimate somehow the filter cepstrum pulse responses for each  $b \in \{0,1\}$  as  $(\tilde{h}'_b(n))_{n=1}^N$  on each of bit interval. Then an attack intended to remove WM could be:

$$\forall n = 1, \dots, N : \tilde{Z}_b(n) = C^{-1} (\tilde{Z}(n) - \tilde{h}'_b(n)) \quad (5)$$

where  $C^{-1}$  is the inverse of the cepstrum transform  $C$  given in (3). (In favor of the attacker, we do not consider here the hardness to perform the transform  $C^{-1}$ .) It is worth to note that an operation to remove a reverberation from an audio signal is called *blind dereverberation*. This problem was investigated in many papers [8], [9], [10], [11], [12], [13] and others. But the goal of such signal transform was to make the audio signal free from additional reverberation interference that may occur in a natural manner.

In our case, it is not sufficient to make the audio signal sufficiently free from reverberation just “by ear”. We require to make impossible WM extraction from the dereverberated signal even with the use of an optimal receiver. Moreover, for the purpose of dereverberation removal there were used multiple microphones placed on some distances one against another [10]. Of course such approach cannot be used in our scenario.

Let us estimate the error probability  $P$  (incorrect bit  $b$  extraction) for the WM system owner using the decision rule (4) where

$$\forall n = 1, \dots, N : \tilde{Z}_a(n) = \tilde{Z}(n) - \tilde{h}'_b(n).$$

It is easy to see from (2), (4) and (5) that even for opposite signals  $\tilde{h}'_0(n)$  and  $\tilde{h}'_1(n)$ ,

$$\begin{aligned} P &= \Pr(1|0) \\ &= \Pr\left(\xi \leq -\sum_{n=1}^N (\tilde{h}_0(n) - \tilde{h}'_0(n)) \tilde{h}_0(n)\right) \end{aligned} \quad (6)$$

with

$$\xi = \sum_{n=1}^N \tilde{S}(n) \tilde{h}_0(n).$$

After a changing of variables we get from (6),

$$P = \frac{1}{\sqrt{2\pi\sigma^2 A}} \int_{-\infty}^{\tilde{A}} \exp\left(-\frac{x^2}{2\sigma^2 A}\right) dx \quad (7)$$

where  $\tilde{A} = \sum_{n=1}^N (\tilde{h}_0(n) - \tilde{h}'_0(n)) \tilde{h}_0(n)$ ,  $A = \sum_{n=1}^N \tilde{h}_0^2(n)$  and  $\sigma^2 = \text{Var}(\tilde{S}(n))$ . (We note that relation (7) holds whenever  $\sigma$  is a zero mean Gaussian sequence with variance  $\sigma^2 A$ .) It is easy to prove that

$$\tilde{A} = A(1 - \eta) \quad (8)$$

where  $\eta = \frac{1}{A} \sum_{n=1}^N \tilde{h}'_0(n) \tilde{h}_0(n)$ . Substituting (8) into (7) we get after a simple transform

$$P = 1 - F\left(\sqrt{\frac{A(1-\eta)^2}{\sigma^2}}\right) \quad (9)$$

where

$$\forall x \in \mathbb{R} : F(x) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^x \exp\left(-\frac{t^2}{2}\right) dt.$$

(If the signals  $\tilde{h}'_0(n)$  and  $\tilde{h}'_1(n)$  are not opposite, then equality (9) holds as a lower bound (in favour of the attacker).

We see from (9) that if  $\eta = 0$ , namely there is a bad estimation of  $\tilde{h}'_0(n)$ , then the attack occurs in an inefficient way. But if  $\eta = 1$ , there results in  $P = \frac{1}{2}$ , which means a “break of the legal WM channel”. Then the estimation attack is effective because it removes completely the WM embedding.

In Fig. 1 there are shown the dependencies of the legal user error symbol probability calculated by (9) against of parameter  $\eta$  for different values of  $\frac{A}{\sigma^2}$ .

We see from the dependencies presented in Fig. 1 that in order to provide high efficiency in the attack it is necessary to get the parameter  $\eta$  close to the value 0.8. Hence, an attacker should correctly estimate the filter pulse responses of legal user. We note first of all that such problem cannot be solved exhaustively over all possible filter pulse response wave forms.

In fact, the typical length of “room pulse” that keeps a good quality of a musical file after embedding, is about 180 samples. Assuming that the pulse response amplitude is at most around 0.2 with respect to audio signal amplitude, we get for a total number of quantization levels 65536 for the format wav, and the number of acceptable levels for pulse response will be about 13107. Then a set of all possible pulse response wave forms appears with cardinality around  $1.4 \times 10^{741}$ , which is certainly an untractable value for an exhaustion attack.

Fig. 1. The dependencies of the legal user error symbol probability  $P$  against  $\eta$  for different  $\frac{A}{\sigma^2}$ .

If we assume that the filter pulse responses  $\tilde{h}_0(n)$  and  $\tilde{h}_1(n)$  differ only by a fixed and known delay  $N_0$  then the attacker could find all bit intervals  $I_0$  corresponding to  $b = 0$  and  $I_1$  corresponding to  $b = 1$ .

Next it is possible to average separately all cepstrum corresponding wave forms in order to get an approximation of the cepstrum pulse response as follows:

$$\begin{aligned} & \frac{1}{L} \left[ \sum_{n \in I_0} \tilde{Z}(n) + \sum_{n \in I_1} T_{N_0}(\tilde{Z}(n)) \right] \\ &= \tilde{h}_0(n) + \frac{1}{L} \sum_{i=1}^L \tilde{S}_i(n) \end{aligned} \quad (10)$$

Using (10) and the expression of  $\eta$  in (8) we get

$$\eta = 1 - \frac{\sum_{n=1}^N \tilde{h}_0(n) \frac{1}{L} \sum_{i=1}^L \tilde{S}_i(n)}{\sum_{n=1}^N \tilde{h}_0^2(n)} = 1 - \varepsilon. \quad (11)$$

Let us find the variance of the random variable  $\varepsilon$  assuming that  $\text{Var}(\tilde{S}_i(n)) = \sigma^2$  and the samples of cepstrum  $\tilde{S}_i(n)$  are *i.i.d.* random values. We can write

$$\begin{aligned} \text{Var}(\varepsilon) &= \frac{\text{Var} \left( \sum_{n=1}^N \tilde{h}_0(n) \frac{1}{L} \sum_{i=1}^L \tilde{S}_i(n) \right)}{\sum_{n=1}^N \tilde{h}_0^2(n)} \\ &= \frac{\sigma^2}{L \sum_{n=1}^N \tilde{h}_0^2(n)} = \frac{\sigma^2}{LA} \end{aligned} \quad (12)$$

Next we can use relation (12) for known cepstrum pulse response  $\tilde{h}_0(n)$  and known parameters  $L$  and  $\sigma^2$  in order to estimate that the parameter  $\eta$  is at most  $3 \text{Var}(\varepsilon)$  with probability 0.997.

a) *Example:* Assume  $\frac{A}{\sigma^2} = \frac{1}{2}$ ,  $L = 360$ , then, by (12),  $\text{Var}(\varepsilon) < 6 \times 10^{-4}$  and the parameter  $\eta$  is at least 0.98 with the probability 0.997. Then, from Fig. 1, we see that for the attack estimation presented above the extracted bit error probability for legal user occurs close to 0.5 and hence this attack be very effective.  $\square$

But a gap in the attack estimation is the fact that so far it is unknown how an attacker could be able to find all bit intervals belonging separately to the embedding of bits.

Since the forms of filter pulse responses are constant for different bit intervals (in line with our previous assumption) and they differ only within a fixed delay, the same situation appears for the corresponding cepstrums. Thus, if for a pair of bit intervals  $I_i$  and  $I_j$  corresponding to equal bits  $b$  and  $\tilde{b}$ ,  $b = \tilde{b}$ , then the following crosscorrelation for the corresponding cepstrum wave forms  $\tilde{Z}_i(n)$  and  $\tilde{Z}_j(n)$  is obtained:

$$\begin{aligned} \Lambda &= \frac{1}{N} \sum_{n=1}^N \tilde{Z}_i(n) \tilde{Z}_j(n) \\ &= \frac{1}{N} \sum_{n=1}^N \left( \tilde{S}_i(n) + \tilde{h}_b(n) \right) \left( \tilde{S}_j(n) + \tilde{h}_b(n) \right) \\ &= \frac{1}{N} \sum_{n=1}^N \left( \tilde{S}_i(n) \tilde{S}_j(n) + \tilde{S}_i(n) \tilde{h}_b(n) + \right. \\ &\quad \left. \tilde{h}_b(n) \tilde{S}_j(n) + \tilde{h}_b(n) \tilde{h}_b(n) \right). \end{aligned} \quad (13)$$

For the case of different embedding on the  $i$ -th and  $j$ -th bit intervals, that is,  $b \neq \tilde{b}$ , we get

$$\begin{aligned} \Lambda' &= \frac{1}{N} \sum_{n=1}^N \tilde{Z}_i(n) \tilde{Z}_j(n) \\ &= \frac{1}{N} \sum_{n=1}^N \left( \tilde{S}_i(n) + \tilde{h}_b(n) \right) \left( \tilde{S}_j(n) + \tilde{h}_{\tilde{b}}(n) \right) \\ &= \frac{1}{N} \sum_{n=1}^N \left( \tilde{S}_i(n) \tilde{S}_j(n) + \tilde{S}_i(n) \tilde{h}_{\tilde{b}}(n) + \right. \\ &\quad \left. \tilde{h}_b(n) \tilde{S}_j(n) + \tilde{h}_b(n) \tilde{h}_{\tilde{b}}(n) \right) \end{aligned} \quad (14)$$

By comparing equations (13) and (14) we conclude that in the first case  $\Lambda$  is larger than  $\Lambda'$  in the second case. Therefore we may select a threshold and to decide that the  $i$ -th and the  $j$ -th interval correspond to the same bit interval,  $b = \tilde{b}$ , if the threshold is exceeded and, otherwise, they correspond to different bit intervals,  $b \neq \tilde{b}$ . Thus it is possible to find the sets  $I_0$  and  $I_1$  for the calculation in (10).

However another question arises: how can an attacker find filter pulse response but not filter cepstrum pulse response using (10)?

It has been proved in [11] that for small embedding amplitude it is possible to take into account only the first term in

Fig. 2. Filter pulse response: a) for bit "1", b) for bit "0".

the Taylor series for the cepstrum expansion of signal in (2). This means that the last equation can be rewritten as

$$\tilde{Z}(n) = \tilde{S}(n) + \lambda h'_b(n) \quad (15)$$

where  $\lambda$  is some scale coefficient,  $h'_b(n)$  is the already filter pulse response but not the cepstrum pulse response in (2).

Expression (15) asserts that if an attacker has estimated correctly the cepstrum pulse response, then he (or she) will be able to find the pulse response after a specification (maybe even though an exhaustive trial) of the coefficient  $\lambda$ .

After the full calculation of the filter pulse responses, an attacker, with the knowledge of bits embedding on each bit interval, may manage to apply the inverse filter pulse response and consequently to remove all the embedded information.

However, in the above theoretical investigation a model for the cover objects unavailable in practice has been suggested. Therefore in the next section we investigate experimentally the proposed attack. In Section IV we modify the embedding scheme in such a way that it will be resistant against the proposed attack.

### III. EXPERIMENTAL INVESTIGATION OF THE PROPOSED DEREVERBERATION ATTACK

We select the filter pulse response (FPR) for both embedding bits  $b = 0$  and  $b = 1$  shown in Fig. 2. The chosen delays for embedding are 30 and 25 samples for bits zero and one, respectively. Cepstrum of these FPR are shown in Fig. 3. These figures confirm the assertions given before that firstly cepstrum delays coincide with FPR delays and secondly, that cepstrum wave forms copy FPR wave forms.

All bit intervals corresponding to bits  $b = 0$  and  $b = 1$  were found with the use of the crosscorrelation  $\Lambda$ , and  $\Lambda'$  given by eq's. (13), (14) respectively.

Fig. 3. Filter cepstrum pulse response: a) for bit "1", b) for bit "0".

Fig. 4. Averaged FCPR in line with eq. (10).

Fig. 5. Estimation of the FPR after a selection of a scale factor.

In Fig. 4 the averaged FCPR is presented in line with eq. (10). We see from this figure that a form of FCPR copies a form of FPR up to some scale factor.

If an attacker is able to find the scale factor then the wave form of the FPR can be easily estimated (see Fig. 5).

Now, the dereverberation attack can be performed with the following steps:

- 1) For a known FPR (Fig. 5) calculate the FCPR (see Fig. 6)
- 2) Reflect with respect to zero the wave form of FCPR
- 3) Find FPR for the attack filter computing inverse cep-

Fig. 6. The FCPR calculated from the FPR given in Fig. 5.

Fig. 8. FPR wave form obtained by (16).

Fig. 7. The FPR for dereverberation attack.

Fig. 9. Wave form of FPR with additional pulse on 21-th sample of bit interval.

strum transform from FPR. The result is presented in Fig. 7. In a similar manner, there can be calculated the inverse FPR for the embedding of the bit  $b = 0$ .

- 4) Apply the inverse filters to the embedded bits “0” and “1” which have been found before in the corresponding bit intervals.
- 5) Use the transition function between bit intervals with linear form that is necessary to keep high quality of audio signal after dereverberation procedure.

In Table I the extracted bit error probabilities before and after dereverberation attack under different parameters of WM system are presented. The wave forms of FPR were presented in Fig. 9. They have finite length equal to 180 samples. We see from this table that before attack the proposed WM system is working acceptably but after the dereverberation attack the bit error probability is close to 50%, that is similar to “break of channel”. (We note the fact that sometimes the probability exceeded 50% owing to an incorrect estimation of scale factor. But it does not affect on our conclusion.)

#### IV. MODIFICATION OF THE WM SYSTEM TO BE RESISTANT AGAINST A DEREVERBERATION ATTACK

In order to protect the WM system from the above proposed dereverberation attack it is necessary to make impossible for an attacker to separate 0-bit intervals from 1-bit intervals.

In fact, if an attacker does not know which bit intervals correspond to the embedding bit “1” and which ones to the bit “0”, then by replacing expression (10) to a summation over all the bit intervals,

$$\Lambda'' = \frac{1}{N} \sum_{n=1}^N \tilde{Z}(n) \quad (16)$$

Fig. 10. Result of crosscorrelation computation with additional pulse on the 21-th sample.

a large corruption of FPR wave form in comparison with original one results. In Fig. 8 a FPR wave form is presented after such “total averaging”

We see that the FPR in Fig. 8 has no any similarity with the original FPR wave form (see Fig. 2), hence an attacker will be unable to arrange a dereverberation attack. (In fact we have checked that the use of such FPR in a dereverberation attack cannot even result in a remarkable increasing of the extracted bit errors.)

In order to prevent a crosscorrelation attack (13), we propose to add to the WM signal short pulses at the beginning of each bit interval. (See Fig. 9 where an additional pulse is presented on the 21-th samples of the bit interval).

The use of the crosscorrelation attack given by (13), (14), results in an occurrence of a single pulse independently on whether there is a coinciding or a discrepancy among the information bits corresponding to signal  $\tilde{Z}_i(n)$  and  $\tilde{Z}_j(n)$  (see Fig. 10) for a confirmation).

Thus we can conclude that a modification of the reverberation-based WM system by additional pulses results

TABLE I  
THE EXTRACTED BIT ERROR PROBABILITIES BEFORE AND AFTER DEREVERBERATION ATTACK FOR DIFFERENT SYSTEM PARAMETERS.

Name of music files and their duration	Delays of WM signal		The length of bit intervals (in number of samples)	The number of the embedded bits	Bit error rate before attack in %	Bit error rate after attack in %
	1	0				
Vysocki "Song of Boxer" (fragment 20 sec)	25	29	4000	142	4.5%	72%
Vysocki "Song of Boxer" (fragment 20 sec)	25	29	6000	94	0%	78%
Vysocki "Song of Boxer" (fragment 20 sec)	15	19	6000	94	17%	63%
Yuta, "Jealousy" (fragment 29 sec)	25	29	10000	55	2%	48%
Yuta, "Jealousy" (fragment 29 sec)	25	29	5000	113	1%	57%
Yuta, "Jealousy" (fragment 29 sec)	20	24	5000	113	7%	61%

in a resistance of this system to a most power blind dereverberation attack.

We have tested the proposed WM system also with respect to audio signal quality after embedding. A group consisting of 5 experts has come into a conclusion that a quality of musical files after WM embedding keeps practically the same as the embedding before.

#### V. CONCLUSION

In this paper an audio WM system resistant to a remove attack is proposed. The embedding of WM in this system is performed by a reverberation of audio signal that is controlled by a secret stegokey. The main advantage of the reverberation based watermarking system is its possibility to provide a high quality of audio signal after embedding. But there exists an effective attack for such WM system known as blind dereverberation attack. We investigated this attack in detail and showed that in fact it is able to remove the embedding information without significant degradation of audio signal quality. Therefore we propose some modification of WM-based system and show that then such attack is useless.

Experimental investigation confirm our conclusion. This system can be practically applied to copyright purposes. It would be interesting in the future to investigate more sophisticated attack on WM-based system although maybe with some degradation of audio signal quality.

□

**Abstract**— The current advances in hardware led to the development of the GPGPU (General-purpose computing on graphics processing units) paradigm. Thus, nowadays, the GPU (Graphics Processing Unit) is used not only for graphics programming, but also for general purpose algorithms. This paper discusses several methods regarding the use of CUDA (Compute Unified Device Architecture) for 2D and 3D image processing techniques. Some general rules for writing parallel algorithms in computer vision are pointed out. A theoretic comparison between the complexity for CPU (Central Processing Unit) and GPU implementations of image processing algorithms is given. Also, real computing times are provided for several algorithms in order to point out the actual performance gain of using the GPU over CPU. The factors that contribute to the difference between theoretic and real performance gain are also discussed.

## I. INTRODUCTION

UNTIL recently, the GPU was used only for graphics programming. The transition from a fixed to a programmable rendering pipeline allowed programmers to write high level code for graphics applications through shaders. Shaders are defined for an element belonging to one of the types that are processed in the graphics pipeline, for example vertex or fragment, and are executed for all the elements of that type in a parallel manner. According to Soller [1], early approaches to using the GPU for general computation date back to the year 2000. However, for this purpose, all tasks had to be mapped to the computer graphics domain. The development of the GPGPU paradigm led to a revolution in terms of computing times for many algorithms. This paper describes some general rules when implementing computer vision algorithms with CUDA, as well as theoretical and real performance gains of GPGPU implementations as compared to sequential ones. The second section discusses the state of the art in GPU based image processing algorithms. The third section presents theoretic comparisons between GPU and CPU implementations of

several 2D image processing algorithms. The fourth section discusses some issues when processing very big volume data. Several comparisons between theoretical results and tests conducted on real hardware are presented in the fifth section. The conclusions are drawn in the final section.

## II. STATE OF THE ART IN GPU-BASED IMAGE PROCESSING

Some of the GPGPU image processing methods are briefly discussed.

### A. Acceleration of 2D Image Processing Algorithms

Takamura and Shimizu [2] describe a denoising filter with genetic programming schemes for dynamic procedure generation. Abdellah [3] presents an easy-to-use CUDA library that implements Fast Fourier Transform-shift operations. Agrawal et al. [4] perform a real-time GPU-based generation of the saliency map for a given image. Lee et al. [5] improve the computing times of the Viola-Jones algorithm for face detection by employing different strategies for CPU-GPU task-level parallelism. Ma et al. [6] propose a CUDA-based acceleration of the Fisher Vector extraction method for various video monitoring applications. Hwang et al. [7] present a CUDA implementation of foreground detection based on background modeling. Yao et al. [8] describe a CUDA-based image inpainting algorithm for virtual viewpoint synthesis.

### B. Acceleration of 3D Image Processing Algorithms

Shewale et al. [9] analyze the performance of different CPU/GPU parallel implementations of the Gaussian filter, k-means clustering based segmentation and Fourier based coefficient registration of medical images such as CTs and MRIs. Valero [10] proposes a GPU-based implementation for accelerating the DARTEL algorithm for diffeomorphic registration of brain biomedical images. Langdon et al. [11] use genetic programming to improve the performance of an existing CUDA implementation for 3D medical image registration.

### C. GPGPU Frameworks

Lee et al. [12] propose optimization strategies for compute- and memory-bound algorithms using the CUDA architecture. They test their optimization strategies on a 3D unbiased nonlinear image registration technique and on a non-local means surface denoising algorithm. Ravishankar et

al. [13] present a domain-specific language for image processing, namely Forma, which provides syntax for stencil computation, sampling and other 2D or 3D algorithms.

### III. IMAGE PROCESSING ALGORITHMS WITH CUDA

From the parallel implementation point of view, most of the image processing algorithms belong to one of four categories: pixel-to-pixel, neighborhood, global and multi-steps (Fig. 1). Each of these classes is discussed below.

Fig. 1 Discussed 2D image processing algorithms

#### A. Pixel-to-pixel (P2P) Algorithms

*Pixel-to-pixel algorithms* assume that each pixel in an image is processed based solely on its characteristics. One of the most common *pixel-to-pixel algorithms* encountered in image processing is pixel value remapping, based only on the value of the current pixel. Value remapping can be used for enhancement of structures characterized by certain intensity values. A particular case of value remapping is segmentation based on thresholds. This type of algorithm is naively parallel due to the fact that each pixel is handled independently by a thread. An easy implementation in CUDA of this type of algorithm is to copy the image or volume into texture memory, so that the access to the pixel values is very fast. The output of the algorithm is an image/volume with the same size as the input.

Let  $C_{pixel}$  be the complexity of the operations applied to one pixel from an image in a *pixel-to-pixel algorithm*. Then the complexity of the entire algorithm for a 2D image in a sequential approach, on the CPU, is:

$$C_{P2P\_CPU} = C_{pixel} \cdot w \cdot h, \quad (1)$$

where  $w$  is the width of the image and  $h$  is its height. As previously mentioned, in a parallel approach on the GPU, each thread handles only one pixel and accesses only the memory related to that pixel. Therefore, the theoretic complexity of the same algorithm in a GPGPU approach is  $C_{pixel}$ . The theoretic performance gain obtained is  $w \cdot h$ .

However, the transfer between host and device memory introduces a latency that decreases the performance gain in real applications. Also, the actual computing time for the operations applied per pixel is not the same for the CPU and the GPU and depends very much on the actual hardware. The memory transfer latency can be reduced through page locked memory and the zero-copy feature, but not significantly.

#### B. Neighborhood-to-pixel (N2P) Algorithms

Spatial filters are applied locally, at the level of each image pixel, by replacing the value of the current pixel depending on the values of the neighboring pixels. Among the *neighborhood algorithms* we can mention the Gaussian filter, for noise removal, or the Sobel filter, for edge extraction. The difference between *neighborhood algorithms* and *pixel-to-pixel algorithms* is the access to memory. In *neighborhood algorithms*, the thread corresponding to one pixel has to access information not only about the current pixel, but also about its neighboring pixels. These algorithms can be implemented in the same manner as the *pixel-to-pixel algorithms*, by copying the image/volume into texture memory. Another possibility is the use of shared memory, as described in [14]. Each thread block can copy parts of the image by loading data from texture to shared memory. The barrier synchronization forces each thread to wait until all the other threads have finished loading the corresponding data from texture to shared memory. Even if shared memory is faster, the transfer between texture and shared memory introduces a lag that determines an insignificant difference between the two implementations. The theoretic complexities for sequential and parallel implementations are similar to those of the *pixel-to-pixel algorithms*. However, the differences between theoretic and actual performance gains are bigger in this case.

#### C. Global (G) Algorithms

*Global algorithms* refer to computations that access information about all the pixels in an image, not just a neighborhood. Examples of global algorithms are the computation of the average intensity or the maximum/minimum intensity in an image. The computation of a global parameter in an image is not intuitively parallel, because it depends on all the pixels in the image.

Let  $C_{pixel}$  be the complexity of the operations applied to one pixel in a global algorithm. For example, when computing the maximum intensity in one image,  $C_{pixel}$  is the complexity of comparing the intensity of the current pixel with the current maximum value and modifying the current maximum value, if necessary. The complexity of a global algorithm in a sequential implementation is  $C_{pixel} \cdot w \cdot h$ . A parallel approach to implementing global algorithms is the *reduction method*. CUDA threads are organized into blocks and grids. The blocks can be structured into a one-dimensional grid of size  $h$  and the threads can be structured into one-dimensional blocks of size  $w$ . Thus, each block handles one row in an image. The threads in a block cooperate in order to determine a partial global parameter which depends only on the current row. For example, when computing the maximum intensity in an image, this partial global parameter is the maximum intensity for the pixels located on the current row. Each block loads the data into shared memory, into an array of size  $w$ . The computation of

the partial global parameter for the current block is done in  $\log_2(w)$  iterations. In each iteration, the number of active threads is divided by 2. The computation of the final global parameter is also accomplished with the reduction method, but in  $\log_2(h)$  iterations. In each iteration, the active threads run in parallel, but before going to the next iteration, they need to synchronize. The theoretical complexity for the parallel implementation of a global algorithm is:

$$C_{G\_GPU} = C_{pixel} \cdot (\log_2(w) + \log_2(h)). \quad (2)$$

The theoretical performance gain obtained when using the reduction method for global algorithms is  $w \cdot h / \log_2(w)$ . Besides the lag introduced by the memory transfers and access, the latency caused by the barrier synchronization in the reduction method influences the real performance gain.

In a multi-GPGPU approach, the image can be divided based on the number of available GPUs. After each GPU computes a partial global parameter, the final global parameter is computed on the CPU in  $N$  iterations. For  $N$  GPUs, the complexity of the global algorithm is:

$$C_{G\_MultiGPU} = C_{pixel} \cdot \left( \frac{\log_2(w) + \log_2(h)}{N} + N \right) \quad (3)$$

#### D. Multi-steps (MS) Algorithms

These algorithms are executed in more iterations, the processing of the  $k^{th}$  iteration depending on the result of the processing from the  $(k-1)^{th}$  iteration. An example of *multi-steps algorithm* is breadth first search (BFS) for images, which starts with a seed pixel and discovers similar pixels connected with this one. The similarity measure can be defined based on the intensity values, the gradient, etc.

An image can be interpreted as a graph where each node is a pixel. The graph edges can be defined based on the similarity of the pixels. A common practice in BFS is to define the edges that connect pixels in a 4-neighborhood. In the worst-case scenario, the seed pixel is the one located in the middle of the image and all the pixels are similar. If the complexity for one pixel is  $C_{pixel}$ , the sequential complexity for the worst-case scenario is:

$$C_{MS\_CPU} = C_{pixel} \cdot (1 + 4 + 4^2 + \dots + 4^{\max(w/2, h/2)}). \quad (4)$$

The CUDA implementation of the BFS in image processing is described in [15]. The complexity for the CUDA implementation of the BFS for the worst case scenario is:

$$C_{MS\_GPU} = C_{pixel} \cdot \max(w/2, h/2) \cdot 4. \quad (5)$$

The theoretic performance gain obtained when approaching the BFS in a parallel manner is:

$$Gain_{MS} = \frac{1 + 4 + 4^2 + \dots + 4^{\max(w/2, h/2)}}{\max(w/2, h/2) \cdot 4}. \quad (6)$$

A recursive algorithm is not suitable for multi-GPGPU approaches. Multiple GPUs can be used only if there are more than one seed pixel in the BFS, or more than one initial image in the recursive splitting.

#### IV. VOLUME DATA (3D) PROCESSING WITH CUDA

The computation of the theoretic complexities can be easily extended to the 3D image processing. A 3D volume can be seen as a stack of  $s$  2D images or slices, each of size  $w \cdot h$ . For the *pixel-to-pixel* and the *neighborhood-to-pixel algorithms*, the sequential complexity is:

$$C_{3D\_P2P\_CPU} = C_{pixel} \cdot w \cdot h \cdot s. \quad (9)$$

The theoretic parallel complexity remains  $C_{pixel}$ , as in the 2D case.

The sequential complexity of the global algorithms is  $C_{pixel} \cdot w \cdot h \cdot s$ . The parallel implementation of a global algorithm assumes the computation of partial global parameters, one for each slice, and the computation of the final global parameter, for the whole volume, with the reduction method, in  $\log_2(s)$  iterations. Thus, the theoretic parallel complexity of the global algorithms is:

$$C_{3D\_G\_GPU} = C_{pixel} \cdot (\log_2(w) + \log_2(h) + \log_2(s)). \quad (10)$$

The BFS extension to 3D assumes the inspection of two more neighbors for each voxel, one on the upper adjacent slice and the other one on the lower adjacent slice. Thus, the sequential complexity for the worst-case scenario becomes:

$$C_{3D\_MS\_CPU} = C_{pixel} \cdot (1 + 6 + 6^2 + \dots + 6^{\max(w/2, h/2, s/2)}). \quad (11)$$

The parallel implementation will have the following complexity:

$$C_{3D\_MS\_GPU} = C_{pixel} \cdot \max(w/2, h/2, s/2) \cdot 6. \quad (12)$$

Many volume data come from CT or MRI scans. The main problem of 3D image processing is the large size of the data acquired from the scanning devices. An example of neighborhood algorithm that processes volumes is marching cubes. The increased complexity of the marching cubes algorithm, caused by the huge number of intersections that are processed, implies slow computing times and high memory usage. The classic CUDA implementation of this algorithm [15] leads to real time surface reconstruction, but can handle only small datasets. GPUs can lead to significant performance gains as compared to sequential implementations, but the GPU memory is limited. We proposed an approach that divides the initial volume into sub-volumes, which can be computed serially on the GPU without exceeding the memory pool [16].

#### V. RESULTS

This section presents results derived from tests conducted on real hardware. The tests were made on an i7-2600K 3.40

GHz processor with 8 GB RAM and an Nvidia GeForce GTX 590 card with 1.5 GB RAM.

Table I presents the computing times of running a value remapping on the CPU and on the GPU.

Table II presents the computing times of applying a Gaussian filter on the CPU and on the GPU. We tested the implementation using only global memory, using shared memory and a multi-GPGPU implementation.

Table III presents a comparison between serial and parallel implementations of determining the maximum intensity in an image.

TABLE I.  
COMPUTING TIMES FOR VALUE REMAPPING

Image size (pixels)	CPU implem (ms)	GPGPU implem (ms)	multi-GPGPU (ms)
256 <sup>2</sup>	0.2	0.19	0.39

512 <sup>2</sup>	2.2	0.88
1024 <sup>2</sup>	2.4	1.68

## VI. CONCLUSIONS

This paper focuses on theoretic comparisons between sequential and parallel implementations of 2D/3D image processing algorithms. It also provides comparisons of real computing times for several CPU and GPU algorithms.

Four main classes of image processing algorithms are discussed. The main issues of CUDA programming in relation to these algorithms are presented. The paper also gives general rules for implementing image processing algorithms in CUDA, such as the type of GPU memory which should be used based on the particularities of the algorithms and the manner of translating non-intuitively parallel algorithms to parallel ones or best practices for multiple GPUs.

In theory, parallel implementations introduce a very high performance gain as compared to sequential implementations. In practice, memory transfer lags, memory

access and real hardware characteristics lead to a smaller performance gain. Still, GPGPU image processing algorithms are undeniably faster than CPU ones.

**Abstract**— This article proposes a laser beam encoding method that is used to control an augmented reality system. Experiments were performed using a red laser emitting a wavelength of  $\lambda = 650$  nm and a power of  $P = 3$  mW. The purpose of the study was to investigate the methods of modulation and demodulation of the encoded laser signal, and to examine the influence of parameters such as laser pulse duration, camera image resolution, the number of recorded frames per second on the demodulation result of the optical signal.

The results show that the proposed coding method provides the transmission of the necessary information in a single laser beam (no less than 36 codes with a decoding efficiency of 99.9%). The developed coding method enables, based on the sequence analysis of video images, the influence on the course of the simulation performed in augmented reality, including distinguishing players and actions taken by them. This is an important advancement in relation to interaction systems used to influence augmented reality.

## I. INTRODUCTION

The impact on augmented reality (AR) can occur while using different types of devices [1 – 3]. It consists in producing intentional and previously planned possible behavior of the system, which for the “player” will create the impression of interaction [4]. The coding and decoding system [5] plays a key role in such communication. Its most important parameters include the code capacity and the time of encoding and decoding the transmitted information. In the case under consideration, the data to be encoded is obtained from the user. They arise as a result of interacting with him/her through patterns or objects presented in the image that force the user to behave in a certain way. This behavior is recognized by it and analyzes the AR system. For this purpose, markers [6, 7], 9 DOF sensors [8] or camera systems including 3D cameras [9, 10] are used. In the augmented reality system that is based on tags, the player is “stuck” with markers and then observed by an optical system consisting of multiple cameras. A similar effect is obtained when a player uses 9 DOF sensors to visualize its movement, Fig. 1. The position and activity of the player is then determined on the basis of data received from

accelerometers, gyroscopes and magnetometers [11]. In the solution shown in Fig. 1, 14 sensors were used to determine the position and movement of the player. In other designs, motion is determined using methods that determine local depth maps [12]. On their basis information undergoes synthesization and selected behaviors of the player are identified [13].

The commercial AR system used in the study has been enhanced with a proprietary control system, the main components of which are the video camera (receiver), the signal decoder (microprocessor device) and the manipulator (mock-up weapon) along with the encoder (encoder). The transmitter uses amplitude modulation of the laser beam. The laser beam is reflected from the screen and recorded by the video camera. The attractiveness of the suggested approach is the ability to influence AR even when the distance between the screen and the player reaches 600 m.

The developed coding method eliminates problems identified as essential in [14]. The coding presented in paper [14] was based on the data transmission protocol used in the RS-232 standard.

## II. HARDWARE DESCRIPTION

The laser beam modulation is implemented by the encoder, Fig. 2. The main component of the encoder is the AT89s8253 microcontroller clocked at  $f = 22.1184$  MHz. The encoder performs the signal coding algorithm discussed in point IV. The result of the algorithm operation, depicted in the form of a sequence of logic signals (binary values), is

Fig. 1 View of player equipped with a 9 DOF sensors system

This work was not supported by any organization

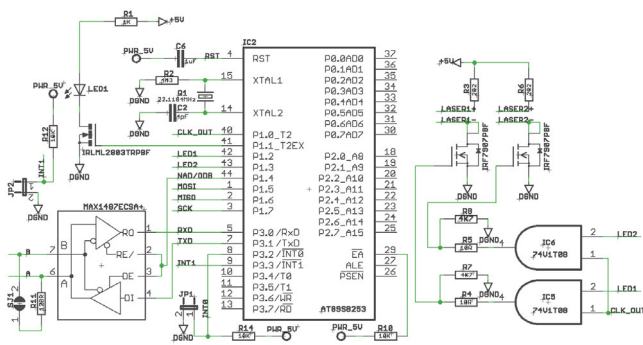

Fig. 2 Diagram of the laser beam modulation system (main elements)

taken out in series to the microcontroller terminals (indicated during configuration) – P1.2 or P1.3. These terminals, in the case of a "1" logic input, add power to the laser diodes power supply (not shown in Fig. 2). The developed version of the system and software makes it possible to simultaneously control two laser beams. In addition, they can be keyed by a binary signal or a rectangular wave generated by the microcontroller on the P1.0 terminal. This property was used in work [15 - 18] to control the brightness of the near-infrared illuminator. Activation of P1.2 or P1.3 terminals occurs after identifying the falling edge of the signal at the P3.2 terminal of the microcontroller (JP1 connector). In the presented layout, the button attached to the JP1 connector was taken out for the user. Similarly, in order to enable manual and remote configuration of the system, a button attached to the JP2 connector was taken out as well as communication connectors operating in the RS - 485 standard. Giving a high signal on line P0.4 (as a result of JP2 connectors short-circuiting) puts the system into the configuration state. The button attached to the JP1 connector is then used to select the player identifier (*Player ID*) in the computer system. The selection is signaled to the user by a LED attached to the P1.1 terminal of the microcontroller and stored in a non-volatile memory (*EEPROM*). These actions can also be performed from the parent program when an encoder device is attached to a PC computer using a communications connector.

The view of the laser coding system is shown in Fig. 3a, and its location on a model of a gun is shown in Fig. 3b.

### III. MEASUREMENT SYSTEM CONFIGURATION

The study of laser beam coding and decoding techniques was performed under controlled laboratory conditions. The experiment was conducted using the Manta G - 201 Allied Vision camera equipped with a focal length lens of  $F = 8 \text{ mm}$  and a bandpass filter for which  $\lambda$  was equal  $650 \text{ nm}$  and the window width  $\Delta\lambda$  was  $\pm 10 \text{ nm}$ , and the OptiTrack 120 Slim camera with a lens with a focal length of  $F = 8 \text{ mm}$ . The laser beam produced by a laser module with a power of  $P \approx 3 \text{ mW}$  emitting a wavelength of  $\lambda = 650 \text{ nm}$  was subjected to modulation. The laboratory stand was created using commercial Virtual Battlespace 3 system (VBS3), which has been supplemented by encoding device developed by the authors, Fig. 3, as well as laser beam decoding device. VBS3 software was used to generate scenarios in which the AR system affected the user. An example scene is shown in Fig. 4a. The generated image was transferred to the 7<sup>th</sup> Sense Delta 2208 multimedia server. The server split the input image between the three projectors that displayed it at  $1920 \text{ px} \times 1200 \text{ px}$ . ProjectionDesign F35 AS3D WUXGA projectors were used in the study as well as a half cylindrical screen, Fig. 4b, measuring  $12 \text{ m} \times 3 \text{ m}$ . The user was about  $3 \text{ m}$  from the surface of the screen. During the test, the player was equipped with a Smith & Wesson Springfield weapon model, supplemented with the coding system shown in Fig. 3a. The task of the player was to shoot in strictly defined situations, enforced by the AR system. These shots were observed by the camera and then decoded in real time.

Fig. 5 Diagram of encoding symbols and code frame for symbol 33

#### IV. METHOD OF LASER BEAM CODING

During developing the laser signal coding method,  $N=36$  encoded symbols were assumed. The default state of the laser module is “off”, which is manifested by the lack of a laser spot on the screen, and thus on the image. At the same time, it was assumed that displaying a single bit frame of code  $T_W$ , frame format  $[D_T, D_L, \dots, D_{L+1}, D_P, D_E]$ , where  $D_T$  – start bit,  $D_P$  – stop bit,  $D_E$  – frame end bit,  $D_k$  – code bit for  $1 \leq k \leq L+1$ . Parameter  $L$  is dependent on  $N$  and is equal to  $L=\text{round}(\text{sqrt}(2N))$ . In the layout of Fig. 2, the next frame bits of code is formed by terminal P1.2, which is responsible for turning on and off the laser module. The start bit and stop bit always have a value of one. The  $D_E$  bit always assumes zero. This corresponds to the transition from the state of emission of subsequent frame bits to the deactivation of the laser module. The impact of the  $T_W$  bit emission time on the effectiveness of decoding transmitted symbols has been verified in the studies of the coding system. The dependency of the required time of emitting the  $T_W$  bit as a function of the frequency of images obtained from the camera was also determined. The principle of encoding a frame is presented in Fig. 5. Thirty six symbols,  $N=36$ , were arranged on eight levels  $L=8$ . At the level of index  $l$  equaling zero, eight symbols were placed. Each higher level contains one symbol less. At the last level  $l=L-1$  only one symbol is placed. For each symbol, for each level, a sequence number  $v$  is assigned. The coded symbol can then be written in the form

Fig. 6 Coding example: a) 6 symbols ( $v=6; l=0$ ); b) 24 symbols ( $v=3, l=3$ ); c) 35 symbols ( $v=2; l=6$ )

of  $S = v + 0.5l(2L + 1 - l)$ , where  $0 \leq l < L$ . The pulse width depends on parameters  $v$  and  $l$ , and the pause time between pulses does not change and equals  $T_W$ . An example of symbol encoding from level  $l=5$  (first from the bottom) and a symbol from level  $l=0$  (second from the bottom) is shown in Fig. 5. In this example, time  $T_W$  was equal to 0.025 s.

The encoding of parameter  $v$  is done by assigning a value of one in the code frame for bits  $D_1$  to  $D_{v-1}$  and the value of zero for  $D_v$ . If the symbol is at level  $l=0$  then the bits from  $D_{v+1}$  to  $D_{L+1}$  are assigned a value of one. Otherwise, bits from  $D_{v+1}$  to  $D_{v+l}$  are set to one and the  $D_{v+l+1}$  bit value is set to zero, which corresponds to the coding of the  $l$  parameter. The other code bits are assigned a value of one. In both cases, the stop bit always assumes a value of one and the frame ends the frame end bit of  $D_E=0$ . Giving a logic zero to the end of P1.2 of the microcontroller disables the laser module. An example of symbol encoding: 6, 24 and 35 is shown in Fig. 6. Taking into account the start and stop bits values (always equal to one), it can be noticed that the width of the first generated pulse is  $vT_W$ . For symbols from level  $l=0$  the second pulse width is equal  $(L+2-v)T_W$ , and for the remaining levels  $lT_W$ . The third pulse is generated only for symbols from levels  $0 < l < L$ . Its width is equal to  $(L+1-v-l)T_W$ .

#### V. METHOD OF DECODING OF LASER BEAM

Decoding the symbol is carried out on the basis of analysis of the sequence of images obtained from the camera. Firstly, the function of laser module activation  $u(t)$  is determined. Decoding the symbol takes place using the extended finite-state machine.

##### A. CALCULATION OF LASER ACTIVATION FUNCTION

Due to the use of the banded optical filter, only the red  $R$  component of the image is used for further analysis. The luminance component is analyzed when using a monochrome camera. It is represented in matrix form in calculations ( $R$  matrix). The value of the laser module activation function  $u(t)$  is determined in discrete moments of the time  $nT_S$ ,  $n \in N^+$  based on the values of the elements of the  $R$  matrix. The pseudo code appropriate for the algorithm determining the values of  $u(t)$  is presented in Fig. 7. Firstly, maximizing

```

Set(p);
while (isRunning)
    Delay(Ts);
    frame = GetLatestFrame();
    R = MaximizeContrast(frame.R);
    E = (R - Average(R)) / Maximum(R);
    if (Maximum(E) > p)
        B = Binarization(E,p);
        M = BiggestAreaImageMoment(B);
        RaiseDecoded(frame.timeStamp, 1, M10/M00,
                        M01/M00);
    else
        RaiseDecoded(frame.timeStamp, 0, 0, 0);

```

Fig. 7 Pseudo code to determine the value of the activation function

Fig. 8 Maximum value of the relative deviation from the mean in the function of time for  $S = 24$  and  $T_W = 0.025$  s

the contrast of the color red is performed. Then, for matrix  $R$ , the matrix of relative deviations from the mean  $R$  is determined, the values of which are determined from formula  $e_{ij} = (r_{ij} - r_{avg}) / r_{max}$ , where:  $r_{ij}$  – is the element of matrix  $R$  with coordinates  $i, j$  obtained by the contrast maximization operation,  $i, j$  – line and column numbers respectively of matrix  $R$ ,  $r_{avg}$  – average value of matrix  $R$  (red color component after the contrast maximization operation),  $r_{max}$  – maximum value of the  $R$  component of the image obtained after the image contrast maximization operation.

In the case of experimenting with a single shooter, at least one laser spot may be observed at a time in the image. This spot is determined based on the values of matrix  $E$ . When the maximum value of an element of matrix  $E$  exceeds the value of the set threshold  $p$ , then the laser is considered to be enabled. At that time the activation function  $u(t)$  assumes the value of one, or otherwise zero. The graph of the maximum relative deviation from the mean in the function of time recorded for symbol  $S = 24$  and the time  $T_W = 0.025$  s is shown in Fig. 8. The detection of the laser spot forces the determination of matrix  $B$  obtained during the binarization of the matrix  $E$ . Binarization is carried out in accordance with formula  $b_{ij} = \{255, \text{for } e_{ij} > p; 0, \text{for } e_{ij} \leq p\}$ , where  $p$  – the

$c_0: (-, -, -, v := 0 \wedge l := 0 \wedge T_E := 0, \phi, q_0)$   
 $c_1: (q_0, in = [T, x, y], 0 < f(T) \leq L, v := f(T) \wedge T_E := time, \phi, q_1)$   
 $c_2: (q_1, in = [T, x, y], h(T) \leq L \wedge f(time - T_E) = 1, l := f(T) \wedge T_E := time, \phi, q_2)$   
 $c_3: (q_2, in = [T, x, y], h(T) = L + 1 \wedge f(time - T_E) = 1, T_E := time, out := g(), q_3)$   
 $c_4: (q_1, in = [T, x, y], h(T) = L + 2 \wedge f(time - T_E) = 1, T_E := time, out := g(), q_3)$   
 $c_5: (q_1, -, h(time - T_E) + 2 > L, v := 0 \wedge T_E := 0, \phi, q_0)$   
 $c_6: (q_2, -, h(time - T_E) + 1 > L, v := 0 \wedge l := 0 \wedge T_E := 0, \phi, q_0)$   
 $c_7: (q_3, -, -, v := 0 \wedge l := 0 \wedge T_E := 0, \phi, q_0)$   
 where:

$f(t) = \text{round}(t / T_W)$   
 $h(t) = f(t) + v + 1$   
 $g() = v + 0.51(2L + 1 - l)$

Fig. 9 Extended finite state machine

given binarization threshold. The results of binarization are areas in matrix  $B$  (spots), the largest of which determines the location of the laser pointer. It is for it image moments  $M_{00}$ ,  $M_{01}$ ,  $M_{10}$  and the center of gravity is calculated. In pseudo-code, Fig. 7, the *RaiseDecoded* has been proposed to be used and transferred to the function of handling: the time stamp, the value of the activation function, and the coordinates of the center of gravity of the area identified with the laser pointer.

## B. EXTENDED FINITE STATE MACHINE

Decoding the symbol is performed by the extended finite-state machine *EFSM*. At the *EFSM* input matrix  $G$  with a structure of  $[T, x, y]$  is given, where  $T$  – pulse width,  $x$  and  $y$  – laser spot coordinates. In the accepted solution, matrix  $G$  represents a single pulse extracted from the activation function of the laser module  $u(t)$ . According to the assumptions given in point IV, each symbol is encoded by several pulses (two or three pulses) depending on level  $l$ . Thus, based on state  $q$  of the *EFSM* machine and the determined  $G$  matrices, the symbols  $S_i \in \{\phi, S_1, \dots, S_n, \dots, S_N\}$  are indicated, where  $\phi$  means “no symbol”,  $S_1, \dots, S_N$  represent decoded symbols, and  $N$  specifies the allowed number of decoded symbols.

The extended finite-state machine was defined as 6-tuple  $EFSM = (Q, q_0, V, I, O, C)$ . The various symbols are:  $Q$  – set of *EFSM* states;  $q_0$  – initial state;  $V$  – a set of *EFSM* variables;  $I$  – pulse matrix described in the form of  $G$ ;  $O$  – a set of possible *EFSM* symbols;  $A$  – a set of allowed transitions between *EFSM* states. The diagram of states and elements of set  $C$  are shown in Fig. 9. A set of  $Q$  states of the *EFSM* machine is defined as  $\{q_0, q_1, q_2, q_3\}$ . State  $q_1$  represents the position of the symbol  $S$  defined within the coding level, and  $q_2$  determines the level on which the symbol is located. The  $q_3$  state is identified with turning off the laser module, and  $q_0$  is the initial state of the *EFSM*. The set of variables  $V$  is defined as  $\{l, v, T_E, time, X, Y\}$ , where the variables  $l$  and  $v$  indicate the parameters of symbol  $S$ , the variable  $T_E$  defines the time of arrival at the input of matrix  $G$ ,  $time$  indicates the elapsed time since appearing at the input of the matrix  $G$ , and  $X$  and  $Y$  denote the coordinates of the laser spot determined for the first pulse. Set  $C$  is defined as  $\{c_k: (q, in, guard, a, out, q')\}$  and means that if *EFSM* is in state  $q$  and matrix  $[T, x, y]$  appears at the *in* input, then the transition to the state of  $q'$  is possible provided that the logical expression *guard* is true. Only in this case will the searched for symbol  $S$  be determined on the *out* output. The output of the machine from its initial state  $q_0$  means putting forward hypothesis  $H_0$  on symbol detection. In subsequent times, if the time limits are not met, the machine automatically returns to  $q_0$ , which is equivalent to rejecting hypothesis  $H_0$ . The assumption of hypothesis  $H_0$  takes place only at the moment the machine goes into state  $q_3$ . Only then will symbol  $S_i$  appear on the output, indicating its recognition. Determining the output symbol is based on

Fig. 10 Detection efficiency in the function of duration of bit  $T_W$  and tested image resolutions

variables  $v$  and  $l$ . In other cases, the *EFSM* output is given element  $\phi$ .

## VI. RESULTS OF RESEARCH

The experiment was carried out for a test set containing  $N=36$  symbols,  $S \in \{S_n; n=1, \dots, N\}$ . Each symbol was encoded with the developed technique (Section IV). In this way, codes were obtained, which individual bits control the laser module (“1” – ON, “0” – OFF). The test consisted of sending the test set  $K=100$  times. Altogether 3,600 symbols were sent and decoded. The experiment was divided into two parts. The first part was the effect of time  $T_W$  on the efficiency of detecting  $S$ . The study was conducted for three camera resolutions: 640 px x 480 px, 800 px x 600 px and 1024 px x 768 px. In each test, the duration of  $T_W$  was changed and accepted values ranging from 0.025 s to 0.055 s with a step of 0.001 s. For each trial, the detection efficiency of the transmitted symbol was determined as well as the average detection efficiency of symbols belonging to the test set, Fig. 10. For the resolution of 640 px x 480 px, images were acquired on an average of 0.015 s ( $FPS=66.66$  Hz). For  $T_W$  of 0.030 s, the detection efficiency was no worse than 90%. Symbol detection efficiency at a level of 100% was achieved when images were acquired at 0.036 s –  $FPS$  equal

Fig. 11 Detection efficiency in the function of duration of bit  $T_W$  for resolution 640 px x 480 px and  $FPS=120$  Hz

Fig. 12 Detection of symbol  $S_{24}$ ,  $T_W=0.025$  s, image resolution 640 px x 480 px

27.77 Hz. Comparative dependencies were obtained for resolutions: 800 px x 600 px and 1024 px x 768 px.

The second part of the study used the OptiTrack 120 Slim miniature high speed camera for motion capture. The camera was equipped with a lens with a focal length of  $F=16$  mm and a bandpass filter of  $\lambda_0=650$  nm and  $\Delta\lambda=\pm 10$  nm. The study was conducted for a resolution of 640 px x 480 px and  $FPS=120$  Hz. The second part of the experiment was divided into two phases. Firstly, it was confirmed that  $T_W$  has a similar effect on the effectiveness of the detecting symbols as was the case in the first part of the experiment. The study was performed by changing the duration of the  $T_W$  bit from 0.014 s to 0.030 s with a step of 0.001 s. In this case, for the time of  $T_W$  greater than 0.025 s, a decoding efficiency of the transmitted symbols was achieved of over 99%. The obtained results are shown in Fig. 12. In the second phase, the effectiveness of symbol recognition for  $T_W$  was 0.024 s and 0.025 s. For  $T_W=0.024$  s, the efficiency of symbol recognition was no worse than 91.67%, Table I. Detailed results are shown in Table II. The lowest efficiency of 67% was achieved with symbol  $S_{12}$ . Efficiency of 100% was obtained for the symbols:  $S_1, S_2, S_3, S_7, S_8, S_9, S_{14}, S_{15}, S_{16}, S_{21}, S_{24}, S_{34}, S_{36}$ . No symbol has been misrecognized. In three hundred cases, the  $q_0$  status was dropped, because no time limit was met, so no symbol was assigned. For  $T_W$  greater than 0.025 s, the detection efficiency was greater than 99%. A detailed result of recognizing symbol  $S_{24}$  is shown in Fig. 12. The laser module activation function consisted of three pulses. Parameters  $v$  and  $l$  of the symbol were determined based on this. Parameter  $v$  was defined based on formula  $v = \text{round}((t_1 - t_0)/T_W)$ , therefore  $l=3$ . Parameter  $l$  was determined from the formula  $l = \text{round}((t_3 - t_2)/T_W)$ ,

$S_{31}$	100	93	93
$S_{33}$	100	92	92
$S_{35}$	100	98	98

therefore  $l=3$ . The detected impulses fulfilled all time limits. On this basis, and based on the proposed coding scheme, Fig. 5, symbol  $S_{24}$  was recognized.

## VII. CONCLUSION

The article presents methods of: encoding and decoding laser signals developed to control the system of augmented reality. Characteristics of the developed coding method are: constant code frame emission time, one or two intervals between pulses, tight time limits for pulse width and intervals between them. Constant time for frame emission equal to  $(3+L)T_W$  to reduce the number of false detection of the transmitted symbol. Adopted strong limitations on pulse width reduce the number of type II errors, but force the use of cameras with a fixed image acquisition time. In turn, a small number of pauses between pulses allows for effective detection when symbols are emitted by multiple encoding devices.

It has been shown that using the proposed methods make it possible to distinguish between commands encoded in a laser beam with an efficiency of 99.9%. In the case of using cameras with similar parameters to the units used, the duration of the  $T_W$  bit should be no less than  $3T_S$ , where  $T_S$  represent the interval between the two acquired image frames.

The laser signal encoding algorithm can be successfully implemented in the embedded system. The implementation of the encoding algorithm required 57.1 bytes of data memory (byte and bit addressing memory) and 3,664 bytes of program memory.

**Abstract**—Interacting with real-time rendered 3D content from powerful machines on smaller devices is becoming ubiquitous through commercial products that enable in-home streaming within the same local network. However, support for high resolution, low latency in-home streaming at high image quality is still a challenging problem. To enable this, we enhance an existing open source framework for in-home streaming. We add highly optimized DXT1 (DirectX Texture Compression) support for thin desktop and notebook clients. For rendered light fields, we improve the encoding algorithms for higher image quality. Within a 10 Gigabit Ethernet (10 GbE) network, we achieve streaming up to 5K resolution at 55 frames per second. Through new low-level algorithmic improvements, we increase the compression speed of ETC1 (Ericsson Texture Compression) by a factor of 5. We are the first to bring ETC2 compression to real-time speed, which increases the streamed image quality. Last, we reduce the required data rate by more than a factor of 2 through foveated compression with real-time eye tracking.

**Index Terms**—in-home streaming, ETC1, ETC2, DXT1, light fields.

## I. INTRODUCTION

“IN-HOME STREAMING” refers to interacting with real-time content on a thin client that has been generated on a more powerful computing device. The user’s inputs are forwarded to the server, which processes these and sends back updated video to the client. “In-home” refers to a local network, either wired or wireless, but not over the Internet. Ideally, in-home streaming is transparent to the user, delivering the perception as if the interactively streamed application were running locally on the target device. To achieve this, latency between user inputs and screen updates needs to be lower than 100 ms [1] and the image quality needs to be high, free of noticeable artifacts. Comparing with the state of the art approaches, these requirements still leave room for significant improvements as we will show in this paper. Our contributions

are extending an open source in-home streaming approach [2] with the following features:

- Support for multiplexed rendered light field images
- Higher image quality through ETC2 support
- Optimizations for ETC1, ETC2 and DXT1 encoding
- Streaming up to 5K resolution using 10 GbE
- Foveated compression through real-time eye tracking

## II. RELATED WORK

The idea of controlling one compute device from another has been around for a long time. Desktop-sharing apps like Microsoft Remote Desktop and VNC (Virtual Network Computing) [3] are used, but are only optimized for 2D content. Cloud gaming approaches like “PlayStation Now” focus on lower bandwidth and use H.264 [4] compression. Specific in-home streaming solutions, supporting 3D real-time rendered content provide an opportunity to deliver a high *Quality of Experience* without the latency of the Internet, and with higher available data rates in the network. We compare our approach with the most commonly known in-home streaming products, which use H.264 internally: SplashTop, NVidia Shield Android TV Box and Steam.

Current in-home streaming approaches are optimized towards sequences of regular 2D images, generated from rendering 3D real-time content. Auto-stereoscopic and light field displays are getting attention again, enabling a way of perceiving stereoscopic content without glasses [5]. To drive these displays, multiple views of the scene are rendered and multiplexed together into a 2D image. This can create high frequency content in the multiplexed image which does not correspond to high frequencies in the single views and hence can lead to artifacts when using classical image or video coding standards.

We present an encoding algorithm optimized for multiplexed images.

Our work is an extension to the open source in-home streaming approach from Pohl et al. [2]. They introduced a client/server model that allows to interact with real-time rendered content created from one or many machines and can be remote controlled over wireless IEEE 802.11ac [6] from mobile clients like smartphones. Compared to using H.264 compression like other commercially available solutions, it relies on using ETC1 [7] (Ericsson Texture Compression), which results in a system with a motion to photons latency of 60–80 ms, compared to NVidia Shield Portable at 120–140 ms [2]. As ETC1 has a fixed 1:6 compression ratio for RGB data, it requires a high data rate inside the network. We extend the framework to significantly reduce encoding times, stream efficiently to notebooks and desktop PCs and enable even higher image quality through ETC2 [8]. Furthermore, as ETC1 and ETC2 native decoding is not supported on all desktop/notebook GPUs (see Table I), we extend the framework to use DXT1 [9] for encoding with our new highly optimized routines.

Guenter et al. [10] introduced a foveated rendering approach, generating and blending together three images of different quality in real-time depending on the inputs from a desktop eye tracker. Instead of using the eye gaze for rendering optimizations, we introduce a foveated compression method to lower the required data rate for in-home streaming. Zund et al. [11] follow a similar approach, changing the amount of pixels used in certain regions of a video for compression based on automatically extracted saliency maps [12]. Ours is based purely on the real-time eye gaze of the user.

### III. SYSTEM

#### A. Hardware Setup

We use two hardware setups. The first uses four workstations with Dual-CPU (Intel Xeon E5-2699 v3, 2.3 GHz, 18 physical cores) with a NVidia GeForce 970. The workstations stream to a desktop PC with an Intel Core i5-6500 (3.2 GHz, 4 cores). As GPU we evaluate both the internal Intel HD 530 graphics and a GeForce 970, connected to the Dell UP2715K 5K monitor ( $5120 \times 2880$  pixels). This setup is depicted in Figure 1. The second setup uses one of the workstations, streaming to the desktop PC connected to either a self-built light field display ( $2560 \times 1440$  pixels) or the low latency monitor Asus MG278Q at the same resolution. All machines use 10 Gigabit Ethernet over the Intel Ethernet Network Adapter X540-T1, connected to the Netgear XS708E-100NES Switch.

#### B. Compression Setup

The open source framework [2] that our work extends, supports ETC1 for encoding. In addition to this, we add ETC2 support for higher image quality. Prior to our work, there have been no real-time ETC2 encoders suitable for in-home streaming. Native ETC1 and ETC2 decoding in texture units works very well on most smartphones and tablets. It has been available in the form of OpenGL ES extensions and was made

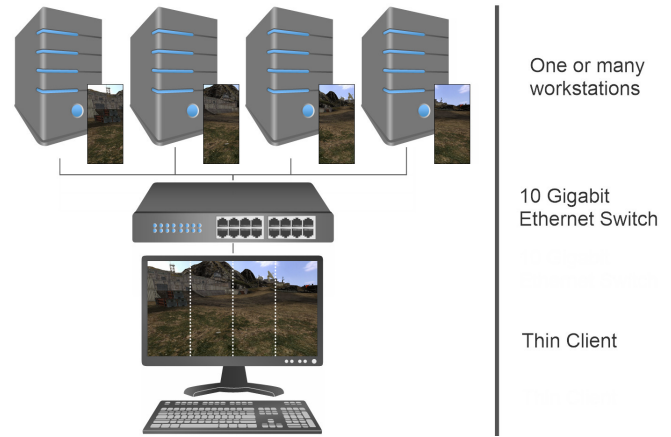

Figure 1. Rendering from multiple machines and streaming the content interactively to a thin client.

Table I  
NATIVE DECODING OF COMPRESSED TEXTURES.

	DXT1	ETC1/2
Mobile GPU	×	✓
NVidia GPU, Maxwell GM20x	✓	×
AMD GPU, GCN 1.2	✓	×
Intel GPU, Broadwell	✓	✓

a requirement in the OpenGL ES 3.0 standard. On desktop and notebook GPUs the situation is different. Despite ETC2 support being standardized in OpenGL 4.3 (ETC2 is backwards compatible to ETC1), we found that most GPU vendors are only doing a slow software decompression in the driver, which is not satisfying for fast in-home streaming. However, on Intel HD graphics (5th generation Core Broadwell and later), we got fast native ETC1/2 displaying. To support more GPUs, we provide a highly optimized DXT1 compression routine based on FastDXT [13]. Just like ETC1 and ETC2, DXT1 uses a fixed compression ratio of 1:6 for RGB data. We highly optimized these encoders for Advanced Vector Extensions 2 (AVX2). As AVX2 expands most integer commands to 256 bits, we packed 16 colors, each 16 bit signed integer, into the 256 bit AVX2 vector. That way, we were able to process more data faster with the AVX2 instructions for multiply and mad. In addition, we exploited the symmetry of look up tables.

As in the original framework, optional lossless LZ4 compression<sup>1</sup> of compressed blocks can be applied. We keep this disabled except in one test case, where we mention it.

#### C. Light Field Setup

Our setup has a microlens sheet on top of an LG G3 mobile phone screen with  $2560 \times 1440$  pixels, which allows to view a light field on a horizontal autostereoscopic display with N views (18 in our case). One lens covers N pixels and depending

<sup>1</sup><https://github.com/lz4>

on the direction the user looks on it, only one of these pixels will be seen per eye. The image is created in a way that  $N$  different views are rendered which are multiplexed together in one final image with the following method: the 1st pixel of the 1st view is copied into the 1st pixel of the final image. The 1st pixel of the 2nd view is copied into the 2nd pixel of the final image and so on. After  $N$  pixels, this pattern repeats with the 2nd pixel of the 1st image. If the resolution is not evenly dividable by the number of views, we fill the remaining pixels in the image with black.

When we compress to ETC1/2, a decision is made if the  $4 \times 4$  pixel block should be split into two  $4 \times 2$  or  $2 \times 4$  sub-blocks for better encoding properties. If encoding requires no real-time, one could make a very careful analysis on which split gives the closest match to the original data. However, as we need fast performance, it could happen that after the repeating pattern of  $N$  pixels, a hard transition is in the center of the  $4 \times 4$  block and the encoder decides to split this into  $4 \times 2$  subblocks. Colors across that transition would get mixed together, even though in the individual views they are not related. Our new idea is to add optional flags to the function that encodes an ETC1/2 block and forcing it to a split decision in these cases. There are also light field display configurations where a lens covers pixels in both horizontal and vertical directions. In that case, our approach can also be used to force a  $4 \times 2$  split, if appropriate. If in both directions a split happens within one block, we use the default algorithm.

#### D. Rendering Setup

For generating 3D real-time rendered content that the client can interact with, we use a self-written ray tracing platform partly accelerated by Intel's Embree [14]. As test scene we use "island" from the game Enemy Territory: Quake Wars. The rendering workload is distributed across multiple workstations and parallelized on each node. Each workstation sends its pixels back to the client after receiving input from the client. The renderer can create out of a 3D scene description both 2D images and multiplexed light field images. In the latter case, the rays are directly shot in a way that multiplexed images are created without individual views.

#### E. Foveated Compression

As DXT1, ETC1 and ETC2 share the same fixed compression ratio of 1:6 for RGB data, the required data rate can become a bottleneck. To facilitate data rate savings, we use a Tobii Pro X120 eye tracker to get the current eye gaze of the user and apply foveated compression depending on it. This could be combined with foveated rendering, but we prefer to stay independent of the image generation method. In more detail, we divide the image into nine rectangular regions. One region covers the foveated area, using the original resolution for encoding. The other eight regions are resized to 50% using a bilinear filter before encoding. We modify the network protocol to send information about the number of bytes that are about to be received, then information on the nine rectangular regions and then the compressed image parts. The client reacts

Table II  
ENCODING TIMES FOR  $2560 \times 1440$  PIXELS. LOWER IS BETTER.

<b>DXT1 (ours)</b>	<b>0.5 ms</b>
<b>ETC1 (ours)</b>	<b>1.0 ms</b>
<b>ETC2 (ours)</b>	<b>1.3 ms</b>
DXT1 (FastDXT)	1.6 ms
ETC1 (Pohl et al. [2])	5.3 ms
Intel Media SDK, Software H.264	20 ms
Intel Media SDK, Software MVC H.264	60 ms
FFmpeg, H.264	60 ms
Intel Media SDK, QuickSync MVC H.264	120 ms
Intel Media SDK, QuickSync H.265	600 ms

accordingly, uploading the nine parts into individual textures. The client combines them together and rescales them through OpenGL, if required.

## IV. EVALUATION

### A. Performance

We achieve 35–55 frames per second, depending on the rendering complexity of the view, using four workstations streaming interactively to a desktop PC at 5K ( $5120 \times 2880$  pixels) resolution with DXT1 compression. Considering a 20 ms frame, 45% of the time is spent for rendering, 5% copying internal buffers, 5% compressing to DXT1, 7% for sending data over TCP. The remaining 38% is spent on waiting for command updates from the client. Rendering one frame ahead using double buffering could fill that gap, but would increase latency. On the client side, 32% of the time is required for receiving TCP data, 12% for texture upload to the GPU and drawing. 56% for waiting on image data from the servers. Again, double buffering would help, but add latency. If the GPU has hardware support in the texture units for the compressed format, decoding does not consume any extra time when blitting data onto the screen which makes this ideal for low latency.

For driving the light field display with streamed content from one workstation, we achieve 50–70 frames per second.

In Table II, we compare the average encoding times for the workload of images with  $2560 \times 1440$  pixels. For DXT1, ETC1 and ETC2 it is performance-agnostic if we compress individual views or multiplexed light field images. We use the H.264 profiles for the highest quality as we assume the availability of high data rate in the in-home setup.

### B. 10 Gigabit Ethernet

Testing various network adapter driver options, we get additional speed ups in the 10 GbE environment. The default maximum transmission unit (MTU) is set to 1500 bytes for Ethernet, which leads to much packet overhead when sending big amounts of data. With the "Jumbo Frame" feature, we can increase the MTU size to 9014 bytes, increasing the frame rate in the 5K setup by five percent.

Table III  
IMAGE QUALITY COMPARISON FOR 2D IMAGE AND LIGHT FIELD IMAGE. PSNR/SSIM: HIGHER IS BETTER.

	Original	H.265 Intel	H.264 Intel <sup>†</sup>	ETC2	ETC1	DXT1	Steam	Splashtop	NVidia Shield

<sup>†</sup> Using the Multi View Coding (MVC) profile for light field images.

### C. Image Quality

We compare the image quality of a compressed 2D image and a reconstructed view of a compressed light field image through PSNR [15] and SSIM [16] in Table III. To highlight the difference, we show contrast-enhanced close up on the images. Wherever possible, we set the quality / bit rate to the highest modes for encoding. For Steam, we had to switch back to the “balanced” settings to avoid frame drops. As the metrics show, using high bit rate for H.264 [4] and H.265 [17] achieves in most cases higher image quality than ETC2, but only at higher encoding times (see Table II).

As described in Section III-C, it can happen in ETC1/2 encoding, that a wrong decision on splitting into sub-blocks is made during hard transitions of the light field image. This is exposed in the color bleeding in Figure 2, where we also show the impact on the recovered individual view and how our forced split fixes this.

### D. Latency

We measure the motion to photons latency with a high speed camera. The starting time is from the video camera frame in which we first touch the mouse on the client for moving. The ending time is when we see pixel changes, sent from the server, displayed on the screen of the client. The results in Table IV. We explain the difference to Pohl et al. [2] from our wired vs. their wireless network.

### E. Data Rate and Foveated Compression

While the latency of 40–60 ms of our pipeline is much better compared to the approaches using H.264, the required data rate is high. For our in-home streaming at  $5120 \times 2880$  pixels at 55 frames per second, it is 3.1 GBit/s. For  $2560 \times 1440$  pixels, 0.8 GBit/s. However, in an in-home network, there is usually a lot of data rate available. Wired approaches like

Figure 2. a) multiplexed light field image; b) uncompressed close-up across transitions (vertical red line added to mark the transition); c) compressed with original ETC1 encoder, orange color is leaking across the transition; d) compressed with our modified ETC1 encoder; e) impact on the reconstructed, stretched individual view: orange leak inside the house; f) leak fixed through forced split.

10 GbE and Gigabit Ethernet deliver up to 10 GBit/s and 1 GBit/s respectively. On the wireless side, data rates up to 3.5 GBit/s can be achieved for IEEE 802.11ac, 4x4 MIMO Wave 2. Looking ahead, 802.11ax will deliver 10–14 GBit/s and 802.11ay up to 100 GBit/s [18]. Nevertheless, we can reduce the required data rate using foveated compression. Depending on the size of the monitor, the distance from it or if an HMD

Table IV  
LATENCY COMPARISON. LOWER IS BETTER.

<b>Our approach (DXT1/ETC1/ETC2)</b>	<b>40–60 ms</b>
Pohl et al. [2] (ETC1)	60–80 ms
NVidia Shield Android TV (H.264/H.265)	100–120 ms
Steam in-home streaming (H.264)	140–150 ms
Splashtop (H.264)	450–550 ms

Figure 3. Foveated compression. Top: the center area around the eye gaze is compressed in original resolution, while the eight other areas have been resized by 2x in each dimension before compression. Bottom: close-up on the green marked rectangle, showing on the left the high resolution image while on the right the area with reduced pixel size is shown, upscaled with bilinear filtering on the GPU.

is used instead of a regular 2D screen, the parameters for this approach can be varied. For our desktop setup, we use 40% of the horizontal resolution for the size of the squared, foveated area (see Figure 3). Then, the required data rate for either DXT1, ETC1 or ETC2 of one image at  $2560 \times 1440$  pixels is reduced by a factor of 2.2 from 1.76 MB to 0.81 MB.

#### V. CONCLUSION

With our novel approaches, we bring in-home streaming to the next generation. We support 5K resolution, improve encoding algorithms for better image quality with light field rendered content and significantly improve the encoding times for ETC1. Furthermore, we design the first real-time ETC2 compression routine, enabling increased streamed image quality over ETC1. A larger variety of thin clients is supported with the option to use DXT1, for which we increase encoding performance by more than 2x. With eye tracking, we show that we can lower the required data rate by more than 2x. Our contributions are put back into the open source community under <https://github.com/ihsf>.

**Abstract**—In this paper we propose a fast method for detecting the ground plane in 3D scenes for an arbitrary roll angle rotation of a stereo vision camera. The method is based on the analysis of the disparity map and its “V-disparity” representation. First, the roll angle of the camera is identified from the disparity map. Then, the image is rotated to a zero-roll angle position and the ground plane is detected from the V-disparity map. The proposed method was successfully verified on a simulated 3D scene image sequences as well as on the recorded outdoor stereo video sequences. The foreseen application of the method is the sensory substitution assistive device aiding the visually impaired in the space perception and mobility.

## I. INTRODUCTION

THE TASK of ground plane detection in images of 3D scenes is an important step in many computer vision algorithms [1], [2], [3], [4], [5], [6], [7], [8]. Segmentation of the ground plane region and estimation of its spatial orientation allows for detecting free space that is devoid of obstacles in the imaged 3D scenes. Such knowledge is of high importance for depth sensing stereo vision based techniques that are applied e.g. in an automotive industry and systems for guiding autonomous robots [1], [2], [3], [9], [10]. Stereo vision camera modules in such systems are mounted in rigs, which limit camera movement versus the world coordinate system to just a single degree of freedom (1 DoF), that is left and right turn (the yaw angle). Such a constraint simplifies image analysis techniques of the scene that are based on the depth maps computed from the stereo matching algorithms [11].

There are, however, mobile applications of the computer vision systems (e.g. in humanoid robots, or electronic travel aids (ETAs) for the visually impaired and blind [8], [12], for which this work is intended to) in which camera movements are not restricted and need to be defined by 6 DoF ego-motion parameters [8], [13]. That is, three parameters defining 3D translational motion vector  $T = [U \ V \ W]$  and three parameters  $\omega = [\alpha \ \beta \ \gamma]$  defining angular motion of the camera. These rotation angles are known as *pitch*, *yaw* and *roll*, respectively (Fig. 1). In such systems the value of roll angle changes during the movement. Moreover, if a camera is attached to the user's body, a constant error value may be added if the camera is not positioned properly or undergoes slight position changes

This project was supported by the European Union's Horizon 2020 Research and Innovation Programme under grant agreement No 643636 “Sound of Vision.”

Fig. 1. Parameters defining the 3D translational and rotational motion vectors

Fig. 2. An example illustrating how the camera roll angle changes during the walk in an open-space outdoor environment with a limited number of obstacles. The camera was mounted on a helmet and the roll angle was estimated using the method described in the article

during the user's movement. Fig. 2 shows how the roll angle of the camera varies during the walk.

In this paper we propose a fast method for detecting the ground plane in 3D scenes for an arbitrary roll rotation of a stereo vision camera. The method is based on the analysis of the disparity map and its histograms termed “V-disparity” representation [14] (Fig. 3). The disparity map is the horizontal displacement  $d = x_l - x_r$  of a position at which the scene object is projected onto the left and right image of the stereo vision camera. Note that the larger the disparity the smaller is the depth of the scene point in relation to the position of the stereo vision camera [15]. An example disparity map is shown in Fig. 4a, in which the disparity value is coded by a greyscale level. The larger the disparity the brighter is the pixel in the disparity image [14].

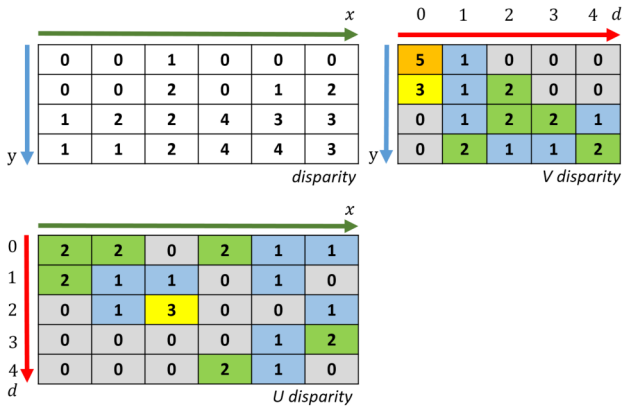

Fig. 3. A visual explanation of how the “UV-disparity” representation of the disparity is calculated

The so-called “V-disparity” representation is built by computing histograms of consecutive rows of the disparity map and presenting them as a monochrome image. Similarly, the “U-disparity” representation contains histograms of consecutive columns of the disparity map. The scheme for calculating those representations is explained in Fig. 3. The number of columns of the U-disparity map equals the number of columns of the disparity map and number of rows of the V-disparity map equals the number of rows of the disparity map. The remaining dimensions (rows of the U-disparity and columns of the V-disparity, respectively) are the histogram bins defined by disparity values  $d$ . The UV-disparity maps can be directly built for the disparity maps calculated with pixel-accuracy only. It is worth noting, that the maximum value of the U-disparity image is the number of columns in the disparity map, and the maximum value for the V-disparity image is the number of rows of the disparity map.

The rest of this paper is organized as follows: in Section II we review the ground plane detection algorithms and discuss advantages and disadvantages of different image processing approaches to this problem. The proposed algorithm for estimating camera roll angle is explained in Section III. Results verifying the performance and robustness of the proposed algorithm are presented and commented in Section IV. Finally, Section V concludes the paper with a summary of the presented work and outlines the foreseen application of the algorithm in an electronic travel aid for the visually impaired.

## II. RELATED WORK

For arbitrary pitch and yaw angles and zero roll rotation of the camera, horizontal line segments of constant depth in a 3D scene are represented by line segments aligned along rows of the disparity map (for a calibrated and rectified stereo vision camera [16]). However, for non-zero roll camera rotations (Fig. 4a) these horizontal lines are no longer aligned along disparity map rows. Thus, detection of the ground plane based on the V-disparity map (note that the V-disparity is computed as a collection of histograms of consecutive rows of the dispar-

Fig. 4. Test scene imaged by a camera rotated by a roll angle  $\gamma = -10^\circ$ : disparity map calculated by using the *Block Matching* (BM) technique [13] for the scene from Fig. 5 (a), V-disparity maps computed for the camera rotated by  $\gamma = 0^\circ$  (b),  $\gamma = -10^\circ$  (c),  $\gamma = -20^\circ$  (d) and  $\gamma = -45^\circ$  (e), respectively

Fig. 5. Results of the ground plane detection based on the V-disparity and Hough Transform in two almost identical artificial scenes rotated by a roll angle  $\gamma = -10^\circ$ . The scenes differ just by a presence of a small bench in one of the scenes. Bright regions represent the detected ground plane (note the poor result, especially for the scene shown in the right hand image)

ity map) becomes a difficult task. This is because the ground plane in the V-disparity domain is no longer represented by a single line segment but by a rather “fuzzy” region for which its angular orientation is difficult to identify (see Fig. 4c–e obtained for the increasing camera roll rotations).

It can be noticed, that results of ground plane detection with the use of the *Hough Transform* (HT) on the V-disparity map are very sensitive even to minor changes in the content of the scene. Note an example of two almost identical scenes shown in Fig. 5. The two scenes differ just by a presence of a small bench in the scene shown on the left. This seemingly minor change has yielded significantly different ground plane detection results (indicated by white regions). In order to improve the plane detection precision, prior to application of the HT technique, the scene image should be rotated by an adequate angle to compensate for the roll angle of the camera (Fig. 6, step 3).

The findings of our literature search on applications of the V-disparity representation for ground plane detection show that the problem of a non-zero camera roll angle is addressed or noticed in very few studies, e.g. [1], [3], [9], [17] among others.

Cong et al. [1] propose a method for detecting ground surface based on the maximum local energy in the V-disparity map. This approach seems to work even if the ground is not a flat surface. However, the problem of a non-zero roll angle was not directly addressed.

Fig. 6. Consecutive steps of the proposed V-disparity based ground plane detection method (including step 3<sup>rd</sup>, which is specific to our method)

Wu et al. [3] introduce a special method for mounting the camera that allows to ignore a non-zero roll angle. On the other hand the ground plane parameters are calculated by using the V-disparity map after removing large image regions representing obstacles identified in the U-disparity domain. An initial road profile is calculated without using the Hough Transform. Instead, the assumption that the maximum intensity in each row of the V-disparity map corresponds to the road lanes is used.

Lin et al. [9] use a RANSAC-based plane fitting algorithm to find the plane equation. The method allows to calculate the road lane of the same depth, which need not to be parallel to the horizontal axis of the disparity image. The authors have noticed the problem of non-zero roll angle for images of sloping roads but they assumed that the proposed plane fitting algorithm is performing well for small values of the roll angles.

Finally, Labayrade and Aubert [17] propose an estimation of the roll, pitch and yaw camera angles. A combined iterative and linear regression methods were applied to the projections of the plane to the V-disparity map to estimate the roll and pitch angle. The Authors noted, however, that this method can be computationally expensive. The value of yaw angle was estimated indirectly by determining the vanishing point.

### III. A METHOD FOR ESTIMATING CAMERA ROLL ANGLE

A general scheme for detecting the ground plane in images of 3D scenes is shown in Fig. 6. The region corresponding to the ground plane is detected in the disparity map through its V-disparity representation. Namely, a plane equation that best fits the surface of the ground is computed on the basis of the line identified in the V-disparity map, e.g. by applying the classical *Hough Transform* [3], [4], [6], [12], [14].

Our method for camera roll angle estimation is based on the observation, that for zero-roll angles any line segment, that is taken from the ground plane and is coplanar with the line  $OLOR$  connecting optical centers of the stereo vision cameras, is projected onto the same  $y$ -coordinates in the stereo vision images and in the corresponding disparity map. Note that any point from such a line assumes the same depth. However, for non-zero camera roll angles these ground plane lines are no longer coplanar with the  $OLOR$  line. Consequently, these scene line segments (of equal depth) are projected onto the disparity map at an angle that is equal to the camera roll angle. In order to identify the camera roll angle a method is proposed in which the disparity map is cross-sectioned by a series of lines  $l$  at varying angles. For each angular position of line  $l_i, i \in \mathbb{N}$  disparity map values at points  $P_1$  and  $P_2$  equidistant to  $l_i$  are collected (see Fig. 7).

Fig. 7. An example ground truth depth image for camera roll angle  $\gamma = 30^\circ$  with superimposed line  $l_i$  and points  $P_1, P_2$  ( $w$  is the number of pixels in a single row of the disparity map and  $d = 0.1w$  was selected in computations)

Note, that only for lines  $l$  that are vertical to  $l_p$  the disparity map points  $P_1$  and  $P_2$  take similar values.

The slope intercept form of line  $l_i$  in the image coordinate system is  $y = Ax + B_1$  with  $A = -\tan(90^\circ - \gamma)$  and  $B_1 = h + \frac{w}{2} \tan(90^\circ - \gamma)$ . Likewise, line  $l_p$  such that  $l_p \perp l_i$  is given by  $y = -\frac{x}{A} + B_2$ . If  $|PP_1| = |PP_2| = d$ , then:

$$(\Delta x, \Delta y) = \left( \frac{d}{\sqrt{1 + (\tan \gamma)^2}}, |\Delta x \tan \gamma| \right) \quad (1)$$

Because  $|\tan \gamma| = |\frac{1}{A}|$ , coordinates of points  $P_1$  and  $P_2$  are:

$$\begin{aligned} P_1 & \left( \lfloor x - \Delta x \rfloor, \left\lfloor y + \frac{\Delta x}{A} \right\rfloor \right) \\ P_2 & \left( \lfloor x + \Delta x \rfloor, \left\lfloor y - \frac{\Delta x}{A} \right\rfloor \right) \end{aligned} \quad (2)$$

where  $\lfloor x \rfloor$  denotes the floor function of  $x$ . Let us assume, that the total number of points  $P = (x, y)$  is  $Q$ , i.e. it is equal to the number of analyzed point pairs.

The proposed method assumes that: the dominant part of the disparity image is occupied by a ground plane and if the image is rotated by  $\gamma$ -degrees, the disparity values at points  $P_1$  and  $P_2$  shall remain the same for a series of lines  $l$  for a given  $\gamma$ . To estimate the roll rotation angle of the camera, the disparity map is dissected by lines  $l$  at different  $\gamma$  angles ( $\gamma \in [\gamma_{min}, \gamma_{max}]$ ), with a predefined step of  $\Delta\gamma = 0.5^\circ$ . For each  $\gamma$  value the parameter  $q(\gamma)$  is calculated:

$$q(\gamma) = \frac{N_E}{N_A} \quad (3)$$

where  $N_E$  is the number of pairs  $(P_1, P_2)$  for which the disparity values are the same and  $N_A$  is the total number of all analyzed pairs.

Finally, the camera roll angle is such a  $\gamma_r$  value for which (3) reaches the maximum (see Fig. 9). The algorithm of the proposed method is shown in Fig. 8.

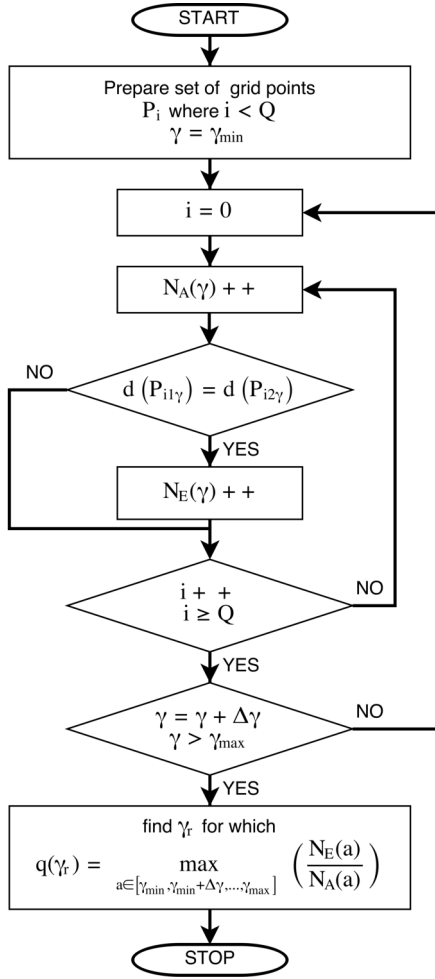

Fig. 8. The block diagram of the proposed method for roll angle estimation of a stereo vision camera

Fig. 9. Plots of  $q(\gamma)$  values for different angles of line  $l_i$  dissecting the disparity map obtained from the two proposed methods (based either on point or grid resolution). Note pronounced maxima for  $\gamma = -10^\circ$  obtained from both methods. These are correct estimations of camera roll angle (see Fig. 4a)

HT: plane detection using the Hough Transform (Fig. 6, steps 4–5)

#### IV. RESULTS

The proposed method for ground plane detection was verified on test image sequences rendered by our SESGen software [13]. The sequence consists of 600 images, for which the roll rotation of the camera ranges from  $-60^\circ$  to  $+60^\circ$  with a step of  $0.2^\circ$ . For each rendered image the SESGen computes the ground truth segmentation map and the ground truth disparity map with a pixel and subpixel accuracy correspondingly.

To measure the accuracy of the plane detection results we used the *Jaccard similarity coefficient* (JC):

$$J(M_D, M_{GT}) = \frac{\text{area}(M_D \cap M_{GT})}{\text{area}(M_D \cup M_{GT})} \quad (4)$$

where  $M_D \cap M_{GT}$  denotes the intersection of the detected and “ground truth” ground plane regions, and  $M_D \cup M_{GT}$  is their union. Those regions are represented by bright regions shown in Fig. 10. The JC is calculated for both the ground truth disparity maps and for the disparity maps calculated using the *Block Matching* (BM) technique [13]. Results are shown in Fig. 11. Note, that the ground plane detection algorithms with no camera roll angle correction tend to fail for roll rotations of more than  $\pm 5^\circ$  for which a significant drop of the JC occurs.

In order to reduce the computational complexity, both the number of steps and the number of lines dissecting the disparity map can be adjusted appropriately. Additionally, in most cases just the bottom part of the disparity image shall be taken into account. We also tested a modification of our method in which  $P_1$  and  $P_2$  are nodes of a grid (with grid size up to 30 pixels). Such a modification slightly decreases the roll angle estimation accuracy (see Fig. 9), but significantly

Fig. 12. Results of the ground plane estimation using the proposed method

Fig. 13. Point pairs from Fig. 12b for which the disparity values are the same for the camera roll angle is such a  $\gamma$  value for which (3) reaches the maximum

reduces the computational complexity which is essential in mobile and wearable platforms. Fig. 12 shows example results of the ground plane estimation methods for the pre-recorded and artificial sequences. Then, Fig. 13 shows point pairs from the scene shown in Fig. 12b for which the disparity values are equal to the camera roll angle for such a  $\gamma$  value for which (3) reaches the maximum. Please note, that these points can be successfully used in the plane fitting algorithm.

An average calculation time of the proposed algorithm (Fig. 6 step 3) for the test images is 0.7 ms on an Intel Core i7-4770 3.4 GHz processor. The computational complexity is estimated as  $O(n^2)$ . The obtained Root-Mean-Squared Error (RMSE) for the SESGen sequences equals  $\text{RMSE} = 0.466^\circ$ .

The proposed method was also verified on a set of disparity images captured in an indoor environment along with the readouts from a digital inclinometer permanently attached to the stereo vision camera. Images were captured using the ZED Stereo Camera ( $1920 \times 1080$  image resolution,  $110^\circ$  field of view and 120 mm baseline [18]). Camera roll estimation results are shown in Fig. 14. The obtained Root-Mean-Squared Error value for this sequence is  $\text{RMSE} = 1.76^\circ$

We encourage the reader to view our material supplementary to this paper [19] (e.g. result video sequences, images in higher resolution, etc.) available at <http://uv-disparity.naviton.pl/>.

Fig. 14. Results of the roll angle estimation for the recorded indoor sequence. Images were captured using the ZED stereo vision camera. The disparity map was computed using the API provided by the camera manufacturer [18]. Green dots denote roll angle read from the digital inclinometer, red dots denote roll angle values for the corresponding readouts from the inclinometer and calculated using the proposed method

## V. CONCLUSIONS

In this paper we propose a reliable algorithm for ground plane detection in 3D scene images from the disparity maps and their V-disparity representation under large roll angle values. From our literature survey we note that the problem of non-zero roll angle in ground plane detection tasks has been noticed in just few earlier studies [1], [3], [9], [17]. Moreover, only the authors of the latter work undertook the problem of roll angle estimation. They, however, did not provide any time performance of their iterative algorithm.

The strong advantage of the algorithm we propose is its computing efficiency and capability of estimating camera roll rotations for large angles (tested from  $-60^\circ$  to  $+60^\circ$ ) with the  $\text{RMSE} < 0.5^\circ$ . Such rotations can occur for 6DoF motions of the camera, e.g. in cameras mounted on drones, robots or 3D scene analysis systems aiding the visually impaired. The identified roll angle allows to rotate the disparity image to zero-roll angle. The so corrected disparity map is then used for detecting the ground plane through the corresponding V-disparity map. The reliably detected ground plane region is a basis for successful performance of further 3D scene analysis algorithms. Finally, we have shown high robustness of our ground plane detection algorithm on simulated 3D scene image sequences and real-world outdoor image sequences.

**Abstract**—The paper sets out and presents a new approach to determine the shape of the flaccid membrane of the extracorporeal pneumatic heart assist pump. This is a continuation of earlier work on the use of image processing and analysis techniques to determine the membrane shape of an artificial ventricle. The study focused on the membrane shape mapping in the actual dimensions - in the real world. The method to transform measurement results in pixels to dimensions in the real world in millimetres as well as the obtained results of this process were presented.

## I. INTRODUCTION

THIS paper presents how to use a new technique, the Depth From Defocus (DFD) type presented in [1 - 5], to determine the shape of the flaccid membrane of the extracorporeal pneumatic heart assist pump, Fig. 1, in the actual dimensions - in the real world. The work carried out in this area provides an opportunity to develop a method for determining the stroke volume of the artificial ventricle. Studies of this type are carried out in the framework of the Polish Artificial Heart (PSS) [6 - 8]. As a result of the lack of satisfactory solutions original works are suspended. Thus, to solve the problem, studies on a visual method of the measurement were initiated; e.g. [9 - 12]. Additionally this method creates the possibility of a practical use of opaque biologically inert layers, which are already developed in the framework of PSS. This should significantly reduce the risk of the formation of clots while maintaining the safe operation of the heart support pump.

## II. MOTIVATION

One of the basic heart function parameters is the stroke volume of the chamber. The instantaneous stroke volume of

Fig. 1 The extracorporeal pneumatic heart assist pump developed in the framework of the Polish Artificial Heart

a controlled pneumatic artificial ventricular can be determined by knowing the momentary shape of its flaccid membrane. Presented in [1 - 5] the Depth From Defocus (DFD) type method has been developed for visual distance measuring. It can also successfully be used for the construction of the sensor defining the shape of the flaccid membrane of the extracorporeal heart support pulse pump. It can take two forms of implementation. Until now the visualization of the shape of the membrane was performed only in the virtual world (augmented reality). Currently, studies are being carried out to lead to the determination of the shape of the membrane in the real world. Mapping the membrane shape of the artificial ventricle in the actual dimensions will enable the user to determine the stroke volume using the numerical integration method.

## III. OBJECT OF THE STUDY

The study was conducted on the extracorporeal pneumatic heart assist pump model, Fig. 2. The model was modelled based on the ReligaHeart® EXT prosthetic, Fig. 1. Using the model is justified because of the significant costs of the original prosthesis. The pneumatic heart assist pump model has a pneumatic chamber and a blood chamber separated by a flaccid membrane. The momentary shape of the flaccid membrane affects the volume of the blood chamber. The membrane is controlled by air into the pneumatic chamber. Pushing out air into the pneumatic chamber results in movement of the membrane downward. This state corresponds to the ejection of fluid from the blood chamber.

Fig. 2 The cross-section of the extracorporeal pneumatic heart assist pump model

The opposite process causes the rising of the membrane and filling bloody chamber with liquid.

Using a flaccid membrane in the pneumatic heart assist pump, even though raises many problems, is necessary from a medical point of view. Such a membrane limits the formation of coagulation and eliminates the problem of sedimentation of blood (dividing into fractions).

#### IV. MEASUREMENT METHOD

The essence of the used measurement method is to observe a surface of the membrane at a close distance with a fixed-focus camera equipped with wide-angle lens and to determine the shape of this membrane in the 3-dimensional space on the basis of a one-shot image.

In the measurement process the image processing and analysis techniques are used. Firstly, the image is acquired from the camera. Next, the image is masked using a circle mask in order to hide unnecessary parts of the image. Then the image segmentation using thresholding is performed. After that, markers are detected. This method works due to markers (in the study, round white markers with a diameter of 3 mm) arranged on the surface of the membrane from the pneumatic chamber side. During the membrane movement the markers do not change their physical size. Their smaller or larger surface area visible in the image is related only to their proximity or distance from the front of the camera. On the basis of pixel coordinates and a surface area of each marker we can determine their location in the 3-dimensional space. Having the determined several dozen markers, the same number of real points on the membrane surface can be obtained. Other points, in the required quantity, are determined using triangulation-based cubic interpolation.

As a result, a grid representing the membrane shape of the artificial ventricle in the actual dimensions is obtained. This method is very fast by the fact that during measurement the position of the camera and all lens and camera settings (focus, aperture and focal length) remain unchanged.

#### V. THE DIMENSIONS OF THE MEMBRANE

The difficulty of determining the real membrane shape of the heart assist pump fitted with a flaccid membrane, Fig. 3, is that the pump has only two membrane states with a known mathematical description. The first state occurs when the blood chamber is fully submerged with blood; the membrane then takes on a convex shape. The second state occurs with full blood pressure from the heart pump; the membrane then takes on a concave shape.

Fig. 3 The flaccid membrane

Fig. 4 The geometric dimensions of the spherical cap

In both these states the membrane takes on a shape of the spherical cap, Fig. 4. For these characteristic states the geometric dimensions can be determined because a few parameters of the pump designed in the framework of PSS are given. The radius of the spherical cap  $a$  equals 35 mm. The volume of this spherical cap  $V$  equals 35 ml and this is a half of 70 ml which is the assumed stroke volume of a heart for an adult man. With the known radius of the spherical cap the geometrical dimensions of the membrane on the X-Y plane are known. To determine the extreme positions of the membrane in the Z-axis the value of  $h$  is required. It can be determined on the basis of the formula (1) and after solving the equation (2).

$$V = ((\pi h^2)/3) \cdot (3R - h) \quad (1)$$

$$h^3 + 3a^2h - 6V/\pi = 0 \quad (2)$$

The calculated value of  $h$  equals 16.8803 mm. Having values of  $a$  and  $h$  the all extreme positions of the membrane in the 3-dimensional space are known.

#### VI. TRANSFORMATION OF THE X- AND Y-COORDINATES

The transformation of the x- and y-coordinates is performed directly based on the pixel coordinates of the image, Fig. 5.

Fig. 5 View of the membrane from camera with the coordinate system added

For transformation purpose, the 2-dimensional shape of the membrane determined in pixels is calculated using a linear transformation for the x-coordinate (3) and for the y-coordinate (4).

$$X = [(x - x_0)/(2 \cdot r)] \cdot (X_{max} - X_{min}) \quad (3)$$

$$Y = [(y_0 - y)/(2 \cdot r)] \cdot (Y_{max} - Y_{min}) \quad (4)$$

In the study, a 900 px x 900 px image, masked by a circle of a radius  $r = 410$  px, is calculated to a range from -35 mm to 35 mm, assuming that the centre of the scale is in the centre of the membrane. For the givens:

$$r = 410 \text{ px}, \quad x_0 = 450 \text{ px}, \quad y_0 = 450 \text{ px},$$

$$X_{max} = Y_{max} = 35 \text{ mm}, \quad X_{min} = Y_{min} = -35 \text{ mm}$$

We obtain the simplified linear transformation equations:

$$X = 0.08537 \cdot x - 38.4146 \text{ [mm]} \quad (5)$$

$$Y = -0.08537 \cdot y + 38.4146 \text{ [mm]} \quad (6)$$

The equations (5) and (6) can be used to the transformation of the x- and y-coordinates from pixels to millimetres. So far a grid defined in such a way presents the determined shape of the membrane dimensioned in the actual 2-dimensional space.

## VII. TRANSFORMATION OF THE Z-COORDINATE

The transformation of the z-coordinate is not performed directly based on the pixel coordinates of the image. To solve the problem, the dependency of the marker area from a distance of the marker to the front of the camera must be determined. This dependency is not constant even for the same artificial ventricle model and will vary due to various factors. The camera and lens parameters, the type of lighting, the threshold value, size and colour of markers, kind of surface and colour of the membrane can affect this relationship. Trial tests confirmed that depending on the mentioned factors, different values of the marker area in the image can be obtained for the same distance. This applies in particular to the central marker which, due to its location, can achieve the largest and the smallest possible surface area in the image and thus determines the extreme values in the Z-axis. Simultaneously it can observe that during changing

Fig. 6 The measurement pattern designed in CAD software

Fig. 7 The ready-made measurement pattern

working conditions of the heart pump, the proportion of the changes of a surface area of the markers at different distances remains constant. This leads to the conclusion that the differences between the markers area at different distances can have a linear character. In order to verify this hypothesis the suitable measurement pattern was designed, Fig. 6. This takes the form of steps of well-known heights. The 3 mm difference between steps (except the extremes) was assumed. The pattern also allows to compare the measurement results with the reference distances of each marker to the front of the camera optical sensor; e.g. for the calibration purpose. The measurement pattern was designed in CAD software. Then it was 3D printed with an accuracy of 0.001 mm on the X and Y axes with a layer thickness on the Z-axis of 0.09 mm, Fig. 7. On the steps of the pattern 14 round, white, markers having a diameter of 3 mm were arranged, one on each step.

For the study, a laboratory stand was designed and built. Different parts of the stand were printed on a 3D printer. After assembly a stable structure was created eliminating random movements and changes in camera viewing angles with respect to the membrane or the pattern in each of the spatial dimensions, Fig. 8. The station allows for quick and easy replacement of the tested membranes or patterns. It is equipped with a miniature monochrome XIMEA camera model MU9PM-MH with a lens with a fixed focal length  $f = 1.8$  mm and a viewing angle of  $126^\circ$ . The camera is connected to a computer using a USB 2.0 port interface. This is completed with the authors' software, which enables measurement and enables real-time imaging.

Fig. 8 The laboratory stand with the measurement pattern

Fig. 9 View of the measurement pattern from camera with detected markers

The pattern was mounted into the laboratory station and the measurement procedure was performed, Fig. 9. The measurement was conducted in three different conditions changing lighting parameters and the threshold value. The obtained values of a surface area of the detected markers for all three cases have been collected in Table I. At the same time, a surface area of all markers at different heights was determined. The height (distance) equal to 0 was assumed on the level of the outline of a circular membrane. The image sharpness was set on this level focusing on the central marker. For a distance greater than 0 (a height less than 0), the appropriate negative value was assumed.

TABLE I.

-16.8803	954	744	349

where E.  $n$  is a number ( $n$ ) of experiment

Fig. 10 Graphs of the dependency of the marker area from the height

The results confirmed that the differences between the markers area at different distances have a linear character. However, the graph of the dependency of the marker area from the height, Fig. 10, shows that two separate dependencies are needed for each case. The approximation of results shown that for the  $z$ -coordinate transformation purpose, it is not necessary to determine a dependency of the marker area from the distance for all possible values, but is enough to measure only two extremes and to know a value of zero from the calibration. This should significantly simplify the sensor calibration and to allow making necessary corrections even during normal operation of the pneumatic heart assist pump.

Assuming that  $A_z$  is a surface area of the current marker,  $A_{zero}$  is a surface area of the central marker on the level of the outline of a circular membrane,  $A_{top}$  is a surface area of the central marker for the membrane in the maximum upper position and  $A_{bottom}$  is a surface area of the central marker for the membrane in the maximum down position, the equations (7 – 9) for the  $z$ -coordinate were determined.

$$z = A_z - A_{zero} \quad (7)$$

$$Z = (z \cdot Z_{max}) / (A_{top} - A_{zero}) \quad \text{for } z \geq 0 \quad (8)$$

$$Z = (z \cdot Z_{min}) / (A_{bottom} - A_{zero}) \quad \text{for } z < 0 \quad (9)$$

In the study, for the givens:

$$A_{top} = 6156 \text{ px}, \quad A_{zero} = 1439 \text{ px}, \quad A_{bottom} = 954 \text{ px},$$

$$Z_{max} = 16.8803 \text{ mm}, \quad Z_{min} = -16.8803 \text{ mm}$$

We obtain the simplified linear transformation equations:

$$Z = 0.00358 \cdot A_z - 5.1496 \text{ [mm]} \quad \text{for } A_z \geq 1439 \quad (10)$$

$$Z = 0.0348 \cdot A_z - 50.0843 \text{ [mm]} \quad \text{for } A_z < 1439 \quad (11)$$

The equations (10) and (11) can be used to the transformation of the  $z$ -coordinate. Finally, using also the previously determined equations (5) and (6), a grid defined in such a way presents the determined shape of the membrane dimensioned in the actual 3-dimensional space.

Fig. 11 The ideal shape of convex membrane in the actual dimensions

### VIII. RESULTS OF RESEARCH

Knowing the suitable transformation equations, the shape of the flaccid membrane of the extracorporeal pneumatic heart assist pump model in the actual dimensions was possible to determine. Firstly, the ideal shapes of convex and concave membrane, Fig. 11 and Fig. 12, in the actual dimensions were determined based on the geometric dimensions of the spherical cap. Then the full measurement procedure was performed for these extreme positions of the membrane, Fig. 13 and Fig. 14. As a result, it was possible to obtain the shape mapping of the membrane in the form of a measuring grid and determining for each point of the grid a reference value. With these two values the measurement errors could be determined and their causes analyzed. Obtained from the measurements, mappings of a shape of convex and concave membrane, Fig. 15 and Fig. 16, in the actual dimensions have confirmed a propriety of the determined transformation equations.

On the surface of the membrane 49 round, white, markers having a diameter of 3 mm were arranged. The study assumed an even distribution of markers forming squares. The distance between the centres of the neighbouring markers was 7.7 mm. Markers were placed starting from the

Fig. 12 The ideal shape of concave membrane in the actual dimensions

Fig. 13 View from camera of convex membrane with detected markers

central marker. Analyzing the results, deformation of the membrane shape around the markers' positions is noticeable. This is due to the interpolation that is used to calculate values between markers.

In the case with a convex membrane the mapping of the membrane shape is appropriate. The achieved shape, almost on the entire surface, is comparable to that of the ideal membrane. For the concave membrane the mapping of the membrane assumes the correct shape of a spherical cap. The greatest errors were obtained for the markers, which are far from the centre of the membrane.

In both cases difference between all of the measurement values and their reference values does not exceed 5%. The shape of the projection is subject to the smallest error in the vicinity of the central marker. The biggest inaccuracy was obtained for markers which position was close to the edge of the membrane. This effect is mainly due to insufficient number of markers located at these places.

Fig. 16 The mapped shape of concave membrane from the measurements

## IX. CONCLUSION

The paper presents a method of the membrane shape mapping of the extracorporeal pneumatic heart assist pump in the actual dimensions. This method can be used to transform results in pixels to dimensions in the real world in millimetres. This was a continuation of works on the use of image processing and analysis techniques for calculating the stroke volume of an artificial ventricle.

In the study the appropriate equations to transformation of the x-, y- and z-coordinates were analyzed and determined. These equations allow the user to obtain a measurement grid which represents the shape of the membrane dimensioned in the actual 3-dimensional space.

The usefulness of the determined transformation equations was confirmed by the conducted measurements for two extreme states of the membrane.

The developed method will enable to determine the stroke volume of the artificial ventricle using the numerical integration method.

# Selective Image Authentication Using Shearlet Coefficients Tolerant to JPEG Compression

Aleksei Zhuvikin

Department of Secured Communication Systems,  
The Bonch-Bruевич Saint Petersburg State University of Telecommunications  
Saint-Petersburg, Russia  
Email: zhuvikin@ya.ru

**Abstract**—A novel selective image authentication system based on the robust digital watermarking is proposed. The discrete shearlet transform is performed in order to extract the feature vector from the image. The cone-adapted version of the transform is used to calculate the shearlet coefficients more precisely and to avoid the biased treatment. The proposed approach allows to use conventional cryptographic digital signature for the image feature vector verification and makes the authentication scheme more secure. In order to embed watermark (WM) into the image the areas HL3 and LH3 of the Haar wavelet transform coefficients are used. Experimental results show that the proposed selective image authentication system is effective in terms of tolerance to JPEG compression, malicious image tampering detection and visual image quality just after embedding.

**Index Terms**—Digital images; selective image authentication; cone-adapted shearlet transform; JPEG; 3-bit hash quantization; Haar-wavelet transform.

## I. INTRODUCTION

AN authentication of digital objects is widely applicable and is commonly used nowadays. The primary aim of this procedure is a saving of data integrity and a confirmation of the truth. Regarding to the digital images and other multimedia kinds of content, there are no problems to perform a content verification in a case of strict authentication type. This definition of the problem assumes that the data integrity is broken even if only one data bit had been changed. Several methods are well known for authentication within cryptography, e. g. digital signature (DS) [1]. The only limitation is that DS is appended to the object itself and can be corrupted or even lost in case of incautious use. As an alternative approach a *digital watermarking* [2] for image content authentication can be applied. There are practical applications implying to keep image exactly as it is. For example, if medical image would contain compression artefacts this could lead to wrong diagnostics. This issue is usually solved with conventional cryptography by *strict image authentication* [3], [4]. However, strict image authentication methods are not applicable in the fields where a certain set of the content manipulations is assumed to be acceptable. So called *selective image authentication* manages to solve this task [2].

A selective image authentication is a well known problem and is a point of interest of many works [5]–[10]. Usually an image compression is classified as a legal image manipulation

since it doesn't change image content, and thus should not break in an authentication. In the proposed method we primarily focus on the tolerance to JPEG compression algorithm [11] for its wide application in legal image processing.

Image features extraction techniques of the most advanced proposed methods for selective image authentication use the following types of the image preprocessing. Method based on the key-points features extraction is presented in [5]. The several algorithms use the image moments calculation [6], [7], content describing by using of wavelet coefficients [8], central-finite differences [9], ridgelet and radon transforms [10], etc. In this paper we present a novel selective image authentication method which uses *shearlet transform coefficients* [12] as an image content descriptor. Recent investigations [13] show that shearlet coefficient properties are well suited for this purpose as a face and pattern recognition. Due to the fact that shearlets are able to describe considered signal in details and sparsely [12] it is reasonable to involve these properties to the problem of selective image authentication. We show that some of the shearlet coefficients are tolerant to JPEG compression and, on the other hand, are sensitive to the image content modifications. Due to the usage of 3-bit quantization technique the extracted image features can be signed and embedded in the image as a digital watermark (WM). Any algorithm robust to JPEG compression can be chosen as a watermark embedding method. We use 3-level *Haar wavelet transform* [14] for watermarking embedding that provides acceptable visual quality just after embedding.

Section II of the paper presents the main properties of discrete shearlet transform and explains the feature vector calculation technique. 3-bit quantization method is covered in Section III. The usage of the embedding and extraction algorithms is considered in Section IV. The simulation results are presented in Section V followed by conclusions in Section VI.

## II. CONE-ADAPTED DISCRETE SHEARLET TRANSFORM AND IMAGE FEATURES EXTRACTION

The shearlet transform was introduced in 2006 [12] for the mathematical analysis of anisotropic features of the multivariate signals. Being a generalisation of wavelets, shearlets provide sparse representations for the large class of multidimensional data by given dilation, shear and translation parameters. We propose shearlet transform to be used for image features

$$\mathcal{SH}_{j,k,m}(I) = \begin{cases} \mathcal{F}^{-1}(\phi(\omega_1, \omega_2) I(\omega_1, \omega_2)) & |\omega_2| < 1, |\omega_1| < 1, \\ \mathcal{F}^{-1}(\psi(4^{-j}\omega_1, 4^{-j}k\omega_1 + 2^{-j}\omega_2) I(\omega_1, \omega_2)) & |\omega_1| \geq 1/2, |\omega_2| < |\omega_1|, |k| \leq 2^j - 1, \\ \mathcal{F}^{-1}(\psi(4^{-j}\omega_2, 4^{-j}k\omega_2 + 2^{-j}\omega_1) I(\omega_1, \omega_2)) & |\omega_1| \geq 1/2, |\omega_2| > |\omega_1|, |k| \leq 2^j - 1 \\ \mathcal{F}^{-1}(\psi^{h \times v}(4^{-j}\omega_1, 4^{-j}k\omega_1 + 2^{-j}\omega_2) I(\omega_1, \omega_2)) & |\omega_1| \geq 1/2, |\omega_2| \geq 1/2, |\omega_1| = |\omega_2|, |k| = 2^j. \end{cases} \quad (3)$$

Fig. 1. Used notations of the calculation cone-areas  $C_v$ ,  $C_h$ , seams  $C_x$  and the middle cap  $C_0$  in the frequency domain defined by the discrete cone-adapted shearlet transform.

calculation procedure. As it will be shown in Section V some of the shearlet transform coefficients are robust to introduce small image noise, wherein allow to describe image content quite enough. Let describe briefly the main features of the shearlet transform and it's algorithmic efficient digital version that was introduced in [15].

For  $\psi \in L^2(\mathbb{R}^2)$  the continuous shearlet system generated by  $\psi$  is defined as  $\{\psi_{a,s,t} = a^{-\frac{3}{4}}\psi(A_a^{-1}S_s^{-1}(x-t)) \mid a > 0, s \in \mathbb{R}, t \in \mathbb{R}^2\}$ . Functions  $\psi_{a,s,t}$  are called shearlets where dilation  $a$  and shear  $s$  parameters determine dilation  $A_a$  and shear  $S_s$  matrices respectively as [15]

$$A_a = \begin{pmatrix} a & 0 \\ 0 & \sqrt{a} \end{pmatrix}, \quad a \in \mathbb{R}^+$$

and  $S_s = \begin{pmatrix} 1 & s \\ 0 & 1 \end{pmatrix}, \quad s \in \mathbb{R}.$

Then, corresponding continuous shearlet transform is given by mapping

$$\begin{aligned} f &\rightarrow \mathcal{SH}_\psi f(a, s, x) = \langle f, \psi_{a,s,x} \rangle, \\ f &\in L^2(\mathbb{R}^2), (a, s, t) \in \mathbb{R}_{>0} \times \mathbb{R} \times \mathbb{R}^2. \end{aligned} \quad (1)$$

So, the values of shearlet coefficients can be found as a convolution of  $f$  with shearlet functions  $\psi_{a,s,t}$  [12]

$$\mathcal{SH}_\psi f(a, s, x) = \int_{\mathbb{R}^2} f(t) \psi_{a,s,t}(x-t) dt = f * \psi_{a,s,t}(x).$$

For we need to use discrete version of the shearlet transform (1), we consider only digital images  $\mathbb{R}^{M \times N}$  as functions sampled on the grid  $\{(\frac{m_1}{M}, \frac{m_2}{N}) : (m_1, m_2) \in \mathcal{G}\}$  with  $\mathcal{G} = \{(m_1, m_2) : m_1 = 0, \dots, M-1, m_2 = 0, \dots, N-1\}$  and periodic continuation over the boundary is assumed. However, due to the known problem of biased treatment of directions cone-adapted version of the discrete shearlet transform is commonly used [15]. In this calculation technique, frequency domain is divided into the cones that are shown in the Figure 1 where  $C_x$  is the cone seam line,  $C_v$  and  $C_h$  represent vertical and horizontal cones of the frequency bands and  $C_0$  is the low-frequency component. The main part of the signal energy is contained in the low-frequency region whereas the bands around represents high-frequency parts.

We define auxiliary functions  $\chi_\kappa, \kappa \in \{x, v, h\}$  equal to 1 for coordinates  $(\omega_1, \omega_2)$  which are in the areas  $C_\kappa$ , i.e.  $(\omega_1, \omega_2) \in C_\kappa$  and equal to 0 for  $(\omega_1, \omega_2) \notin C_\kappa$ . In this notation the cone-adapted version of discrete shearlet transform is the mapping

$$\begin{aligned} I &\rightarrow \mathcal{SH}_\psi I(j, k, m) = \langle I, \psi_{j,k,m} \rangle, \\ (j, k, m) &\in \mathbb{R}_{>0} \times \mathbb{R} \times \mathbb{R}^2 \end{aligned} \quad (2)$$

where  $j \in \mathbb{Z}, 0 \leq j < \lfloor \frac{1}{2} \log_2 \max\{M, N\} \rfloor$  and  $k \in \mathbb{Z}, -2^j \leq k \leq 2^j$  are the discrete versions of the dilation and shear parameters,  $I(m) = I(m_1, m_2) \in L^2(\mathbb{R}^2)$  is the function of the  $\{M, N\}$ -dimensioned discrete image with translation parameter  $m = (m_1, m_2) : m_1 = 0, \dots, M-1, m_2 = 0, \dots, N-1$ . By means of the cone-adapted scheme the coefficients  $\mathcal{SH}_{j,k,m}(I)$  of the shearlet transform can be obtained similarly to (3) [15], where  $(\omega_1, \omega_2)$  are the coordinates  $(m_1, m_2)$  mapped to the frequency domain,  $\mathcal{F}^{-1}(g(\omega_1, \omega_2))$  is the inverse two-dimensional discrete Fourier transform [16] of function  $g(\omega_1, \omega_2)$  and

$$\begin{aligned} \psi^{h \times v}(\omega_1, \omega_2) &= \psi_1(\omega_1, \omega_2) \chi_x + \\ \psi_1(\omega_1) \psi_2\left(\frac{\omega_2}{\omega_1}\right) \chi_h &+ \psi_1(\omega_2) \psi_2\left(\frac{\omega_1}{\omega_2}\right) \chi_v, \end{aligned} \quad (4)$$

$$\psi(\omega_1, \omega_2) = \psi_1(\omega_1) \psi_2\left(\frac{\omega_2}{\omega_1}\right), \quad (5)$$

where  $\psi_1, \psi_2$  and  $\phi$  are the predefined scaling functions. In the proposed method we use Meyer's wavelet-based functions for (3)-(5) that can be chosen as in [15].

The frequency tiling that represent different directions and scales of the shearlets up to  $j = 1$  and low-pass band with correspondent values of parameters  $(j, k)$  are shown in the Figure 2.

In the proposed method, we use only (1, 1), (1, 3), (1, 5) and (1, 7) frequency bands (that are highlighted in the Figure 2)

for the image feature vector calculation due to the following reasons. These bands have tolerance to the introduced small image noise as well as to JPEG compression. On the other hand, it was found that chosen bands are sensitive to image content modifications and malicious image tampering. It is worth to note, that the more scale parameter is selected, the more sensitivity to image modifications is achieved and, at the same time, the less tolerance to the JPEG compression is observed. Our experiments showed that scale parameter  $j = 1$  is a good candidate for the trade-off between noise sensitivity and malicious tampering detection. Secondly, we choose bands with dilation indices  $k \in \{1, 3, 5, 7\}$  just to insure to proposed image feature vector be more sparse and occupy less memory space.

Due to the considerations above, let us define four vectors  $d_{\mathcal{H}_k}$  of used shearlet coefficient amplitudes

$$d_{\mathcal{H}_k} = (\|\mathcal{SH}_{j,k,m}(I)\|)_{j=1, m \in \mathcal{G}}, \quad k \in \{1, 3, 5, 7\}. \quad (6)$$

Elements  $d_{\mathcal{H}_k}$  can be calculated according to (3) for given image  $I$ . In order to compress image features up to available size we propose to use *average downsampling* technique [17] with integer parameter  $h$ , divisor of  $M \times N$ :  $\forall(i) \in \{1, \dots, \frac{M \times N}{h}\}$  as follows

$$d_k(i_k) = \frac{1}{h} \sum \{d_{\mathcal{H}_k}(m) \mid h(i_k - 1) < m \leq hi_k\}$$

Finally, we define *image feature vector*  $d \in \mathbb{R}^L$  as

$$d = (d(i))_{i=1}^L = \left( \bigcup_{k \in \{1, 3, 5, 7\}} d_k(i) \right)_{i=1}^{\frac{M \times N}{h}}, \quad L = \frac{4(M \times N)}{h} \quad (7)$$

Calculated by (7) image feature vector  $d$  gives the compact representation of the image features. However, coordinates of the image feature vector  $d$  are the real numbers and they should be digitised before signing and embedding into the image as WM.

### III. RECOVERING OF IMAGE FEATURE VECTOR AFTER JPEG COMPRESSION BY 3-BIT QUANTIZATION TECHNIQUE

Digital watermarking techniques expect that data to be embedded have the binary form and of a finite length. Also, as we mentioned in the Section II, in order to apply digital signature to the image feature vector (7) it should be pre-digitized.

Let quantize the values of  $d$  with step  $\Delta \in \mathbb{R}$  called *image features quantization parameter* as

$$d_{\Delta}(i) = \left\lfloor \frac{d(i)}{\Delta} \right\rfloor + 1 \quad (8)$$

where  $\lfloor \cdot \rfloor$  is the floor map.

Now, it would be possible to authenticate the tested image  $(\tilde{I}(m))_{m \in \mathcal{G}}$ , given the embedded vector  $d_{\Delta}$  and the corresponding vector  $\tilde{d}_{\Delta}$  calculated for the image  $(\tilde{I}(m))_{m \in \mathcal{G}}$ .

Fig. 2. Frequency tiling and respective notations with parameters  $(j, k)$  and the low-pass band (LP). Bands used for the feature vector calculation in the proposed method are highlighted.

Then, the following condition should be taken for the authentication rule

$$(\tilde{I}(m))_{m \in \mathcal{G}} \text{ is authentic} \iff \max_i |\tilde{d}_{\Delta}(i) - d_{\Delta}(i)| \leq 1. \quad (9)$$

However, the use of the authentication rule (9) is inconvenient for two reasons. First, the size of the authenticator  $d_{\Delta}$  is large enough to be embedded into the image without significant corruption. Second, any adversary might be able to forge the authentication process because no cryptographic technique was used. In order to overcome the difficulties mentioned above, we propose to hash the feature vector  $d_{\Delta}$  and to obtain its digital signature. On the other hand, hashing the vector  $d_{\Delta}$  after its corruption by JPEG compression leads to error expansion. In order to recover  $d_{\Delta}$ , after jumps of their coordinates in at most one quantization level, it is possible to use so called *3-bit quantization* technique [18] briefly considered below.

Let introduce an *auxiliary perturbation vector*  $p$  of dimension  $L$  where its  $i$ -th coordinate contains three bits  $p_{1i}, p_{2i}, p_{3i}$  computed as follows [18]

$$(p_{1i}, p_{2i}) = [d_{\Delta}(i) \bmod 4]_2 \quad (10)$$

$$p_{3i} = \begin{cases} 1 & \text{if } d(i) \in [a_i, b_i) \\ 0 & \text{if } d(i) \in [b_i, a_{i+1}) \end{cases} \quad (11)$$

with  $a_i = \Delta d_{\Delta}(i)$ ,  $b_i = \Delta (d_{\Delta}(i) + \frac{1}{2})$ , and  $[\cdot]_2$  the binary representation of the integer argument. An example mapping of the value  $d(i)$  into the bits  $p_{1i}, p_{2i}, p_{3i}$  and  $d_{\Delta}(i)$  is illustrated in the Figure 3.

Then the digest of vector  $d_{\Delta}$  by means of any convenient hash function can be calculated. The obtained hash is signed with the use of cryptographic DS [1] and then this DS is embedded jointly with the auxiliary perturbation vector  $p$  into the image  $I$ . Verification of DS is performed by conventional cryptographic methods, where it is necessary to recover the

Fig. 3. An example mapping of the value  $d(i)$  into the bits  $p_{1i}, p_{2i}, p_{3i}$  and  $d_{\Delta}(i)$  by means of 3-bit quantization technique.

feature vector  $\tilde{d}_{\Delta}$  only, which corrupted possibly by JPEG compression of the original feature vector  $d'_{\Delta}$ . This can be performed as follows [18]

$$d'_{\Delta}(i) = \left\lfloor \frac{d'_{\Delta}(i)}{\Delta} \right\rfloor \quad (12)$$

where

$$d'_{\Delta}(i) = \begin{cases} \tilde{d}(i) + \Delta & \text{if } \alpha_i = 0 \text{ \& } \tilde{p}_{3i} = 0 \\ \tilde{d}(i) + \Delta & \text{if } \alpha_i = 0 \text{ \& } \tilde{p}_{3i} = 1 \text{ \& } p'_{3i} = 1 \\ \tilde{d}(i) - \Delta & \text{if } \alpha_i = 1 \text{ \& } \tilde{p}_{3i} = 1 \\ \tilde{d}(i) - \Delta & \text{if } \alpha_i = 1 \text{ \& } \tilde{p}_{3i} = 0 \text{ \& } p'_{3i} = 0 \\ \tilde{d}(i) & \text{otherwise} \end{cases}$$

and

$$\alpha_i = \begin{cases} 0 & \text{if } [p'_{1i} p'_{2i}]_{10} = ([\tilde{p}_{1i} \tilde{p}_{2i}]_{10} - 1) \bmod 4 \\ 1 & \text{if } [p'_{1i} p'_{2i}]_{10} = ([\tilde{p}_{1i} \tilde{p}_{2i}]_{10} + 1) \bmod 4 \\ 2 & \text{otherwise} \end{cases} \quad (13)$$

Here  $[\cdot]_{10}$  is the decimal representation of the binary integer;  $(\tilde{p}_{1i}, \tilde{p}_{2i}, \tilde{p}_{3i})$  are the three bits of each entry  $\tilde{p}_i$  of the perturbation vector  $\tilde{p}$  extracted as a WM, and  $(p'_{1i}, p'_{2i}, p'_{3i})$  are obtained from the perturbation vector  $p'$  calculated by (10), (11) given by the corrupted image  $(\tilde{I}(m))_{m \in \mathcal{G}}$ ;  $\tilde{d}(i)$  is the  $i$ -th element of the feature vector given by (8) and the image  $(I(m))_{m \in \mathcal{G}}$  is the original one before recovering.

It has been proved in [18] that the feature vector  $\tilde{d}_{\Delta}$  can be recovered exactly by (12)–(13) if the extracted auxiliary perturbation vector  $\tilde{p}$  is correct and rule (9) is achieved. This rule will be fulfilled if a corruption of the quantized feature vector coordinates  $\tilde{d}_{\Delta}(i)$  have transitions to at most one neighbour quantization level. In this case the proposed authentication method will be tolerant to JPEG compression if the quantization step was chosen in such a way that the last requirement holds with the high probability. Clearly, the method of embedding and extraction is also assumed to be robust to JPEG compression.

#### IV. WATERMARKING METHOD BASED ON 3-LEVEL HWT COEFFICIENTS QUANTIZATION

In this section we consider a digital watermarking method providing acceptable error probability of both feature vector signature and auxiliary perturbation vector. An authentication

Fig. 4. Notations of 3-level Haar wavelet transform coefficients submatrices. The used HWT areas LH3 and HL3 are highlighted.

data, that is usually briefly called *authenticator* [2], is embedded into the image with one of the existing watermarking techniques. Authenticator of the proposed method consists of both feature vector  $d$  signature and the auxiliary perturbation vector  $p$  have been explained in the Section III. There are several necessary properties for the embedding algorithm for the proposed selective image authentication system namely

- tolerance to JPEG compression;
- capacity that is enough for both  $d$  and  $p$ ;
- lower computational complexity; and
- high visual quality of the watermarked image right after embedding.

Taking into account the requirements presented above, the embedding algorithm based on coefficients quantization of 3-level discrete *Haar Wavelet Transform* (HWT) [14] was selected. Only LH3 and HL3 submatrices for WM embedding were chosen because of their robustness to small noises that can be introduced by JPEG compression. According to the experimental results, the coefficients of LL3 which have more evident influence on visual image quality after embedding whereas second level coefficients are less tolerant to JPEG compression. So, in this method, LH3 and HL3 areas are selected as a compromise. Let assume for simplicity that the DI is square of order  $2^l \times 2^l$ . Note that if the image  $I$  is not represented by a square matrix then it can be padded with zero elements. According to [14], two-dimensional forward and inverse HWT of the square image luminance values  $(2^l \times 2^l)$ -matrix of the image  $I$  can be found as:

$$S_H = H_l I H_l^T, \quad I = H_l^T S_H I, \quad (14)$$

where  $l$  is the level of HWT,  $S_H$  is the matrix of the HWT coefficients, and the upper index  $T$  denotes matrix transposition. The recurrent relations [14]

$$H_0 = [1], \quad H_l = \frac{1}{\sqrt{2}} \begin{bmatrix} H_{l-1} & H_{l-1} \\ H_{l-1} & -H_{l-1} \end{bmatrix}, \quad l \in \mathbb{Z}^+$$

Fig. 5. Dependencies of PSNR and SSIM image quality measures just after WM embedding against HWT coefficients quantization parameter  $\gamma$ .

determine the  $(2^l \times 2^l)$ -Haar single level matrices  $H_l$ . The next level  $l$  of HWT can be obtained if, the  $(2^{l-1} \times 2^{l-1})$ -submatrix of HWT approximation coefficients is used instead of the original image  $I$ . Figure 4 shows the 3-level HWT coefficients submatrices with conventional notations and the used HWT areas LH3 and HL3 as highlighted ones.

We chose only LH3 and HL3 coefficients as they represent low-frequency components of the image and have explicit robustness to the distortions introduced by JPEG compression, see Figure 5. The used approach allows to minimize DI corruption after embedding. The general scheme of proposed selective image authentication method including embedding and extraction procedures with correspondent notations is presented at Figure 6.

The quantized feature vector  $d_\Delta$  is hashed and signed by any standard cryptographic algorithm [1] giving strong digital signatures  $s$ . Next, this DS and perturbation vector  $p$  is concatenated into one binary string  $b$ . In order to increase efficiency of authentication data transferring in the presence of corrupting noise *Low-Density Parity-Check* (LDPC) code [19] was applied. Encoded block  $b_e$  represented by digits  $b_{e_k}$  is embedded into the coefficients  $S_k$  belonging to HWT areas HL3 and LH3 (Figure 4) by the following rule:

$$\tilde{S}_k = \begin{cases} \gamma \left( \left\lceil \frac{S_k}{\gamma} \right\rceil + \frac{1}{4} \right) & \text{if } b_{e_k} = 1 \\ \gamma \left( \left\lceil \frac{S_k}{\gamma} \right\rceil - \frac{1}{4} \right) & \text{if } b_{e_k} = 0 \end{cases} \quad (15)$$

where  $\gamma$  is the quantization interval of HWT coefficients,  $\lceil \cdot \rceil$  is the nearest integer of a real number, and  $\tilde{S}_k$  is the coefficient after embedding the bit  $b_{e_k}$ . In order to complete embedding procedure an inverse HWT is performed by (14) using quantized coefficients from (15).

An obtained watermarked image  $\hat{I}$  is then sent through insecure channel and is possibly have been forged by an attacker

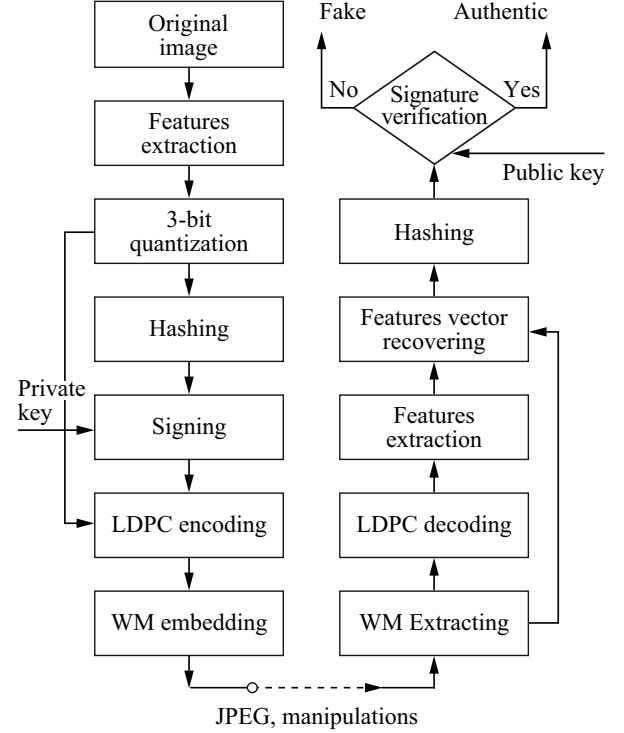

Fig. 6. General scheme of the proposed selective image authentication method.

or have been processed using non-malicious manipulations. In order to verify that DS is authentic, see Figure 6, it is necessary to take a decision  $\tilde{b}_{e_k}$  regarding the digits of the binary string  $b_e$  using the decision rule

$$\tilde{b}_{e_k} = \begin{cases} 1 & \text{if } \tilde{S}_k - \gamma \left\lceil \frac{\tilde{S}_k}{\gamma} \right\rceil \geq 0, \\ 0 & \text{if } \tilde{S}_k - \gamma \left\lceil \frac{\tilde{S}_k}{\gamma} \right\rceil < 0. \end{cases} \quad (16)$$

Here  $\tilde{S}_k$  are the coefficients  $S_k$  of areas HL3, LH3 that might be corrupted by some image processing. Decoding of received code word  $\tilde{b}_e$  is performed with *iterative belief propagation* technique [20].

The elements of the perturbation vector  $\tilde{p}$  are extracted from decoded data using (16) and the vector  $p'$  calculated directly from the image by (10), (11), and then recover  $d'_\Delta$ , given the vectors  $\tilde{d}_\Delta$ ,  $\tilde{p}$  and  $p'$ . Then the recovered vector  $d'_\Delta$  is hashed to  $h'$  and compared with the hash  $\tilde{h}$  obtained from the DS  $\tilde{s}$  with use of the corresponding public key. If  $h' = \tilde{h}$  then DI is recognized as authentic, otherwise it is assumed as a fake one.

## V. EVALUATION OF EFFECTIVENESS OF PROPOSED SELECTIVE IMAGE AUTHENTICATION

In this paper we focus ourselves on JPEG compression related to the set of manipulations that not change an image content. Thus, it is necessary to investigate the sensitivity of the authentication system to JPEG compression. The proposed

Fig. 7. Dependencies of the  $P_{\text{TPR}}$  against JPEG compression quality factor  $Q$  depending on the different feature vector quantization parameters  $\Delta$ .

Fig. 8. Dependency of the required value of feature vector quantization parameter  $\Delta$  against JPEG compression quality factor  $Q$  that gives  $P_{\text{TPR}} = 100$  over the test image base.

method will be tolerant to such compression if the rule (9) is met. We have selected 100 different  $512 \times 512$  DI having varied content, textures and so forth. Then the HL3 and LH3 areas of HWT contains  $2 \times (2^6)^2 = 2^{13} = 8192$  coefficients. According to the rule (15), each HWT coefficient allows to embed one bit.

As we mentioned before, in order to provide some redundancy, the length of the feature vector  $d$  was  $2^{10} = 1024$  corresponding to the length of  $2^8 = 256$  of the matrix  $b_k$ . This requires  $h = 2^{10} = 1024$  in (6). Thus, the auxiliary perturbation vector  $p$  has  $3 \times 2^{10} = 3072$  bits length. As a hash function, the standard SHA-2 [1] and the DS algorithm based on RSA cryptosystem [1] with length of modulo 1024 bits were used. The total size of the embedded bits is  $3072 + 1024 = 4096$ . Given the total number of HWT coefficients in HL3 and LH3 areas it was chosen the (8192, 4096)-LDPC code to achieve appropriate error correction.

It is worth to note, that proposed selective image authentication framework allows one to choose any other hash, digital signature and error correcting algorithms which are suitable for the available watermark capacity. After the selection of the main parameters, the investigation of the authentication system efficiency was carried out. Figure 7 shows the dependencies of the True Positive Rate  $P_{\text{TPR}}$  against JPEG compression quality factor  $Q = 0, 1, \dots, 12$  depending on the different feature vector quantization parameters  $\Delta$  used in the formation of  $d_\Delta$  by (8).

It can be seen from Figure 8 that the greater is the Quality

Fig. 9. Dependencies of the  $P_{\text{TNR}}$  against the size  $\rho$  of malicious image tampering areas depending on the different feature vector quantization parameters  $\Delta$ .

Fig. 10. Dependency of required value of feature vector quantization parameter  $\Delta$  against the size  $\rho$  of malicious image tampering areas that gives  $P_{\text{TNR}} = 100$  over the test image base.

factor  $Q$ , the better is image authentication method tolerant to JPEG compression.

The strongest requirements should be formulated for the opportunity to detect all image pixel modifications except for JPEG compression, for instance, some random modifications or malicious attacks intended to compromise the original image, for the thing, changing of car plate numbers for DVR systems, or fingerprints and photos of criminals in police offices. It is a trivial problem for exact authentication, provided that the cryptographic components, namely hash function and DS were selected in an appropriate manner. But it is a relevant problem for semi-fragile authentication because in this case some modifications can not be detected. In order to verify such opportunity for the system under consideration we arranged the following experiment. It was selected a truly random circle areas with  $(\rho/2)$ -pixel radius and inside these areas truly random luminance of pixels was chosen. At least 50 such areas were taken for each image and the number of different typical images was 100. The results of testing are presented in Figure 9, where a dependence of True Negative Rate  $P_{\text{TNR}}$  is showed as a function of areas size  $\rho$  depending on quantization step  $\Delta$  of the feature vector coordinates.

From Figure 9 it can be seen that, in accordance with our expectations, the less is a quantization step  $\Delta$ , the more probably to detect small image modifications.

In Figure 10 a curve showing a dependence of the requested values of quantization steps  $\Delta$  against the size of modification

Fig. 11. Examples of the original test image «Lena» and the watermarked version just after embedding with PSNR = 41.3 dB with  $\gamma = 9$ .

area  $\rho$  given a by  $P_{\text{TNR}} = 1$  is presented for the whole test image base.

Summarizing the experimental results, we can conclude that the proposed authentication method is tolerant to JPEG compression with parameter  $Q \geq 1$  providing simultaneously  $P_{\text{TNR}} \geq 1$  for modification area size  $\rho \geq 8$ .

Image quality of DI just after WM embedding is also very important criterion of authentication system efficiency. We evaluate both *Peak Signal-to-Noise Ratio* (PSNR) [21] and *Structural Similarity Index Measure* (SSIM) [22] as commonly used measures and for 8-bit digital images can be calculated as

$$\text{PSNR} = 10 \log_{10} \left[ \frac{255^2 MN}{\sum_{m \in \mathcal{G}} (I(m) - \hat{I}(m))^2} \right], \quad (17)$$

$$\text{SSIM} = \frac{(2\mu_I \mu_{\hat{I}} + c_1)(2\sigma_{I\hat{I}} + c_2)}{(\mu_I^2 + \mu_{\hat{I}}^2 + c_1)(\sigma_I^2 + \sigma_{\hat{I}}^2 + c_2)}, \quad (18)$$

where  $\mu_I, \mu_{\hat{I}}$  are mean values,  $\sigma_I, \sigma_{\hat{I}}$  are variances and  $\sigma_{I\hat{I}}$  is covariance calculated for  $I$  and  $\hat{I}$  respectively,  $c_1 = 255^2 \cdot 10^{-4}$ ,  $c_2 = 255^2 \cdot 3 \cdot 10^{-4}$  are the constants.

In Figure 5 the curves of image quality assessments PSNR and SSIM given by (17), (18) depending on the quantization step  $\Delta$  are presented. We can see that the greater is  $\Delta$ , the worse is the visual comprehension of the images. On the other hand the proposed system requires to keep  $\Delta$  be not very small in order to WM be tolerant to JPEG compression.

In Figure 11 the visual effect of WM embedding for some chosen WM system parameters is displayed. There is no opportunity to find any differences between images (a) and (b). However, it is worth to note that reliable detection of the image modification has a greater importance than false detection after JPEG compression, because in the last case an error can easily be recognized, whereas the authenticated image content corruption may lead to fatal consequences.

It is obvious that for valid authentication system operation, the *bit error rate* BER after LDPC decoding of code block  $b_e$  should be equal to zero even after image compression. Figure 12 (a) specify this problem. This figure shows a dependencies of *bit error rates* (BER) against quantization step  $\gamma$  for HWT coefficients depending on different values of JPEG compression factor  $Q$ . It can be seen that there exist

Fig. 12. a) Dependencies of the BER versus HWT coefficients quantization parameter  $\gamma$  given by different JPEG compression quality factor  $Q$  with and without LDPC error correction code. b) Dependency of HWT coefficients quantization parameter  $\gamma$  allowing to extract WM without errors against JPEG compression quality factor  $Q$ .

values of  $\gamma$  leading to BER=0 in case when LDPC coding is applied, whereas in the case of watermarking without error correction code (ECC) BER is mostly non-zero. Figure 12 (b) presents the dependence of the quantization intervals  $\gamma$  on JPEG compression quality factor  $Q$  given the condition BER=0.

Figure 12 shows that the selection of the quantization interval  $\gamma$  equal to 10 provides a resistant authentication method to JPEG compression with quality factor  $Q \geq 4$  and quality assessments  $\text{PSNR} \geq 40$ ,  $\text{SSIM} > 0.98$  that can be assumed as acceptable values.

## VI. CONCLUSION

The article introduces the new selective image authentication system. The novelty of the method is application of the discrete shearlet transform coefficients for the image features vector calculation procedure. An image authenticator consists of two parts. The first one is the DS of the quantized image feature vector and the second one is the auxiliary perturbation vector generated by 3-bit hash quantization technique. It provides a recovering of hash function even after jumps of the vector coordinates due to JPEG compression.

Quantization of 3-level discrete HWT coefficients as a watermarking technique which allows us to embed authentication data into the digital image was used. Due to the high capacity of this watermarking method an additional redundancy was achieved. This property was used for the error correction code.

We embed WM only into HL3 and LH3 areas of the HWT as it keeps visual image distortion smaller than in case of LL3 area usage. Experimental investigation showed that proposed authentication method provides a good reliability to verify image authenticity even after JPEG compression with  $Q \geq 3$  and simultaneously an opportunity to recognise even small content image modifications and image quality assessments  $PSNR \geq 40$  and  $SSIM > 0.98$  just after WM embedding.

Proposed selective image authentication allows one to adjust system parameters so that resulting BER,  $Q$ , PSNR, SSIM, TNR, and TPR became acceptable with the needs.

# 6<sup>th</sup> Workshop on Advances in Programming Languages

**P**ROGRAMMING languages are programmers' most basic tools. With appropriate programming languages one can drastically reduce the cost of building new applications as well as maintaining existing ones. In the last decades there have been many advances in programming languages technology in traditional programming paradigms such as functional, logic, and object-oriented programming, as well as the development of new paradigms such as aspect-oriented programming. The main driving force was and will be to better express programmers' ideas. Therefore, research in programming languages is an endless activity and the core of computer science. New language features, new programming paradigms, and better compile-time and run-time mechanisms can be foreseen in the future.

The aims of this event is to provide a forum for exchange of ideas and experience in topics concerned with programming languages and systems. Original papers and implementation reports are invited in all areas of programming languages.

## TOPICS

- Automata theory and applications
- Compiling techniques
- Context-oriented programming languages to specify the behavior of software systems and dynamic adaptations
- Domain-specific languages
- Formal semantics and syntax
- Generative and generic programming
- Grammarware and grammar based systems
- Knowledge engineering languages, integration of knowledge engineering and software engineering
- Languages and tools for trustworthy computing
- Language theory and applications
- Language concepts, design and implementation
- Markup languages (XML)
- Metamodeling and modeling languages
- Model-driven engineering languages and systems
- Practical experiences with programming languages
- Program analysis, optimization and verification
- Program generation and transformation
- Programming paradigms (aspect-oriented, functional, logic, object-oriented, etc.)
- Programming tools and environments
- Proof theory for programs
- Specification languages
- Type systems
- Virtual machines and just-in-time compilation
- Visual programming languages

## BEST PAPER AWARD

To celebrate WAPL's 10 years old, the 1<sup>st</sup> edition was in 2007, a Best Paper award will be offered to distinguish a work of high quality presented in the workshop. Award comprises a certificate for the authors and will be announced during the conference dinner.

## KEYNOTE SPEAKERS

# Welcome to WAPL'2017

Pedro Rangel Henriques

**I** WOULD like to take the chance to welcome all of you to the 6th Workshop on Advances in Programming Languages, WAPL'2017, that will happen 10 years after the 1st edition hold in Wisla, Poland, in 2007.

A long way has been traversed since the first version of FORTRAN in November 1954. Many research was done, both focussing the theory of formal Languages and Grammars or the development of Programming Language Tools.

Programming Languages appeared to realize the evolution in Computer Science that proposed new programming paradigms; also the birth of new areas for computer application motivated the design of new languages. New languages require new parsing techniques and new compilers. In this context, many years ago language engineers introduced a revolutionary approach to program development: the 'generative approach' based on the existence of tools that can generate effective programs from a formal specification of the program (in that case, from a grammar).

However the appearance of languages tailored for specific targets, the so-called Domains Specific Languages (DSL), aiming at offering an easier and more elegant way to cope with problems in concrete applications, justified the never ending

evolution of research work in the field of formal language processing. After the focus in the design of languages and the construction of their interpreters or compilers, in the last 20 years a new field of research rose up: program comprehension and the underlying need for (source) code analysis (techniques and tools).

In this context and being sure that "programming languages are programmers' most basic tools" WAPL aims at providing a forum for exchange of ideas and experience in all the topics concerned with programming languages and systems, from Automata theory and Compiling techniques to Programming tools and environments or Visual programming languages. This year the program that we have put is composed of 10 papers (2 full and 8 short or position papers) that cover different topics, as expected and as we would desire: language definition, grammars and parsing; Compilers and High-performance computing; source-code annotation/analysis and their applications; Modeling and Testing.

I hope you enjoy and take the best from your attendance. Being sure that your active participation is crucial for the success of the Workshop, we look forward to seeing you all, together with any newcomers, in the next editions.

# Use Case Driven Modularization as a Basis for Test Driven Modularization

**Abstract**—While in waterfall-like processes changes are expected to happen mostly after the main development has finished, agile approaches have incorporated response to changes into the main development itself, which raises the importance of the ability to respond to changes effectively to a *sine qua non*. Changes are specified from the perspective of how users actually use systems, i.e., usage scenarios, which does not correspond to a common object-oriented code modularization. In their complete form, usage scenarios can be directly observed in user acceptance tests. Unit tests reveal parts of usage scenarios, too. Logically, tests follow the modularization of the code they are related to. Thus, in common object-oriented code, user acceptance tests, which play a very important role in any kind of software development process and which follow the procedural modularization, would be scattered and, consequently, hard to maintain. In this paper, we propose a new approach capable of achieving test driven modularization, i.e., organizing code according to tests. Besides pure test driven modularization, which can be based on user acceptance tests, unit tests, or both, the approach also enables combining use case and test driven modularization.

**Keywords:** modularization, use case, user acceptance test, unit test, test driven development, Cucumber

## I. INTRODUCTION

WHILE in waterfall-like processes changes are expected to happen mostly after the main development has finished, agile approaches have incorporated response to changes into the main development itself, which raises the importance of the ability to respond to changes effectively to a *sine qua non*. Changes are specified from the perspective of how users actually use systems, i.e., usage scenarios, which does not correspond to a common object-oriented code modularization.

In their complete form, usage scenarios can be directly observed in user acceptance tests. Unit tests reveal parts of usage scenarios, too. Test driven development [18] and its red-green-refactor loop makes tests very close to code, but the developers have to switch between tests and code hundreds of times to make their test “green.” Although a test itself is contained within a small number of mock modules, the tested code remains spread throughout many modules, which significantly increases tracing.

Logically, tests follow the modularization of the code they are related to. Thus, in common object-oriented code, user acceptance tests, which play a very important role in any kind of software development process and which follow the procedural

modularization, would be scattered and, consequently, hard to maintain. This is of particular importance, since it is known that user acceptance tests immensely improve code comprehension, as can be seen in the Cucumber approach [7].

User acceptance tests are highly related to use cases [22], and there are several approaches capable of preserving use cases in code, such as DCI (Data, Context and Interaction) [4], aspect-oriented software development with use cases [12], and our own approach of inter-language use case driven modularization [1]. However, all these approaches fail to fully support expressing user acceptance tests because user acceptance tests are actually based on user interfaces, and good use cases are kept independent of user interface details.

Use case driven modularization and mechanisms that are used to achieve it remain a good basis for establishing a new kind of modularization—test driven modularization—which we propose in this paper. Keeping user interface code coupled with the corresponding application logic code is essential for this kind of modularization. Modern user interfaces tend to be written in dedicated languages and this is where inter-language use case driven modularization, which enables mixing fragments of code written in different programming languages in so-called virtual files with their continuous merging into compilable and executable units [1], provides the necessary capabilities missing in other approaches to preserving use cases in code.

The rest of the paper is organized as follows. Section II explains briefly how inter-language use case driven modularization is implemented. Section III proposes the new approach that enables test driven modularization. Section IV compares our approach to related work. Section V concludes the paper.

## II. INTER-LANGUAGE USE CASE DRIVEN MODULARIZATION

Several approaches capable of organizing code according to use cases are available. However, since each language is intended for its specific use, an approach suitable for test driven modularization has to support mixing different languages in program modules. Literal inter-language use case driven modularization [1] enables exactly this. In this approach, code for a use case is located in a *use case module*, which is simply a file: a *use case file*. On top of the use case file there is a

use case in its text form, a *use case text*, written in form of a comment. Under the use case text is a class which represents the use case, and its methods represent the use case steps. A framework executes the methods representing the use case steps based on the use case text. The mapping between the text of the steps and the corresponding methods is maintained with a naming convention: method names are actually derived from the use case step text by turning it into the camel case format.

The use of different languages is enabled by so-called *virtual files*. Virtual files are defined using particular comment conventions directly within the methods that implement use case steps. All virtual files are extracted out of use case files, merged, and saved by a *preprocessor*, which also resolves possible virtual file duplicities and gathers the code from partial virtual files that contain partial namespaces or classes. The preprocessor saves the files containing the merged code, which are actual files, to their *virtual file paths* as indicated in the corresponding virtual files. Subsequently, the merged code can be executed, which may require a compilation depending on the programming language.

Additions and alterations of virtual files in use case files are propagated to the merged code and to other use case files by the preprocessor. Accordingly, deletions and alterations in the merged code are propagated to use case files, too. Since there is no way of knowing to which use case are additions to the merged code related, these additions are not propagated to virtual files in use case files. All changes to use case files and merged code, including the direct changes by developers, are displayed to developers and logged. This process of change propagation is actually *synchronization*, as will be referred to further.

### III. INCLUDING TESTS IN USE CASES

Test driven modularization aims at organizing code according to tests keeping their representation in code. For this, the synchronization mechanism from inter-language use case driven modularization was employed accompanied by the new mechanism of use case coverage calculation that we propose here.

Via test driven modularization, our approach provides yet another view on software under development. This view may be combined with literal inter-language use case driven modularization, but what is always available is the modularization of the merged files (recall Section II). Developers can switch between these modularizations and get the perspective that suits best their current needs. Of course, all three modularizations have to be maintained. However, the tools capable of synchronizing changes can automate this process.

Section III-A explains the details of writing tests within use case modules. To enable keeping track of how well tests cover use cases, the approach embraces a continuous calculation of this value, which is described in Section III-B. Writing user acceptance tests is described in Section III-C. Test representation is described in Section III-D. Section III-E

provides a brief information on the experience we have in applying our approach.

#### A. Tests in Use Case Modules

In literal inter-language use case driven modularization, use case steps appear in the classes representing use cases as comments along with the related code. but comments are hard to write and maintain and development environments do not support code completion and syntax highlighting for code inside of comments. To address this problem, we propose to use the Markdown format in use case files. Consider the *Add Product into Cart* use case:

```
# Use case Add Product into Cart
## Main scenario
1. User selects to add a product into cart
2. System saves the product into cart
3. System notifies user about updating shopping cart
4. Include "Show Cart"

# Code                                     ## controller/public.js
## view/product-detail.html               ``js
``html                                   (function () {
<h3>{%=o.product.name%}</h3>              this.addToCart
<p>{%=o.product.description%}</p>         = function (event) {
<div>{%=o.product.price%}</div>           require({
<a id="add-into-cart">                     Cart:  "model/Cart.js"
  Add into cart</a>                        `` ...
``                                         `` ...

## model/Cart.js
``js
({ add: function (id) {...} })
``

# Tests
## tests/features/cart.feature            ## tests/unit/cart.js
``feature                                ``js
Feature: Shopping cart                    ...
Scenario:                                 Cart.empty();
  Adding products into cart               assert(
  Given I am on the test page              Cart.getAll().length === 0,
  When I click on "Add into cart"          "The empty cart should have
  Then I should see "Test pro."           zero items");
  And I should see "120 EUR"               Cart.add("1");
``                                         assert(
``                                         Cart.getAll().length === 1,
``                                         "...");
``                                         ``
``                                         ``
```

As can be seen, the actual use case implementation follows the use case text. This part constitutes a separate section in Markdown. It consists of virtual files (recall Section II) with virtual file paths represented by second level Markdown headers.

The tests for the use case, placed into a separate, *test section* of the use case file, follow the code section. The test section consists of virtual files, thus the same synchronization mechanisms apply to tests as in the code section. The example contains two tests: the *Adding Products into Cart* user acceptance test written in the Cucumber's Gherkin language [7] and the *Cart* unit test.

For the merged files, we used common object-oriented modularization with the Model-View-Controller architectural pattern, but any other kind of modularization, such as functional or procedural, can be used as well. Use case driven or test driven modularization can be built upon any kind of underlying modularization.

If a test from the test section is moved to the top of a use case file, the preprocessor treats virtual files in this section as use

cases in the use case section in use case driven modularization, where each line of the test is treated as a use case step in the main flow.

### B. Use Case Coverage

Each use case should be covered by the corresponding code. This can be measured as a percentage of the words from the use case found in the declarations residing in its code. Also, each use case should be covered by the corresponding tests. In the same way, the coverage of use cases by the tests can be measured as a percentage of the words from the use case found in the declarations residing in its tests.

With each change in use case files, the preprocessor recalculates and displays in its console output the coverage for each use case step along with the words that are missing in the code and in the tests. The missing words are the words present in use cases, but not covered by code or tests. Conjunctions, prepositions, and articles can be ignored, which can be specified in the *ignored words file*.

Missing words can also be pseudo-covered by code if they are included in comments inside of four asterisk symbols (denoting the bold font in Markdown). In the same way, they can be pseudo-covered by tests, too. Consider this virtual file as an example:

```
## view/bank-transfer.html
'''html
<!-- **provide bank transfer instructions** -->
<p>Please send the payment to the address below.</p>
'''
```

Although the “provides” word is missing in the corresponding use case step, the preprocessor captures its form “provide” introduced in the comment and considers it as being covered by code. Here, the difference algorithm [15] is used. The similarity of 70% or higher is considered to indicate the words are the same.

By presenting the percentage of how well use cases are covered in both code and tests encourages developers to work on increasing it, which is achieved by a better test and use case driven modularization.

Conveniently, the links between use cases and code—i.e., between a use case step and a line of code or a line of test—can be visualized by using our tool (see the relationship walkthrough video at <https://youtu.be/N1hbu3K0yp4>).

### C. Writing User Acceptance Tests

As can be seen from the *Add Product into Cart* use case example introduced at the beginning of this section, user acceptance tests closely follow use cases, which makes them appropriate for use case driven modularization. User acceptance tests can also be written in the form of use cases to ensure they cover the corresponding use cases fully. The main steps of a user acceptance test would then actually be the same as the steps of a use case. Each such step is followed by a sequence of actual test steps that specify the corresponding testing actions. This is the first step of the test from our *Add Product into Cart* use case example: “User selects to add a product into cart” is followed by the following actual test steps:

```
When I click on "Add into cart"
Then I should see "Test product"
```

The test steps are then expressed by code. Here is the code for the use case step:

```
this.When(/^user selects to add a product
into cart$/, function () {
  this.clickOn("Add into cart");
  this.shouldSee("Test product");
});
```

### D. Writing Unit Tests

Unit tests follow the modularization of object-oriented code which is different than use case driven modularization. However, unit tests are capable of testing use case steps at least partially. Consider the following example of the test for the “System saves the product into cart” step of the *Add Product into Cart* use case:

```
function testSaveProductIntoCart() {
  product = {...}
  assert(Cart.save(product) === true,
    "System should save the product into cart");
}
```

A use case step can be implemented as an exception, too. For this, the `Cart.save()` call in the `testSaveProductIntoCart()` function should be wrapped into a try-catch block. If the call fails, an assert function will raise an exception with the “System should save the product into cart” message from the use case step. Notice that all the words are the same as in the use case step except for “should,” which is characteristic for tests.

### E. Experience with the Approach

Being encouraged by the positive results of two studies of our approach to use case driven modularization, one of which embraced our own e-shop application with its seven use cases (including the use case presented in Section III-A), while the other one consisted of remodularizing the well-known OpenCart e-commerce platform into 55 use cases,<sup>1</sup> so far, we successfully applied our approach to test driven modularization to our own e-shop application. We implemented a combined use case driven and test driven modularization version and a pure test driven modularization version (based on user acceptance tests).<sup>2</sup>

## IV. RELATED WORK

DCI [4], [19], aspect-oriented software development with use cases [11], [12], InFlow [2], and behavioral programming [8] preserve use cases in code. Each approach enforces a specific use case representation in code, e.g., DCI does this via roles, while aspect-oriented software development with use cases employs aspects. In our approach, use case representation can be freely chosen while the approach still achieves use case representation in code. Approaches to generating object-oriented code from use cases [6], [23] do not actually represent use cases in code.

<sup>1</sup>See [github.com/useion/opencart](https://github.com/useion/opencart).

<sup>2</sup>See [youtu.be/zK8QKsIOkOg](https://youtu.be/zK8QKsIOkOg) and [github.com/useion/useion-e-shop](https://github.com/useion/useion-e-shop) (the test modules can be found in the context/behavioral folder). More information is available at [useion.com](https://useion.com).

Software artifacts were combined previously in literate programming [14], too. Literate programming brings code into documentation, but not tests into code. The code is extracted and combined by the noweb tool [13], which is basically a preprocessor or code generator [5]. This is similar to our approach and literate programming is even capable of expressing use case modules as our approach. However, without synchronization, code duplication would occur, which would be unbearable.

Code defragmentation can be achieved also by applying Object Teams [10], subject-oriented programming [17], and symmetric aspect-oriented composition [3], [9], but none of these approaches achieves this at the level of multiple languages, as we do.

Different structuring of code provides different views on software. Although dynamic structuring has been reported [16], [21], it was not achieved at the file system level, but using a particular editor. Our approach provides use case and test views, which are synchronized at the file system level and can be used simultaneously.

The Cucumber project [7] enables test execution based on the text specification written in Gherkin, but each step has to be expressed in code. This is similar to our approach where code can be structured according to the text specification of use cases while each their step has to be expressed in code.

While in our approach a web based interface is used to display the links between use cases or user acceptance tests and code, exposing them directly in the development environment using, for example, information tags [20] could help in making developers pay more attention to use case coverage.

## V. CONCLUSIONS

In this paper, we propose a new approach capable of achieving test driven modularization. It enables organizing code according to tests. The approach employs inter-language use case driven modularization, which provides a good basis for keeping code modularized according to user acceptance tests and enables mixing different kinds of languages, which is particularly useful when dedicated languages are used for user interface development. Besides pure test driven modularization, which can be based on user acceptance tests, unit tests, or both, the approach also enables combining use case and test driven modularization.

**Abstract**—High-performance computing increasingly makes use of heterogeneous many-core parallelism. Individual processor cores within such systems are radically simpler than their predecessors; and tasks previously the responsibility of hardware, are delegated to software. Rather than use a cache, fast on-chip memory, is exposed through a handful of address space annotations; associating pointers with discrete sections of memory, within trivially distinct programming languages. Our work aims to improve the programmability of address spaces by exposing new functionality within the LLVM compiler, and then the existing template metaprogramming system of C++. This is achieved firstly via a new LLVM attribute, `ext_address_space` which facilitates integration with the non-type template parameters of C++. We also present a type traits API which encapsulates the address space annotations, to allow execution on both conventional and extended C++ compilers; and illustrate its applicability to OpenCL 2.x.

## I. INTRODUCTION

THE MAJORITY of today's architectures are heterogeneous. This means they contain at least two different types of processors or different local memory units. A familiar example of this is the modern personal computer (PC) which contains both a graphics processing unit (GPU) and a central processing unit (CPU). These architectures have immense potential as the extra processors tend to be specialized for particular tasks. For example, GPUs are specialized for rendering graphics. However, the parallel structure of the GPU lends it incredibly well to single instruction multiple data (SIMD) tasks on large data sets. This is commonly referred to as general-purpose computing on graphics processing units (GPGPU). Due to this several programming models centered on taking advantage of this aspect have been created. The two most iconic are OpenCL [1] and CUDA [2]. GPUs are exceptional at performing SIMD tasks, so much so that several of the supercomputers in the TOP500 list [3] use them.

However, power often comes at a cost. In the case of heterogeneous architectures, the complexity of the program increases for software aiming to take full advantage of the power available. One of the more common added complexities is memory management. Memory management is an important aspect of several heterogeneous architectures, as auxiliary processors of these architectures can have separate memory from their primary processor. One such architecture are PCs containing GPUs. Each GPU has dedicated memory and data must explicitly be transferred across from main memory by the CPU. Current GPGPU programming models also segment GPU memory into several distinct address spaces with different properties that help increase throughput.

## Figure 1 C++ Address Space API

```
add_as_t<int,42> i = 12345;
static_assert(get_as_v<decltype(i)>==42);
assert(i == 12345)
```

In some cases, *named address space* qualifiers have been introduced to help associate variables with certain address spaces and thus certain properties. Named address space began in the Embedded C Extension [4], a set of optional extensions to the C programming language for use with embedded processors and have since spread. In fact, several GPGPU programming models make use of them for example CUDA, OpenCL and Metal [5]. An example from OpenCL is the `__private` qualifier which restricts the scope of a variable to a thread. Other programming models such as OpenACC [6] aim to promote a higher level view of GPGPU programming and abstract away address spaces from the programmer.

Both C and C++ are commonly used or extended in GPGPU programming. In fact all of the above mentioned programming models and languages with address spaces use or extend C/C++ in some way to achieve their goal. However, despite the number of models that make use of both C/C++ and address spaces, there is no standard compiler or library support for address spaces within C/C++. We believe that a C++ library-based approach could assist greatly in bringing address space support to C++. An API that new programming models could explore and integrate with would help improve portability and programmability. Having an API like this available also removes the requirement to extend the compiler for named address space support. As such we have created an C++ template API that takes inspiration from the C++ standard libraries type traits, an example can be found in Figure 1.

To aid in showcasing our API's viability we have decided to use the Clang [7] compiler's address space implementation. The Clang compiler's address space implementation is different from named address spaces. It takes the generic approach of accepting an integral parameter, provided by an end-user, to specify the value's address space, instead of having a fixed name set while building the compiler itself. This lends itself well to our API, which proposes integral parameters to index address spaces. Modifications to the LLVM compiler were made to add support for C++ *non-type* template parameters; since submitted as a patch. Note however that the API works

with or without our LLVM extension, having two separate implementations hidden behind one interface.

## II. THE PROGRAMMABLE ADDRESS SPACE

The named address space implementation of address space qualifiers does not lend itself easily to user programmability. The main reason for this is that they have fixed names that differ per architecture, this makes creating portable libraries dealing with address spaces challenging. This type of qualifier can be found in Embedded C, OpenCL and CUDA.

The Clang compiler has chosen another more generic direction with its address space qualifier choosing an attribute as its basis, an example can be found in Figure 2. In this variation, a single qualifier is developed for applying address spaces to a variable; rather than separate names for each address space in an architecture or programming model. The attribute accepts a constant integer as an argument. This argument can be hard coded as shown in the example in Figure 2 or be a constant integer provided that it is not from a function or template argument. Each unique integer value corresponds to a unique address space.

Whilst Clang's current address space qualifier is a lot more generic and portable than named address spaces, it is not standard C++; rather being a non-standard extension of LLVM. It is also not as programmable as we might like, as it *cannot be used with template parameters*. As such we have built on Clang's address space qualifier and created a variation named `ext_address_space`. This variation allows non-type template integer parameters to be used as arguments.

**Figure 2** An address space attribute in the Clang compiler

---

```
__attribute__((address_space(1))) int*as;
```

---

## III. C++ TRAIT API

The implemented address space has increased programmability and allows for a variety of C++ template API's to be put in place; which in turn can make using address spaces easier and safer. In our case, we created an API that borrows from the C++ standard library's *type traits*. Type traits are used for gathering compile time type information and manipulating types. This C++ API lends itself to being overloaded, allowing other types of address spaces to be encapsulated inside. This allows it to act as an interface for different types of C++ programming models. This is exemplified in this section, as our API does not require our Clang address space extension to function; instead it acts as an interface for it when present and falls back on another implementation when it's absent.

### A. The Traits API with `ext_address_space`

Our address space API uses three main class templates. The first is `get_as` (Figure 5), which allows the retrieval of the address space value from a type. The other two are `remove_as` (Figure 4) and `add_as` (Figure 3) which allow the programmer to both remove and add the address space on

**Figure 3** The `add_as` class template and its type alias

---

```
template <typename T, unsigned Nv>
struct add_as {
    using type = T __attribute__((
        ext_address_space(Nv)));
};

template <typename T, unsigned Nv>
using add_as_t = typename add_as<T,Nv>::
    type;
```

---

a type respectively. This allows explicit and easy manipulation of the address space as a qualifier similar to `const` and `volatile`. In fact, `remove_as` and `add_as` are parallels to `remove_const`, `remove_volatile`, `add_volatile` and `add_const` from the standard library.

The `add_as` class template accepts a typename parameter `T` and unsigned integer `Nv`. The parameter `Nv` denotes the address space which we qualify the passed in type `T` with. The new type can then be accessed with the classes type alias `type`, this keeps with common template metaprogramming practice. Another common practice is the use of type aliases like `add_as_t` to simplify template class calls. We stick to this general pattern throughout our API, however future aliases will be elided for brevity. The `add_as` template works similarly to `add_const` in that it only adds the qualifier to the top most level of a type.

The `remove_as` class template requires specialization. The `remove_as` class template similarly to `add_as` accepts in a type and an address space. However, in this case the address space is ignored, instead it will be deduced from the type passed in. Deducing the value in this way allows the template to generically remove all available address spaces. Without this an explicit specialization for each template would have to be generated. The return value of `remove_as` is the passed in type with the address space qualifier removed. Both `const` and `volatile` qualifiers should remain untouched if present. The base template of `remove_as` specializes for types with no qualifier and returns the base type. Other specializations specialize for different combinations of qualifiers on the type and then return the type with the address space removed. The most specialized example of this specializes for `const`, `volatile` and the address space qualifier. It returns a type with the address space removed and other qualifiers intact. We showcase this specialization but elide the rest for brevity.

The class template `get_as` accepts the same parameters as the other class templates. However, like `remove_as` the address space parameter will be deduced. The output of this template class is a value that corresponds to the address space of the passed in type. Sticking with template metaprogramming practice it's named `value`. The base template and specialization is again similar to `remove_as`. The base template with no address space qualifier returns 0. As 0 is the default address space. Its specialization again fits all address space values and deduces the address space which is then returned.

**Figure 4** The `remove_as` class template

---

```

template <typename T, unsigned Nv = 0>
struct remove_as {
using type = T;
};

template <typename T, unsigned Nv>
struct remove_as<T __attribute__((
    ext_address_space(Nv)))> {
using type = T;
};

template <typename T, unsigned Nv>
struct remove_as<T const volatile
    __attribute__((ext_address_space(Nv)))
    > {
using type = T const volatile;
};

```

---

### B. The Traits API with `as_val`

Each API function has a fall-back version for compilers that do not support the `ext_address_space` extension. This means that the API will not cause compilation errors or undefined behaviour, ensuring portability. Outwardly the API calls do not change, nor do the required includes. Only the implementation of the functions change significantly. This is handled by macros that check if the `ext_address_space` attribute is implemented, then includes the relevant header files.

**Figure 5** The `get_as` class template

---

```

template<typename T, unsigned Nv = 0>
struct get_as {
static const unsigned value = Nv;
};

template <typename T, unsigned Nv>
struct get_as<T __attribute__((
    ext_address_space(Nv)))> {
static const unsigned value = Nv;
};

```

---

A template class facilitates the API implementation's mimicking of the address space qualifier. The `as_val` class template (Figure 6) accepts a template type parameter and two non-type template parameters. The type parameter represents the type the address space qualifier is to be applied to. The two non-type template parameters represent the address space of the top most pointer (the `Nv` parameter) and the address space of the pointee (the `Np` parameter). For example, `as_val` would only support address space qualifiers on the first two pointers of a pointer to a pointer to an integer type. The integer itself would not be qualifiable. Of the parameters, only the type is

stored, the two address space values are stored at a type level and can be deduced. Through C++ implicit conversion the various overloaded functions allow the user to use assignment operators and dereference operators as if they were using the base type. This means there should be no discernible difference between using a normal pointer type and `as_val`.

Whilst the implementations of the templates are different using the `as_val` class template. The change is not drastic. The functions all take in another non-type template parameter for the pointee address space (`Np`). However, this is hidden from the programmer using type aliases for each template.

The `get_as` implementation changes very little. Instead of deducing the value from the `ext_address_space` attribute currently tied to the type. It deduces the address space from the `Nv` parameter of the `as_val` class template.

**Figure 6** The `as_val` class template

---

```

template <typename T, unsigned Np = 0,
    unsigned Nv = 0>
struct as_val {
    as_val( ) {}
    as_val(T x) : x(x) {}
operator T() { return x; }
    T x;
};

```

---

The implementation of `remove_as` is simplified. Instead of having multiple specializations for every qualifier combination. We can simply specialize for `as_val`. There is however a base case and specialization as we cannot simply return the type with the `as_val` (address space) removed. As there is also a pointee address space tied to `as_val`. The base case checks for an `as_val` with an 0 address space and pointee address space and returns `as_val`'s stored type. The specialization checks for values greater than 0 in the `Np` parameter through deduction; then returns an `as_val` type with an `Nv` parameter set to 0 whilst keeping the same type and `Np` parameter.

For `add_as` we require a base template for non-`as_val` types and a specialization for types with `as_val`'s. The base template wraps the given type with an `as_val` and sets the `as_val` types address space parameter to the given address space. Whereas the specialization simply replaces the current address space parameter of the `as_val` type with the newly given address space.

### C. The `add_pointee_as` and `remove_pointee_as` Traits

From the description of these templates it's possible to notice that there is no way to set the pointee address space of an `as_val` template class. As such there are another two template classes that allow manipulation of the pointee. They are `add_pointee_as` and `remove_pointee_as`.

For the `ext_address_space` attribute extension the `add_pointee_as` template class requires base classes and specializations similar to the `remove_as` template. They also

provide a similar use, to peel off `const` and `volatile` qualifiers from the passed in type and then reapply them to the return type. The template parameters and type alias in this case are also identical to `add_as`. The next step is to peel off the top level pointer to get access to its pointee (if it has one) and then apply an address space to it. This is achieved by a helper template which breaks down the type using the C++ standard libraries `pointer_traits` template class and then rebuilding it. It does this in three steps, first it uses `pointer_traits::element_type` parameter to get the pointees type. Secondly it applies the address space to this type. It finally uses `pointer_traits::rebind` to bind the new type to the old type. The final result will be a type with a new address space on the pointee of the original pointer. For the non-extension implementation this is again much simpler. It is identical to `add_as`, except the pointee address space parameter is set instead.

#### IV. EXAMPLE USE CASE

**Figure 7** OpenCL Reverse Array Example

```
__kernel void
reverseArray (add_pointee_as_t<float *, 1>
              d, int size){
    add_as_t<float [64], 2> s;
    int t = get_local_id(0);
    int tr = size-t-1;
    s[t] = d[t]
    barrier(CLK_LOCAL_MEM_FENCE);
    d[t] = s[tr]
}
```

The example we chose to showcase the C++ API can be found in Figure 7. The example is an OpenCL kernel function that will reverse one dimensional array data passed into it. The kernel function is based off a CUDA shared memory example found on NVIDIA's developer blog [8]. The idea is that each thread within a block will run an instance of this kernel and swap the relevant value based on its thread id. In this example the OpenCL named address spaces have been traded out for API calls which represent them as integer values. In the context of this example global is represented by the value one, local by the value two and private by the lack of a qualifier.

In the example the kernel accepts a pointer to some floating point data `d`. Alongside an integer `size` that represents the number of elements contained within `d`. The float pointer type is wrapped in an `add_pointee_as_t` class template from our API with an integer representing the global address space. This applies the address space to the target of the float pointer. Which makes the type equivalent to `__global float*`. Further down we create a statically allocated array of floats `s` which we can store values from `d` in for swapping later. We apply `add_as_t` to its type alongside an integer representing the local address space. Which makes the type of `s` equivalent to `__local float[64]`. The function then creates two

index values `t` and `tr` which represent the values we wish to swap within the current thread. After which we use the `t` index to copy a value per thread from `d` in global memory to `s` in local memory. However, before we can swap the data we must place a local barrier to prevent data races. After the barrier we can proceed to reverse the array.

A feature of our API is that if the attribute extension for `ext_address_space` is not found in the compiler it will still compile. It will fall back on the implementations that make use of the `as_val` template class which stores the address space value and variable within itself. Despite the variable now being wrapped within `as_val` it can still be used as if it was the raw type. This works through overloading certain operators in the class so that implicit conversion allows access to the underlying data. This fall-back functionality is provided by including all the required API functions through a single include file. This include file can then add different API implementations based on the presence of the `ext_address_space` attribute. This functionality has been tested with the GCC and Clang C++ compilers. Despite choosing OpenCL as the language for the example, the C++ API should be usable in the same way for C++ and C++ based programming models.

#### V. CONCLUSION

In conclusion, we have presented a C++ template API that we believe improves the programmability of address spaces. The API borrows concepts from C++'s type traits. We believe this API will help facilitate bringing address space qualifiers further into the C++ type system allowing further template metaprogramming and type safety opportunities. To help showcase the ability of our API to integrate existing address space implementations, we integrated it with Clang's address space attribute. However we also presented an API implementation that would also allow it work as a standalone implementation of address spaces that requires no compiler extensions.

**Abstract**—Each programmer has his own way of programming but some criteria can be applied when analysing code: there are a set of best practices that can be checked, or "not so common" instructions that are mainly used by experts that can be found. Considering that all programs that are going to be compared are correct, it's possible to infer the experience level of the programmer or the proficiency level of the solution. The approach presented in this paper has as main goal to compare sets of solutions to the same problem and infer the programmers profile. This can be used to evaluate the programmer skills, the proficiency on a given language or evaluate programming students. A tool to automatically profiling Java programmers called PP (*Programmer Profiler*) is presented in this paper as a proof of concept.

## I. INTRODUCTION

TWO given solutions that solve the same problem can be very different. The style of programming, the proficiency on the programming language, the conciseness of the solution, the use of comments and so on, allow to compare programmers through static analysis of their code. It is possible to measure the proficiency on a programming language in the same way that we measure the proficiency on a natural language [Pos14]. Using, for example, the *Common European Framework of Reference for Languages: Learning, Teaching, Assessment* (CEFR) method<sup>1</sup> it is possible to classify individuals based on their proficiency on a given foreign language. Statically analysing code, it should be possible to extract a set of metrics and using a set of best practices to infer the proficiency and style of programming. The main idea is to evaluate the programmers' profiles, comparing code, without the need to construct a standard solution to perform that comparison. When facing a class of students or when evaluating a group of candidates to a programmer position at a company, we only need to compare them to each other to find the best one or to create a rank. Of course we can include a best solution in the group in order to perform an absolute evaluation, especially needed in non-academic environments. The attributes or metrics that will allow to infer a profile can be defined a-priori by hand (using intuition) or can be extracted through data-mining techniques as can be seen in [KCM07]. However this last approach requires the availability of huge collections of programs assigned to each class.

Pietrikova in [PC15] also explores techniques aiming the evaluation of Java programmers' abilities through the static analysis of their source code. Static code analysis may be defined as the act of analysing source-code without actually executing it, as opposed to dynamic code analysis which is done on executing programs. The latter is usually performed with the goal of finding bugs or ensure conformance to coding guidelines. In our approach the goal is to further explore the discussed techniques and introduce new ones to improve that evaluation, with the ultimate goal of creating a tool that automatically profiles a programmer only using static analyse of code. Notice that in our work we do not cope at all with automatic code assessment or program verification; we only focus on the programmers' ability to master a programming language.

Concerning the knowledge about a language or the capability to write 'naive/expressive' sentences on that language, a possible set of profiles would be: novice, advanced and expert. Moreover, other relevant information is expected to be extracted, such as the classification of a programmer on his code readability (indentation, use of comments, descriptive identifiers), hid defensive programming style, among others.

There are some source-code elements that can be analysed to extract the relevant metrics to appraise the code writer's proficiency such as: number of statements and declarations, existence of some repetitive patterns, number of lines (code lines, empty lines, comment lines), use of indentation, quality of the identifiers, use of not so common instructions and other characteristics considered as good practices. In this work code with errors will not be taken into consideration for the profiling. This is, only correct programs producing the desired output will be used for profiling.

In order to build the PP tool to automatically extract metrics from programs and to profile the owners of those programs, language processing techniques will be used. This process will be complemented with the use of a tool, called PMD<sup>2</sup>, to get information on the use of good Java programming practices. PMD is also a source code analyser that finds common programming flaws like unused variables, empty catch-blocks,

<sup>1</sup>[http://www.coe.int/t/dg4/linguistic/cadre1\\_en.asp](http://www.coe.int/t/dg4/linguistic/cadre1_en.asp)

<sup>2</sup><https://pmd.github.io/>

unnecessary object creation, and so forth. For these reasons this tool proved to be very useful.

The paper will follow with Section II where related work will be reviewed in order to identify techniques and tools commonly used to deal with this problem. Section III is devoted to present our proposal for an automatic programmer profiling system based on source code analysis. The analyser implemented and the set of metrics extracted are presented in Section IV. In Section V we will discuss the correlation between metric values and profiles. A complete case study will be described in Section VI in order to show all the PP functionalities. The paper is closed at Section VII with conclusions and future work.

## II. RELATED WORK

As it was said, the main motivation for the work described in this paper came from the study [PC15] of Pietriková and Chodarev. These authors propose a method for profiling programmers through the static analysis of their source code. They classify knowledge profiles in two types: subject and object profile. The subject profile represents the capacity that a programmer has to solve some programming task, and it's related with his general knowledge on a given language. The object profile refers to the actual knowledge necessary to handle those tasks. It can be viewed as a target or a model to follow. The profile is generated by counting language constructs and then comparing the numbers to the ones of previously developed optimal solutions for the given tasks. Through that comparison it's possible to find gaps in language knowledge.

In [TRB04], Truong et al. suggest a different approach. Their goal is the development of a tool, to be used throughout a Java course, that helps students learning the language. Their tool provides two types of analysis: software engineering metrics analysis and structural similarity analysis. The former checks the students programs for common poor programming practices and logic errors. The latter provides a tool for comparing students' solutions to simple problems with model solutions (usually created by the course teacher).

Flowers et al. [FCJ<sup>+</sup>04] and Jackson et al. [JCC05] present a tool, *Gauntlet*, that allows beginner students understanding Java syntax errors committed while taking their Java courses. This tool identifies the most common errors and displays them to students in a friendlier way than the Java compiler. *Espresso tool* [HMRM03] is also a reference on Java syntax, semantic and logic error identification. Both tools have been proven to be very useful to novice Java learners but they focus mainly on error handling.

Hanam et al. explain [HTHL14] how static analysis tools (e.g. *FindBugs*) can output a lot of false positives (called unactionable alerts) and they discuss ways to, using machine learning techniques, reduce the amount of those false positive so a programmer can concentrate more on the real bugs (called actionable alerts). We are not considering the use of machine learning and data mining techniques in our approach. Our idea is to use a set of pre-defined criteria to evaluate programs and infer profiles.

## III. PROFILE DETECTION: OUR PROPOSED SOLUTION

Programmer profiling is an attempt to place a programmer on a scale by inferring his profile. The first step towards achieving this profiling is to define what will be the profiles. A classification that could encapsulate a broad range of programming knowledge was developed.

The **Novice** is someone who's not familiar with all the language constructs, does not show language readability concerns and does not follow the *good programming practices*. The **Advanced Beginner** starts to shows variety in the use of instructions and data-structures. He also begins to show readability concerns by writing programs in a safely manner. The **Proficient** is a programmer who is familiar with all the language constructs, follows the *good programming practices* and shows readability and code-quality concerns. Finally, the **Expert** is someone that masters all the language constructs and focuses on producing effective code, sacrificing on readability.

The example seen in Listing 1 could be a bit exaggerated but may help shed some light on what is meant by the previous scale. Each one of the following methods has the same objective: calculating the sum of the values of an integer array, in Java. Each method has features of what may be expected from each profile previously defined. It's hard to represent all 4 classifications on such a small example, so the Advanced Beginner profile was left out.

Listing 1. "Examples of programs corresponding to different Profile Levels"

```
int novice (int[] list) {
    int a=list.length;
    int b;int c= 0;
    for (b=0;b<a;b++) {
        c=c+list[b];}
    return c;
}

//Sums all the elements of an array
int proficient (int[] list) {
    int len = list.length;
    int i, sum = 0;
    for (i = 0; i < len; i++) {
        sum += list[i];
    }
    return sum;
}

int expert (int[] list) {
    int s = 0;
    for (int i : list) s += i;
    return s;
}
```

The Novice has little or no concern with code readability. He will also show lack of knowledge of language features. In the example we can see that by the way he spaces his code, writes several statements in one line or gives no meaning in variable naming. He also shows lack of advanced knowledge on assignment operators (he could have used the *add and assignment operator*, +=).

The Expert, much like the Novice, shows no concern for language readability, but unlike the latter, he has more language knowledge. That means that the Expert has a different kind of bad readability. The code can be well organized but the programming style is usually more compact and not so explicit.

As an example of language knowledge, the Expert uses the *extended for loop*, making his method smaller in lines of code.

Finally, the Proficient will display skills and knowledge, much like the Expert programmer, while keeping concern with code readability and appearance. The code will feature advanced language constructs while maintaining readability. His code will be clear and organized, variable naming has meaning and code will have comments for better understanding.

Since the goal is to classify programmers automatically, that classification can only be carried through the analysis of the programmers' source code. Since the interest is in language usage, in various aspects, static code analysis was the selected technique to perform the extraction of the data to be analysed.

The two main aspects of code that were of interest to this project are the language knowledge and the readability of code. To classify the abilities of a programmer regarding his knowledge about a language and the way he uses it, we considered two profiling perspectives, or group of characteristics: language **Skill** and language **Readability**.

- **Skill** is defined as the language knowledge acquired and the ability to apply that knowledge in an efficient manner.
- **Readability** is defined as the aesthetics, clarity and general concern with the understandability of the code written.

We believe that these two groups contain enough information to obtain a profile of a programmer, regarding his ability to write proper language sentences to solve problems. Then, for each group, and according to the score obtained by the programmer, Table I gives a general idea of how programmers can be profiled. Notice that (+) means a positive score, while (-) means a negative one.

TABLE I  
PROPOSED CORRELATION

Profile	Skill	Readability
Novice	-	-
Advanced Beginner	-	+
Expert	+	-
Proficient	+	+

What constitutes a lower and a higher score for each group must be defined. For every programmer, the goal is to compare each metric value among all solutions to identify those who performed better or worse on that metric, and then, assemble a mathematical formula which allows to combine the metrics' results into a grade for each of the two groups. Taking those two grades and resorting to Table I we can easily infer the programmer's profile in regards to the subject problem.

#### IV. SOURCE CODE ANALYSIS: METRICS EXTRACTED

After some testing and experimenting, we've created a set of metrics that we consider appropriate for programmer profiling. The range of metrics extracted is quite large, and it's obvious that not all metrics should have the same weight towards inferring the profile of programmers. Considering that, each metric has an associated priority (or weight) that directly relates to the impact that metric will have towards inferring

TABLE II  
METRICS EXTRACTED AND RULES WITH THEIR PRIORITIES

Metric	Rule	Priority
Number of Classes	+ =>+R +S	2
Number of Methods	+ =>+R +S	2
Number of Statements	- =>+S	8
Number of LOC	+ =>+R	5
Percentage of LOC	- =>+R	5
Number of Locom	+ =>+R	3
Percentage of Locom	+ =>+R	3
Number of Empty Lines	+ =>+R	3
Percentage of Empty Lines	+ =>+R	3
# Control Flow Statements	- =>+S & + =>+R	5
Variety of Control Flow Statements	+ =>+S	4
# Not So Common CFSs	+ =>+S	6
Variety of <i>Not So Common Operators</i>	+ =>+S	5
# Declarations	- =>+S -R	5
# of Types	+ =>+S	4
# Readability Relevant Expressions	+ =>+R	3

the profiles. Table II formally specify the following rules that we are extracting for each solution to a given exercise. For instance, the first rule, should be read as: More classes imply more Skill points and more Readability points.

##### Code Size Metrics

- These metrics are related with code size. We believe code size is mainly related with readability concerns.

##### Control Flow Statements Metrics

- Control flow statements (CFS) are the heart of the algorithms. Knowing how to properly use them says a lot about programming knowledge.

##### *Not So Common Operators* Metrics

- Java is a vast language with numerous operators. Some of them are very specific and most programmers don't know about them. When correctly applied these can reduce the code size and even improve the program's performance.

##### Variable Declaration Metrics

- Similarly to the case of the Control Flow Statements, the usage of Declarations could be an indication of a programmer's capabilities.

##### Other Relevant Expressions Metrics

- This metric was created to hold other important language features that for some reason or another didn't fit in the other descriptions.

##### PMD Violations Metrics

- The PMD Violations Metrics are very important because they allow us to detect problems in code that otherwise would be very hard to catch. PMD rules have their own priorities.

#### V. RELATING METRICS WITH PROFILES

As time progressed, our idea of the profiles shifted a bit from the original idea that we saw in Table I. We decided that the Experts should be the ones with maximum focus on Skill,

the Proficients on Readability and the Advanced Beginners should more precisely divided. A new profile was also created. The final version of the profiles is the following:

- **Novice (N):** Low Skill and Low Readability
- **Advanced Beginner (AB):** Low-to-Average (LtA) Skill and Readability
- **Proficient (P):** LtA Skill and High Readability
- **Expert (E):** High Skill and LtA Readability
- **Master (M):** High Skill and High Readability

Keep in mind that the definition of the groups (Readability and Skill) is not the common meaning of the word. Saying that an Expert has low Readability means only that he scored a low value on our axis of Readability (based on the metrics we've seen in the previous section) when comparing to other solutions to the same problem.

## VI. CASE STUDY

Taking, for instance, two students solutions for the following Java exercise: *Write a Java program that reads positive integers (number 0 will terminate the input). Compute and print the amount of even numbers, odd numbers, and the average (real number) of the even numbers.*

Listing 2. "Solution to P1 made by S"

```
import static java.lang.System.out;
import java.util.Scanner;

public class P1_S {

    public static void main(String[] args) {
        int nEven = 0, nOdd = 0, sum = 0;

        while(true){
            out.println("Insert a number:");
            Scanner ipt = new Scanner(System.in);
            int num = ipt.nextInt();

            if(num == 0) break;
            if(num%2 == 0) {
                nEven++;
                soma += num;
            }
            else nOdd++;
        }

        double average = 0;
        if (nEven != 0) average = sum / nEven;

        out.println("Even: " + nEven);
        out.println("Odd: " + nOdd);
        out.println("Even Avrg: " + average);
    }
}
```

Listing 3. "Solution to P1 made by Z"

```
import java.util.Scanner;
public class P1_Z {
    public static void main(String[] args) {
        Scanner in = new Scanner(System.in);
        int value = in.nextInt(), evens = 0,
        odds = 0;
        double evensSum = 0;
        /*I'm assuming the input is viable,
        i.e. all input numbers are
        positive integers*/
        while(value != 0){
            if((value & 1) == 0){
                evens++;
                evensSum += value;
            } else odds++;
            value = in.nextInt();
        }
    }
}
```

```
System.out.println(evens + "\n" + odds);
System.out.println(evens > 0?
    evensSum / evens : evensSum);
}
```

Looking at the structures of both solutions, we can see they are both divided in the same way. Inside the main method, the first lines are used for variable declaration and initializations. Then we have the main cycle, where numbers are read and the variables are assigned. Finally, in the last lines we have our results output.

One thing we can easily observe is the size of both solutions, in regards to the number of lines. The first solution has 61% more lines of code than the second one. A closer inspection shows us that *S* had the concern of leaving empty lines between some code instructions, while *Z* didn't leave a single one. This is one of the most clear signs of concern for readability. Empty lines and indentation are probably most important things when creating readable code. Although it was not possible to implement the verification of correct usage of indentation (tabs or spaces) the usage of empty lines was, and it will weight for the readability grade.

Regarding the use of variables, *S* declares a total of 4 ints, 2 Scanners and 1 double while *Z* only needs 3 ints, 1 Scanner and 1 double.

The number of required variables reflects the capacity that the programmer has in reusing variables. Therefore, less number of needed variable declaration reflects a higher skill in the language. Of course that has the fallback of generally making the code less understandable (the same variable has different purposes), so there is a loss in readability as well.

That takes us to the main loop. *S* makes the mistake of reinitializing a Scanner and a int in every cycle iteration, that is a violation that is detected by the PMD tool. *Z* on the other hand reuses his variables.

Another bad practice detected by PMD on *S*'s solution is the use of a *while(true)* cycle. This is generally regarded as an avoidable practice, because it then forces the programmer to explicitly end the cycle using, as is seen in this case, a *break* condition. *Z* avoids this by simply reading the numbers in the cycle's test and checking if the number is equal to zero. As explained in the previous chapter, detected PMD violations are "punished" in the skill or readability grades. Each violation is related to one of the groups. In this case, both violations punish the skill group.

The parity check was also made differently in the two solutions. While *S* compares with the traditional (and easier to understand) way of *if(n % 2 == 0)*, *Z* used the more advanced approach of *if( (n & 1) == 0)*. This is much more efficient than using the *%* operator, especially for large numbers. The bitwise and bitshift operators allow programmers to perform bit-level operations and have a very high potential to those who know to use them. These operators are considered advanced, so their usage will increase the skill level of a programmer when detected by PP.

Finally, we can see that in the first solution, *S* has to declare one last variable, use another if-condition, and call one final

`println` method just to compute and output the average of the even numbers. *Z* on the other hand does everything in a single line, using the ternary operator (also known as inline if). All these extra statements used by *S* will have a negative effect on *S*'s Skill (or a positive effect on *Z*'s). After all, *Z* did the same in less statements. The usage of the ternary if condition is considered an advanced operator that also benefits Skill.

After running these two solutions (together with five others) through the PP tool, all data detailed in IV will be extracted. Then, those individual metric values are normalised across all solutions. Finally we apply the weight to those normalised values and achieve a final score by adding the individual metrics results. That final score is composed by two numbers: one for Skill another for Readability.

Wrapping up the analysis, we see that *Z* shows greater language knowledge and skill, but not much concern for readability. *S* is less skillful and programs in a more novice way. Figure 1 shows the final scores obtained by all seven solutions that were analysed for this particular case study. In these small examples, *S* was classified as *Adv. Beginner* (leftmost on the plot) with a readability focus, obtaining a (S,R) score of (20.9, 15.9), and *Z* was classified as *Expert* (rightmost on the plot) with a score of (32.2, 10.7). This complies to their programming background, which was stated previously.

Fig. 1. Profile inference made for Exercise P1

## VII. CONCLUSION

The research hypothesis that led the project here reported was *whether was possible to infer the profile of a programmer through the analysis of his source code*. We proved that research hypothesis by means of demonstration.

The developed tool, Programmer Profiler Tool, takes as input a set of correct solutions to a given programming problem, written in Java, by different programmers.

Each one of the metrics extracted and bad practices identified are linked to one of two groups, Skill and Readability, and can have a positive or negative effect on the two groups. The Skill group is related to language knowledge and ability of creating effective code. The Readability group relates more to understandability of code, and coding style related practices.

By comparing all results among each other, and applying previously defined rules of how the metrics and defects affect the groups, a numeric score is calculated for each group and for each programmer. Each one of these rules, applies the results of an extracted metric (or PMD violation) to either increase or decrease the score of the two groups (S and R), thus reaching a final value for each group.

By applying the described method to several exercises, a set of scores is calculated for each programmer, and by combining those scores a final score is calculated, for each group, that portrays how the programmer performed in comparison to the solutions of other programmers.

The final scores are mapped to a set of previously defined programmer profiles, and thus the profile is inferred for each one of programmers. The results can then displayed in a plot, to better interpret how each programmer performed on the different exercises as well as on the global scope.

All the profiles inferred on the tests performed agreed to the teacher's manual evaluation done in Java course of the University of Minho. Which leads us to state that PP Tool can correctly infer the profile of Java programmers. Although this it would be interesting in the future to include more information about each student namely learning ability and soft skills.

More data and information regarding this project can be found at <http://www4.di.uminho.pt/~gepl/PP/>.

**Abstract** — Contemporary tools aimed at information system (IS) development often use models to generate system implementation. Starting from an IS model, these tools commonly generate database implementation schema as well as code for generic CRUD operations of business applications. On the other hand, at the level of platform-independent models (PIMs) there is a lack of support for specification of more complex functionalities associated with events. In this paper, we present an approach aimed at specification of events at the level of PIMs. We introduce new concepts to describe context in which an event may occur, while we use our IIS\*CFuncLang language to define event business logic. We also developed adequate transformations to generate executable program code from these specifications.

## I. INTRODUCTION

SIGNIFICANT efforts have been invested into the research of approaches and tools, aimed to completely, or partially, automate the IS development process. In these approaches, models play a key role in the IS development process [1]. Usually, a model is transformed into (i) a database implementation schema and (ii) program code of business applications performing simple CRUD (create, retrieve, update, and delete) operations over the generated database [2]. Beside these typical functionalities, business applications usually include more complex functionalities, i.e., business logic, that is specific for the application domain. For example, such application-specific functionalities include complex calculation and validation tasks, series of database operations triggered by an event, etc.

A similar classification of application functionalities may be found in [3], where authors classify application program code as: (i) generic; (ii) schematic; and (iii) individual. Generic and schematic program code is common for various applications domains and has patternable structure. Individual program code is specific for an application, and it is hard to generate it from such a model [3]. The approaches and tools aimed at the IS development, support modeling of typical functionalities as well as generation of program code for these functionalities. Unfortunately, modeling of application-specific functionalities associated with events,

and the generation of appropriate program code often is not supported by these approaches and tools. Manual customization of generated program code is used for implementation of these functionalities. In order to formally specify business logic of application-specific functionalities at the level of platform-independent models (PIMs) we have developed a domain-specific language (DSL) named IIS\*CFuncLang [2]. Research efforts presented in this paper are extension of our previous work devoted to a formal specification of application-specific functionalities ([4]).

In the paper we will present an approach for modeling application-specific functionalities associated with IS events. This approach is aimed at specifying IS events at the abstraction level of PIMs. An event specification consists of two parts: (i) business logic that has to be executed upon event occurrence, and (ii) context in which the event may occur. For the specification of business logic we use the IIS\*CFuncLang language. In order to formally specify an event context we introduce a new PIM concept named *Event*. Using this concept a designer may specify event properties such as event source, an action that trigger the event execution, and level that the event is handled at. Also, we have developed algorithms aimed at transformation of event specifications into executable program code. In this way we generate complete program that implements application-specific functionalities associated with events.

## II. FUNDAMENTALS

Commonly, the application-specific business logic is executed upon the occurrence of an event. Therefore, specification of events is an important part of an IS model. We analysed several approaches and tools aimed at IS modeling and code generation, and in the most cases, specification of events is only partially allowed at the PIM level. Business logic for an event is specified at the lower abstraction level by amending the generated program code. This approach may raise several concerns such as portability, operational maintenance, and synchronization between generated and hand-written program code [2]. Also, a developer must possess expertise in the target programming language and platform services. In our approach IS events are completely specified at the abstraction level of PIMs, and complete program code is generated using the

<sup>1</sup>The research presented in this paper was partly supported by Ministry of Education, Science and Technological Development of Republic of Serbia, Grant III-44010.

transformation algorithms. In this way, generated program code does not require additional customization, which may help in overcoming aforementioned problems caused by amending generated program code. A designer does not need to be familiar with a target language nor target platform services. Also, it is easier to achieve portability since emergence of a new platform or a target language does not require customization of the generated program code. Only new transformation algorithms for the platform need to be implemented. Furthermore, usage of DSLs instead of manual writing of code in a general-purpose programming language (GPL) brings additional benefits as it is discussed in [5].

For the practical verification of our approach we have chosen the IIS\*Case tool ([6]). Starting from PIMs, IIS\*Case provides generation of a database implementation schema for various relational database management systems (RDBMSs) as well as executable business applications and transaction programs. However, until now this tool did not provide modeling of application-specific functionalities associated with events. IIS\*Case is an open source tool, and the authors of the paper are actively involved in its development.

#### A. IIS\*CASE PRELIMINARIES

At the abstraction level of PIMs, IIS\*Case currently provides conceptual modeling of database schemas and business applications of an IS. Starting from such PIM models as a source, a chain of transformations is performed so as to obtain executable program code of business applications and database SQL/DDDL scripts for a selected target platform ([7], [8]).

The form type is a central concept for design and integration of database schemas in the IIS\*Case tool. It generalizes document types, i.e. screen forms used for communication with an IS. Each form type is a named tree structure, whose nodes are called component types. In the transformation process a component type will be used as a starting point for generation of both screen forms and database tables. Analogously, attributes in component types are mainly used as a source for generation of columns in database tables, as well as input and output fields in screen forms. The component type and attribute are amended with new concepts in order to formally specify events. These new concepts are described in detail in Section 3

#### B. IIS\*CFUNCLANG

The IIS\*CFuncLang language is a textual DSL aimed at specification of an application-specific business logic [2]. In our approach we use this language to define business logic associated with events. In this section we present the main concepts of IIS\*CFuncLang that are important for specification of events.

IIS\*CFuncLang includes commands specific for the domain of database applications, such as commands for performing operations over database records, commands for updating properties of screen forms, etc. In addition to the commands from the concrete domain of business

applications, the language includes concepts from GPLs, such as control-flow statements, variable and array declarations, various operators etc. In this way, when some application-specific functionality cannot be described with domain concepts a designer may use less abstract concepts from GPLs. In Listing 1, an example of an IIS\*CFuncLang function is presented. The function checks if the input parameter is an empty string, and in that case reports an error and aborts the transaction.

```
FUNCTION ValidateName(In1 STRING)
RETURNS BOOLEAN
VAR
  i INT;
END_VAR
BEGIN
  IF (Len(In1) = 0) THEN
    i := ShowErrorMessage('Error!!!');
    signal(abort_trigger);
    RETURN FALSE;
  ELSE
    RETURN TRUE;
  ELSE;
END
```

Listing 1 An example of IIS\*CFuncLang function

The IIS\*CFuncLang execution semantics is based on the interpreter approach. The compiler transforms IIS\*CFuncLang specifications into intermediate code. The intermediate code is similar to Java byte-code, and it is prepared for interpretation. Also we have developed transformation from IIS\*CFuncLang specifications to SQL program code for database triggers. This approach is suitable when some application-specific functionality has to be implemented at the level of a RDBMS.

Each event is associated with one IIS\*CFuncLang function. When event is handled at the level of business applications, then the compiler generates intermediate code for the function. The interpreter is embedded into the business application. Upon the event occurrence within system, business application starts interpreter that executes intermediate code for the event function. The interpreter returns control to the business application after code execution. If event is handled at the level of database server then appropriate database triggers are generated and deployed to the target server.

### III. EVENTS

Frequently, an application-specific functionality is executed when an event occurs within a system. In order to formally describe such a scenario, we introduce a concept named Event. Each event has the following attributes: (i) source, (ii) IIS\*CFuncLang function defining business logic, (iii) event handling level, and (iv) type.

An event source may be exactly one instance of the following concepts: form type, component type, or attribute in a component type. Let's suppose that a form type or a component type is selected as an event source. Starting from a form type or a component type specification, the code generator creates screen forms and database tables. The

event business logic will be executed when appropriate action is performed over the generated screen form (e.g., mouse clicked), or over the database table (e.g., a record is inserted).

There are three levels of event handling: (i) the database server level, (ii) the application server level, and (iii) the client application level. If an event is handled at the level of a database server, then a function associated with the event will be transformed into the PL/SQL program code of database triggers. Currently, we provide generation of program code aimed to be executed by Oracle RDBMS. A generation of program code for other RDBMSs is a matter of further research. If an event is handled at the level of an application server or a client application, then intermediate code will be generated as described in the previous section.

The event type determines the type of action that triggers the event. It includes typical software event types common for various programming environments, such as mouse events, keyboard events, and events over database tables and columns. The set of allowed event types has more than forty elements and it will be presented in detail in the rest of the section.

#### A. EVENTS IN COMPONENT TYPE ATTRIBUTES

Each attribute in a component type may be associated with a set of events. There are events, such as *Mouse Clicked*, *Key Pressed*, and *Focus gained*, that are only handled at the client application level. They are activated when a user performs appropriate operations mouse over the screen form fields generated for the attribute that the event is associated to. Events such as *After Update Record* and *Before Update Record* are activated before and after the update operation is performed over the database column generated for the attribute to which the event is associated. These types of events are only handled at the database server level.

#### B. EVENTS IN COMPONENT TYPES

Component type specifications are used as a starting point for the generation of screen forms and database tables. We extended this concept so a designer may associate set of events to each component type. These events may be divided into two categories.

Events such as *After Update Record* and *Before Update Record* belong to the first category. They may be handled at the database server, client application or application server level. If event is handled at the database server level then the generated trigger will be activated when appropriate operation is performed over the database table generated for the component type to which the event is associated. When the event is handled at the client application level, then it will be activated when a user presses the *Save* button in the screen form generated for component type to which the event is associated.

The second category includes events related to the typical software events performed over screen forms, e.g., mouse clicked, focus gained, the *Save* button pressed, etc. These events are only handled at the client application level.

#### C. EVENTS IN FORM TYPES

We amended the form type concept with list of events. These events are related to the screen forms generated for the form type. There are two events that belong to this category: *On Open Form*, and *On Close Form*. These types of events are only handled at the client application level. Events are activated when the screen form generated for the form type is opened or closed.

#### IV. USE CASE

In this section we will describe a use case from the application subsystem for university administration that we have developed using IIS\*Case. In order to specify the application subsystem, we defined two form types with the following component types: (i) DEPARTMENT(DepId, DepName), and (ii) STUDENT(Sid, Name, DateOfBirth, Status). Beside typical functionalities, the user requirements also included the following: (i) department name must be non-empty string, and (ii) if a student status is changed to part-time, i.e., value of the *Status* attribute is set to 'PT', all statuses of his or her enrolments must be changed accordingly.

In order to realize these requirements, two new events are defined. The first one is associated with the *Department* component type, and it is activated before a new record is inserted into the database table generated for the component type. The second is defined for the *Status* attribute in the STUDENT component type, and it is activated before an update operation is performed over the database column generated for the *Status* attribute. Business logic of events is defined by the functions presented in Listing 1, and Listing 2. If the event is handled at the database server level, then PL/SQL program code will be generated. Generated code consists of two parts. The first part is a package implementation containing a function generated from the function defining business logic. The second part contains a database trigger. In the trigger header it is specified that the trigger is activated before each update of a row, or before each update of the appropriate attribute. The trigger body is rather simple, including only invocation of the generated function from the package.

Let's assume that the event should be handled at the client application level. In this case, generated intermediate code and the interpreter are embedded into the generated business application. Also, the business application is extended in order to include an event handler listening the specified event, i.e., a record is updated when a user presses the *Save* button. When the event occurs within system the event handler invokes the interpreter to execute the intermediate code. The interpreter returns result and various execution statuses to the business application. Based on the result and statuses, the business application determines whether the operation will be aborted or committed. For example, IIS\*CFuncLang provides *SIGNAL* command that informs the execution environment about specific state of the execution. If this command is executed with the *abort\_trigger* argument, then the business application should abort the current operation.

```

FUNCTION UpdateStatuses(Sid INT, Status
String)
RETURNS INT
VAR
    RES INT;
END_VAR
BEGIN
    IF Status == 'PT' THEN
        RES := Execute_NonQuery('update ENROLLMENT
set Status='\PT\' where Sid=' ||
To_String(Sid));
        return RES;
    END_IF;
END

```

## V. RELATED WORK

Nowadays, many commercial tools allow PIM modeling of database schemas and ISs. We analysed tools that also provide modeling of application-specific functionalities associated with events. Usually, these tools, such as *IntegraNova Modeler* ([8]) and *SOloist* ([10]), provide only partial specification of events is at a level of PIMs, while business logic is implemented by customizing generated program code by means of a target language. Potential problems with this approach are already discussed in the Section 1, such as synchronization of generated and hand-written program code. However, we propose a specialized language and concepts to fully specify events at the level of PIMs. Also, we provide adequate transformations for generating a complete program that implement business logic for events. Such a generated program code does not require additional customization.

Executable UML (xUML) is an approach aimed at creating models detailed enough to enable generation of complete system implementation [11]. Object Management Group (OMG) introduced an action language in order to allow specification of system procedural behaviour using algorithmic concepts. This language includes concepts for specification of system events, such as event, signal, input and output pins etc. In our approach, we provide number of high-level commands from the domain of business applications, such as commands for aborting transactions, executing queries, and updating GUI properties.

## VI. CONCLUSION

In this paper we presented an approach aimed at complete specification of IS events at the level of PIMs. During the

research we have also identified several directions for future research. We plan to extend the set of allowed event types. For example, introduction of the *Value Change* event type will allow a designer to specify actions that will be executed after each change of input fields in generated screen forms. A future research will encompass the development of a new group of commands that will act as a query language over PIM concepts, such as form type and component type. Additionally, we intend to transform such commands into SQL program code aimed to be executed over various RDBMs.

Email: {michal.sicak, jan.kollar}@tuke.sk

**Abstract**—We present an improved version of algorithm that can transform any context-free grammar into a supercombinator form. Such a form is composed only of lambda calculus' supercombinators that are enriched by grammar operations. The main properties of this form are non-redundancy and scalability. We show the improvements that we've made to create smaller supercombinator set than in our previous algorithm's version. We present experiments performed on Context-free grammars obtained by transformation from Groningen meaning bank corpus. Experiments confirm that our form has a theoretical maximum limit of possible supercombinators. That limit is a mathematical sequence called Catalan number. We show that in some cases we are able to reach that limit if we use large enough input data source and we limit the size of supercombinator permitted into the final set. We also describe another benefit of our algorithm, which is the identification of most reoccurring structures in the input set.

## I. INTRODUCTION

LAMBDA calculus is a formalism that describes computation with the use of expressions, variables and applications. Combinators are lambda expressions without free variables. We use more restricted form of combinators, supercombinators in our work. The term supercombinator was coined by Hughes in [1] and it means an expression that can contain only constants or another supercombinators. In this paper we show an algorithm that can transform input grammar or a set of grammars into a single supercombinator form that is non-redundant yet retains the descriptive ability of its input grammars.

The main fuel of our work are grammars. We can use them for purposes, which exceed their usual application like the description of a language. The possibilities of wide grammar usage has been presented by Klint et al. in [2]. They argue that grammars are a strong formalism method that are already used in many areas of software engineering. We have presented in our work [3] a way to use grammars as a prime object of internal language incremental evolution.

We have shown in our previous work [4] that any Context-free grammar (CFG) can be transformed into a supercombinator form. Which means that we can abstract the structure from the data (represented in grammars as terminal symbols). The experiment performed in mentioned work showed that we can reduce the amount of grammar elements with this

approach rather significantly. We have parsed samples of natural language with the Sequitur [5] algorithm and then converted resulting grammars into a supercombinator form. We have proven that our algorithm abstracts CFGs rather well. In this paper we are using a source that comes from a more meaningful background, short newspaper articles that have already been parsed with the use of Combinatory Categorical Grammars (CCG). We need a large enough data source that can be converted to CFG form for further processing. However, we do not process those data for some semantic related purpose. Our goal is not to create new meaning parser, but to analyze the possibilities of a CFG abstraction, to explore their structure and even contribute to the field of grammar metrics. Our ultimate goal is to create single scalable supercombinator structure that contains data non-redundantly.

The main contributions of this paper are:

- We present updated algorithm for supercombinator form acquisition that runs more smoothly than the one from our previous work [4]. Short description of its basic functionality and a list of performed changes are shown in the section III. We also explain there, why are those changes beneficial for the entire process. The improvements of our algorithm are described in the section III-D.
- We describe various experiments that we have performed on 62008 grammar samples taken from 10000 short newspaper articles included in the Groningen Meaning Bank (GMB) [6] corpus. We show in the section IV that growth of our supercombinator form is limited by a mathematical sequence called Catalan number. The achieved grammar element reduction performed on GMB inputs is still significant, as it was in our previous work where we have used Sequitur generated grammars.
- We show that supercombinators that have been merged to achieve non-redundancy can be tracked during that merge operation in order to acquire more information on the input data themselves. The results in the section IV-D show that we can identify the most reoccurring structures in the input form, as the structure is directly translated into supercombinators.

## II. MOTIVATION

One of motivations behind our work is the ability to process data stream of grammars at the input. As a grammar needs not to be predefined, it can be acquired from a plain text

This work was supported by project KEGA 047TUKE-4/2016 "Integrating software processes into the teaching of programming".

by a process called grammar inference. It is a well studied problem. We know that we cannot infer a grammar from a set of positive samples purely algorithmically. That has been proven by Gold in [7]. Usually in the communication we do not possess the knowledge about what is and what is not a correct sentence. There exist researches that study this phenomena in human to human communication. For example Onnis, Waterfall and Edelman found out in [8] that people, and especially little children, use cues called variation sets to differentiate utterances as grammatical or not. In the realm of formal languages, by using heuristics like statistical analysis or evolutionary algorithms, we can infer a grammar from positive samples with certain proficiency, see Stevenson and Cordy [9]. And such grammars might have a form of a CFG, therefore we can apply our process on them and obtain highly parallel, non-redundant structure that is scalable. We describe experiments in the section IV that give out the evidence to these claims.

One of the other reasons why we have created this process is to battle the phenomena called structural explosion [10]. This occurs for example when we are trying to create a finite state automaton from a regular expression that contains structurally identical parts. Let's have the expression (1) as an example.

$$a(b)^* | c(d)^* | e(f)^* \quad (1)$$

Three parts of that expression located in between alternative operators  $|$  are structurally identical, yet carry different symbols. We can see in Fig. 1 how the structural identity is reflected in the automaton created from the expression (1). Each strand representing identical structures has its own state and transitions. Although we can see that they are structurally identical, they are still fully present in the resulting automaton. Should we want to process a grammar set of substantial size and then store it in a memory, this could pose a problem, where we would end up with lots of identical structures in the memory. With our process, we are able to transform those structures into one unified supercombinator form. For example, three structurally identical branches of the automaton from Fig. 1 would yield supercombinators<sup>1</sup> showed in (2) and (3), where  $L^0$  represents identity combinator. Terminal symbols from the original grammars are now stored separately, although they are still connected to the supercombinators by references. Should we apply our supercombinators on arguments, we would obtain the original grammar structure.

$$L^2 = \lambda x_1. \lambda x_2. L^0 x_1 + L^1 x_2 \quad (2)$$

$$L^1 = \lambda x_1. \lambda x_2. (L^0 x_1)^* \quad (3)$$

Although the algorithm presented in this paper is capable of processing virtually any form of a CFG, we are leaning towards using it for the natural language processing. Formal grammars describing formal languages tend to be rather short and therefore it is not so relevant to process them further. But with the acquisition of a large enough grammar set we can

<sup>1</sup>Note the inclusion of grammar operations in the lambda expressions, see section III for further details.

Fig. 1. Finite state automaton of a regular expression  $a(b)^* | c(d)^* | e(f)^*$ .

actually see valid results. This of course does not mean, that our process is restricted to the natural languages only.

### III. TRANSFORMATION OF CONTEXT-FREE GRAMMARS INTO A SUPERCOMBINATOR SET

Our process transforms CFGs into a non-redundant supercombinator set. We have CFGs in the extended Backus-Naur form (EBNF) on the process' input. EBNF consists of rules and a set of terminal and nonterminal symbols. Rules are composed of symbols and grammar operations. In EBNF case, these operations are concatenation, alternative, closure and option. Our algorithm can process any number of defined operations, as they can be abstracted away the same way as the terminal symbols are. Every operation that occurs in the input grammar form is translated to our supercombinator form, yet the meaning of the operation remains the same. In the following example we use only concatenation and alternative operations for the simplicity sake.

Let's have a grammar defined by rules (4) and (5).

$$A \rightarrow a B a \quad (4)$$

$$B \rightarrow b | A \quad (5)$$

Rules (4) and (5) represent a simple CFG. We can see that this grammar generates language  $a^n b a^n$ . It contains a cycle, which will spice the things a bit. It also has only two rules, which in the resulting form would not show the full benefits of our process as there are no reoccurring structures. However, it is sufficient for this explanation.

The rule (4) is a plain sequence of three symbols. Rule (5) on the other hand is an alternative. Both rules refer to each other. This simple grammar can be transformed into a set that has three supercombinators, see Table I.

Supercombinators are lambda expressions. We use enriched lambda calculus, where the standard definition of lambda calculus has been enriched with grammar operations of the processed grammar. Hence in our example, only alternative and concatenation are added to it<sup>2</sup>. Supercombinators created from the grammar in (4) and (5) are shown in the Table I. Supercombinators are designated with the  $L$  symbol. Grammar operations are designated with the standard  $|$  symbol for alternative and  $+$  symbol for concatenation<sup>3</sup>.

<sup>2</sup>The example in the section II uses concatenation and closure.

<sup>3</sup>We have chosen the plus symbol since standard symbols for concatenation, either dot ( $\cdot$ ) or an empty space already are used in the lambda calculus.

TABLE I  
SUPERCOMBINATOR FORM OF THE GRAMMAR IN (4) AND (5).

Name	Supercombinator Body	Arguments
$L^0$	$\lambda x_1. x_1$	$\{a, b\}$
$L^A$	$\lambda x_1. \lambda x_2. L^0 x_1 + L^B x_2 x_1 + L^0 x_1$	$\{a b\}$
$L^B$	$\lambda x_1. \lambda x_2. L^0 x_1 \mid L^A x_2 x_1$	$\{b a\}$

The arguments on the right side of the Table I are a part of our set. They represent permissible arguments for each supercombinator. They are stored non-redundantly as well. They are connected to the starting (top) supercombinator that roughly corresponds to the starting nonterminal symbol of a grammar. Should we apply those arguments to that supercombinator, we obtain the original grammar back. Therefore our supercombinator form is equivalent to the original CFG.

In the Table I we see that the grammar represented by rules (4) and (5) has been transformed into three supercombinators. As mentioned above, the fact, that we have obtained three supercombinators from two rules is due to the simplicity of the input grammar. What is important however, is the fact that our form is non-redundant. When we have larger grammars with repeating structures, our process works rather well, as we show later on in the section IV. Let's just imagine that we have expanded the grammar in (4) and (5) with same structured rules that have different terminal symbols. In that case, our form would not contain any new supercombinators, since it looks only at the structure and abstracts terminals away. Only new terminals and their links would be the new additions to our form.

#### A. Construction of Node Graph

The first version of our algorithm [10] could process only regular grammars. Construction of the form was straightforward and rather simple. In [11] we showed a method how to extend this process to CFGs. There we note that nonterminals could be treated similarly as terminals. Nonterminal in a rule's body means a jump to another nonterminal rule. And as we see on the grammar in (4) and (5), those jumps can create cycles.

Each rule produces its own subset of supercombinators. They are merged together later on, but at this stage they are treated as separate entities. On a plus side, this opens a possibility for a parallel processing. Since each subset of supercombinators contains a top supercombinator of that rule, i.e. a supercombinator that corresponds to the nonterminal from the left side of a rule, each subsequent call of another supercombinator inside of a rule's body can be replaced by that particular subset's top supercombinator. We just need to know the possible arguments and therefore the arity of that supercombinator.

In order to obtain that information, we need a graph constructed from the entire grammar. We need to know how many arguments are permissible for each nonterminal symbol. For that we are going to use depth first search from that

Fig. 2. The graph constructed from the grammar in (6).

node. To better show what we mean, let's have this following grammar (6):

$$\begin{aligned}
 A &\rightarrow a B a C \\
 B &\rightarrow b D c C \\
 C &\rightarrow c c A \\
 D &\rightarrow d d
 \end{aligned} \tag{6}$$

In this case we have four nonterminal symbols  $A, B, C$  and  $D$  and four terminals  $a, b, c$  and  $d$ . The graph of this grammar is depicted in Fig. 2. By using depth first algorithm from the node  $A$ , we obtain the following string:  $A a B b D d d c C c c a$ . By deleting nonterminals and removing all duplicates, we obtain the resulting argument string  $abdc$ . Now we can create a dummy version of a top supercombinator from the rule  $A$ . We know that it has four arguments and that is sufficient for us to use it inside of another supercombinator's body.

But do we need to remove duplicate terminals from that string? It seems that it is a logical step to retain the non-redundancy property. Yet as we show further on (see section III-D), this may not be the case. By not removing duplicates in this step we can obtain larger amount of similar structures, where the only trade off is an increased amount of connections to arguments.

#### B. Initial Supercombinator Construction

As all of our references to other rules are taken care of, we can now process each rule separately into a supercombinator form. Usually this yields at least two supercombinators per rule, the identity function supercombinator that we call  $L^0$  and a top supercombinator of that rule. In case that the rule is more structured, other supercombinators are created. The amount depends on the structural complexity of each grammar rule. Each grammar operation inside of a rule creates its own supercombinator. As mentioned above, each nonterminal is replaced by the reference to its top supercombinator, which does not need to be created yet. This allows us to process rules in any order, even in parallel. After this step, we can proceed to the merge process that merges all structurally identical supercombinators together. This is done on the level of a single

Fig. 3. Visualization of iterative merge operation.

rule and then over the entire set, thus creating unified non-redundant form.

Let us explain the merge process in more detail here. In Fig. 3 we see an example of supercombinator applications. On the left side we see a tree structure, where bottom nodes are supercombinators that are a part of supercombinators above them. This means that supercombinator with the identifier 0 contains in its body supercombinators 1 and 2. And they contain each only one subsequent supercombinator (3 and 4) in their bodies. We find out at the beginning of our merge process that nodes 3 and 4 are identical. We merge them together to a single node, designated as 3. Even if the nodes 1 and 2 are structurally identical, they are not merged yet, since they both contain different references. After the first merge iteration, we update references and now nodes 1 and 2 can be merged together assuming they are identical. We show the result on the right side of the Fig. 3. The set now contains only three supercombinators out of the original five. Needless to say, supercombinators that are different in the structure are not merged together, as they represent separate structures. The merge process stops when no new identical supercombinators are found after the reference update.

### C. Transformation to a Single Set

We already have all basic functions to create a unified set of supercombinators. After processing each rule separately, we may merge them together with the same process that we have used before. After that we have a non-redundant set.

However this set is not necessarily final, we can still add another processed grammar into it, hence we achieve scalability. Imagine that we have processed a grammar  $G_1$  to a set  $S_1$ . A new grammar  $G_2$  appeared on the input. First we need to process that grammar into its own supercombinator set  $S_2$  and then merge it with the  $S_1$ . Unification of grammars can be described as the following expression  $G_1 + G_2 = S_1 \cup S_2$ . Therefore we can continuously add grammars to a single set.

The ability to incrementally expand the set is an important property of our process. We can thus create one set of supercombinators from multiple grammars. We show how our set grows with the addition of new grammars in the section IV.

As already mentioned before, our algorithm is capable of transforming any CFG into a set of supercombinators. CFG is a formalism that can describe languages with certain properties. All rules of this grammar type are basically derivations of

nonterminal symbols, as the basic structure of a CFG rule is  $A \rightarrow \alpha$ , where  $A$  is nonterminal symbol and  $\alpha$  is a sequence of terminal and nonterminal symbols. We see that a sequence is an operation, which is transformed along with its arguments into a supercombinator. Each grammar operation creates exactly one supercombinator in this step. We can therefore say that any type of a rule can be transformed into a supercombinator. However, we obtain better results when we use restricted forms of CFGs as there is a higher chance that the repeating structures will occur. For example cycles in a grammar are quite restricting and limit that occurrence to a certain degree, as we can see on an example presented in the Table I.

### D. Room For Improvement

The results presented in this paper are achieved with the use of our algorithm that has been improved and now differs in some points from the one presented in [4]. We have unified the merge operation and also used more efficient data structures that increased the speed of grammar processing. In the previous version, we have differentiated between the merger of rules within a single grammar and the merge in between the grammars. As we ultimately are getting a single set, the differentiation was unnecessary and now we are using the same merge operation during the entire transformation process.

As we have mentioned a bit earlier (see III-A), one of another improvements is the possibility of not deleting duplicate arguments from a string obtained from the grammar's graph. One of our process' core principles is the fact that we do not store the same element twice in the final set and not deleting duplicates might pose the risk of introducing redundancy. However, we argue that this is not the case and it can even reduce the amount of supercombinators, where only the number of connections would rise.

Let's have supercombinators (7) and (8):

$$L^A = \lambda x_1. \lambda x_2. x_1 + x_2 \quad (7)$$

$$L^B = \lambda x_1. x_1 + x_1 \quad (8)$$

We see that the first one has two distinct arguments, where the second has only one. Yet the structure of their bodies is suspiciously similar. It is just a simple concatenation of two arguments. What we see is that if we delete duplicate arguments, as it is in the case of supercombinator (8), we obtain supercombinators that are structurally similar yet different in their arity.

Should we treat all arguments as unique entities, the supercombinator (8) would not exist, as it would be merged with the (7), see the right side of Fig 4. We see that by treating arguments as unique elements, we actually obtain more compact form. At least here it is clear only in a theory. We have performed experiments to confirm this hypothesis, see section IV-B.

But does the inclusion of all arguments violate our non-redundancy criteria? No, it does not, since the arguments are stored separately, only the connections (in fact references)

Fig. 4. Visualization of our old and new approach to argument connections.

Fig. 5. Example of input sample in CCG form.

are actually attached to supercombinators. We see this fact in Fig. 4, where we see that this improved approach does not store anything more than once.

#### IV. EXPERIMENTAL RESULTS

We present various experiments that show the abilities and properties of our algorithm in this section. As already mentioned, we are no longer using grammars generated with the Sequitur algorithm as we have done in [4]. We have decided to use different kind of input data.

In order to properly examine our algorithm, we need to have a rather large dataset. We are taking our input grammars from Groningen Meaning Bank (GMB) [6]. It is a large base of news articles parsed with Combinatory Categorical Grammar (CCG) [12]. At the time of writing this paper, GMB consisted of 10 000 short newspaper articles, 62 008 sentences in total. We want to have a set of structural data that is sufficiently large enough, and this bank matches that criteria. Normally, CCGs are used for parsing natural language sentences along with their semantics. However, we do not use those grammars in a traditional way, since they are already parsed and combined with deep semantics. We transform the tree structure of each parsed sentence into one CFG in a straightforward fashion. As an example, we can see input CCG in Fig. 5. It is a parse tree of a sentence "No explanation was given". This is the third sentence from the GMB sample no. 88/0248. It is short enough to serve as an example. The resulting CFG from that sentence is shown in Fig. 6.

To complete the picture, we show in the Table II supercombinators that are created from this sample. Arguments were omitted for brevity. You can see that rules 2 and 3

- 0  $\rightarrow$  1 < . >
- 1  $\rightarrow$  2 3
- 2  $\rightarrow$  < No > < explanation >
- 3  $\rightarrow$  < was > < given >

Fig. 6. Context free grammar created from input sample.

TABLE II  
SUPERCOMBINATORS CREATED FROM THE GRAMMAR SHOWN IN FIG. 6.

Name	Supercombinator Body
$L^0$	$\lambda x_1.x_1$
$L^1$	$\lambda x_1.\lambda x_2.L^0 x_1 + L^0 x_2$
$L^2$	$\lambda x_1.\lambda x_2.\lambda x_3.\lambda x_4.L^1 x_1 x_2 + L^1 x_3 x_4$
$L^{top}$	$\lambda x_1.\lambda x_2.\lambda x_3.\lambda x_4.\lambda x_5.L^2 x_1 x_2 x_3 x_4 + L^0 x_5$

Fig. 7. Input grammars' rule amount distribution.

from Fig. 6 are structurally identical and they translate to the supercombinator  $L^1$ . Should we perform  $\beta$ -reduction of  $L^{top}$  with the arguments (in this case words), we would obtain the input sentence. Therefore our form is complete and fully represents the input sentence.

These grammars are different from the Sequitur grammars that we have used before. They are still simple CFGs that generate sentences and use only sequencing. However, and this is important to stress out, these CFGs are no longer just compiled from repeating phrases, but are purposely parsed based on their linguistic categories. We capture the structure of these parse trees, which in it self might show interesting information about the input form.

##### A. Input Data

We have obtained large amount of data by using GMB data transformed to CFGs. These data can show, how our algorithm works and what are its strong parts. We have transformed a total number of 62 008 sentences to the equal number of CFGs. The average number of rules per grammar is 20.838, with the median of 20 and the mode is 19. Standard deviation of rule amount is 7.947. We can see in Fig. 7 that the distribution of grammar rules roughly resembles the gauss curve, therefore it can be considered a normal distribution.

We have mentioned earlier in the section III-B that each grammar is processed into its own supercombinator set. How we can relate CFGs with the supercombinators created from them? We could look at the maximum arity of a supercombinator set, i.e. the arity of the top supercombinator. We see in the Fig. 8 that the distribution of maximum arity is also normal and very similar (although not identical) to the distribution of grammar rules. The other values are similar as well, where

Fig. 8. Maximum arity of a supercombinator per supercombinator set created from input samples. Each input grammar generates one set, they were not merged yet at this stage.

Fig. 9. Comparison of cumulative incremental merge between older and newer approach, described in the section III-D.

the average arity is 21.84, with the median of 21 and the mode of 20. Standard deviation is almost identical, 7.95. The arity is important property of supercombinators, as with it we can find out the theoretical maximum amount of created supercombinators.

### B. Comparison of Approaches

We have described in the section III-D our performed tweaks to the algorithm. As this is the result section, we present the comparison results here. We have said that by allowing the same argument to be applied in one supercombinator more than once, we gain the reduction of elements.

To check our hypothesis, we have performed following experiment. We have taken the entire sample set and incrementally built a supercombinator set. This means that we have started with the first sample, created supercombinator set from it and then incrementally merged each next sample's set with it (see section III-C). In Fig. 9 we see that the growth of supercombinator amount in the form is lower in the case of our improved method. So these results confirm our hypothesis that the resulting form would contain fewer supercombinators.

Fig. 10. The amount of supercombinators in the final form divided by their arity.

TABLE III  
AMOUNT OF SUPERCOMBINATORS SEPARATED BY THEIR ARITY.

Arity	Amount	Catalan no.	Arity	Amount	Catalan no.
1	1	1	9	878	1430
2	1	1	10	1836	4862
3	2	2	11	3474	16796
4	5	5	12	5686	58786
5	14	14	13	8470	208012
6	42	42	14	11328	742900
7	128	132	15	13859	2674440
8	360	429	16	16099	9694845

### C. Scalability of the Supercombinator Form

You may notice from the Fig. 9 that the growth of our form seems to be linear. That is because the maximum arity of our input samples is rather high. In the Fig. 10 we show the amount of created supercombinators in the final set split by their arity.

The intuition tells us that the amount of supercombinators that can be created for each arity is limited. If we have a non-redundant form, there must be some amount that cannot be surpassed. The limit of theoretically possible supercombinators created from CFGs with binary rules is known as the Catalan number (9).

$$C(n) = \prod_{k=2}^n \frac{n+k}{k} \quad (9)$$

This fact makes sense, since we are using binary CFG rules, and one of the counting problems that Catalan number describes is the number of successive applications of a binary operator. Should we split our form by the arity, we see in Fig. 11 that in each case the total amount never surpasses the Catalan number. Note that 0th Catalan number equals to our arity of 1. As Catalan number grows exponentially, we use exponential y-axis in Fig. 11. Even with it, the Catalan number (red line) rises steeply, quickly surpassing the amount of created supercombinators of higher arities.

In Table. III<sup>4</sup> we see the amount of supercombinators taken

<sup>4</sup>We do not show the entire set for brevity.

Fig. 11. Arity split supercombinator form with a logarithmic scale along with the Catalan number limit.

from our set split by arity up to the number of 16. We obtain all theoretically possible supercombinators up to the arity of 6. Then we see that the amount of supercombinators with larger arities is orders lower than their corresponding Catalan number.

Although our set shows linear growth (blue line in Fig. 9), should we restrict the supercombinator creation process to some arity, we should see logarithmic growth. Arity restriction means that we do not allow any supercombinator with higher arity to enter the final set. As we use grammars that do not contain cycles, supercombinators cannot contain inside of them any higher or equal arity supercombinators, therefore our limiting does not require any special attention.

To demonstrate this limit, we have chosen to restrict arities starting above the number 8. This number has been chosen since it produces sizable amount of supercombinators yet the Catalan number for it is not that much higher, as it is for higher arities, see Table III. In Fig. 12 we see that our growth is now logarithmic, it does not surpass the limit imposed by the sum<sup>5</sup> of the first 8 numbers of the Catalan number (red line).

#### D. Identification of the Reoccurring Structures

Each supercombinator represents some part of a grammar structure. It is reasonable to assume that some structures do occur more often than others. That information is not available in our final set, since the set is not redundant. However, we can capture that information during the merge operation.

When we perform incremental growth of our form, we merge a supercombinator set created from one grammar with the rest of already created supercombinators. Therefore, we just need to count how many times has any supercombinator been merged. That would give us another parameter to our supercombinator form, the merge rate. In other words a number designating how many times has a certain supercombinator tried to enter the output set.

<sup>5</sup>We need to sum the first 8 numbers of Catalan number sequence, as the set now contains supercombinators with arities of the range from 1 to 8.

Fig. 12. Cumulative sum of supercombinators constrained with the arity of at most 8, along with the maximum limit, which is sum of the first 8 values of Catalan number.

TABLE IV  
FREQUENCY OF OCCURRENCE OF STRUCTURES.

Frequency interval	Amount	% After merge	% Before merge
$\geq 1000$	59	0.024	47.07
$< 1000, \geq 500$	43	0.018	3.38
$< 500, \geq 100$	317	0.129	7.33
$< 100, \geq 50$	348	0.141	2.77
$< 50, \geq 10$	2717	1.103	6.08
$< 10, \geq 5$	3794	1.54	2.78
$< 5, \geq 2$	19142	7.77	5.38
$=1$	219894	89.252	25.2

With this information, we can find out the most reoccurring structures inside the input data. We have split our final supercombinator set by the merge rate, see Table. IV. For better representation, we have split the set to intervals, so it could be more evident how many times has a unique supercombinator tried to enter the final set. In the second to last column that represents actual percentage of supercombinators in the final set after merge operation, we see that the majority of supercombinators are unique in the first place, as 89% have never been merged. Around 7.77% of supercombinators have been merged only once. Therefore we can conclude that only a fraction of supercombinators present in the final form occur frequently as structures in input grammars.

Now let's focus on that fraction. In the last column of the Table IV we see the actual rate of occurrence before merge operation. It is no wonder that the supercombinators that have been merged more than 1000 times have more than 47% of the share. These are the most occurring structures in the input set after all. In the Table V we show ten supercombinators that have been merged the most times. The number in the first (and fourth) row means its order in sequence and next to it is its composition, therefore (0,1) means that this supercombinator is composed of identity  $L^0$  supercombinator and the supercombinator in that table with the rank of 1,

TABLE V  
TEN MOST MERGED SUPERCOMBINATORS.

Rank	Arity	Merged	Rank	Arity	Merged
1 (0,0)	2	62008	6 (0,4)	6	16025
2 (0,1)	3	60114	7 (1,1)	4	14602
3 (0,2)	4	48851	8 (2,3)	5	12651
4 (0,3)	5	30343	9 (0,8)	5	8433
5 (1,0)	3	17028	10 (0,6)	7	7995

which is  $L^1 = \lambda x_1. \lambda x_2. L^0 x_1 + L^0 x_2$ <sup>6</sup>. We see that  $L^1$  exists in each set created from input grammars, as its merge rate equals the amount of grammars processed. Should we look at it from the CCG perspective, it represents a basic application of two elements.  $L^0$  also exists in all input grammars sets, yet it is not present in the table due to the implementation simplifications. It has the arity of 1 and it is always present in every supercombinator that we create.

Note that the supercombinator  $L^1$  has its rate of occurrence equal to the amount of grammars. We have not been counting how many times has this supercombinator been created while creating a single set from one grammar, we are only counting merge rate when merging already created supercombinator sets (created from input grammars) with the final set. This might be a threat to validity of this results, but we argue that even in the current state our process is able to identify the most reoccurring structures, as we are identifying structures in between the input CCG trees.

The second most occurring supercombinator has the arity of 3. It does not occur in all grammars however, as its merge rate is 60114. This is possible due to the fact that there exists another supercombinator with the arity of 3 that has the occurrence of 17028. Both of those supercombinators might be present in a single input set, since their arity is rather low. Yet we see that the first one occurs around three times more often than the second one.

We can say that we have found a way to identify the most reoccurring structures in our input samples. Each supercombinator directly translates to the structure. For better explanation, we present the Fig. 13 that contains two most occurring structures with the arity of 8. There are 429 possible permutations of supercombinators with the arity of 8, out of which only 360 existing in our set. Supercombinators in Fig 13 are the most occurring with that arity. We see that these structures are plain binary trees, the black nodes mark the spot where the arguments enter our supercombinator form, i.e. they represent the  $L^0$  supercombinator. Next to each tree is their merge rate. We see that the most occurring structure with the arity of 8 is the deepest possible tree for that amount of leaf nodes. Tree structure like that can represent a list structure. The second most occurring supercombinator with the arity of 8 contains the same structure with the arity of 5, and it contains above mentioned supercombinator  $L^1$  twice.

Fig. 13. Two most occurring supercombinators with the arity of 8.

## V. DISCUSSION

We have presented large scale experiments on CFGs that have been taken from the structure of CCGs samples from GMB corpora. This is in contrast to our previous work [4] where we have used generated Sequitur grammars. These grammars are representable by trees, like our current samples, but Sequitur CFG tree nodes can have zero-to- $n$  subtrees, where the trees of CFGs presented in this paper are binary. This means that current grammars tend to be narrower but they are also deeper. The largest supercombinator is represented by a tree with the depth of 22. It has the arity of 104, which means that it has 104 leaf nodes. It represents the longest sentence in the original GMB source.

Restriction to binary trees has allowed us to pinpoint the theoretical limit of our resulting form. In case of binary trees it is the Catalan number, and as we show, the amount of created supercombinators never surpasses the maximum possible amount set by this mathematical sequence. In fact, only supercombinators with the arity up to 6 are fully present in our final set. This result has been expected. A single natural language sentence can be parsed by CCG in multiple ways, caused by what is known as spurious ambiguity. Yet the final selected tree form is usually the most simple one. Therefore it is logical to expect that we won't have all possible supercombinators in our final form. Yet we have found out that a fraction, specifically 0.024% of supercombinators in the final form represents 47.04% of all structures in the input grammars that we have processed. This shows that natural language parsed with CCG tends to create similar structures rather than to create arbitrary ones. This conclusion is in order with the CCG spurious ambiguity property mentioned above.

The results presented in the section IV-D show that we can find the most used structures in the entire input set. This might be a little contribution to the field of grammar metrics as we can now measure, observe and locate the substructures of grammars. However, the purpose of this paper is not a creation of a new metric. This might be the topic of our future research.

The results from section IV-B show that we might obtain smaller final forms, should we allow the identical arguments to be treated individually. This reduces the amount of supercombinators, as we reuse already created supercombinators. The

<sup>6</sup>The composition of  $L^1$  is therefore (0,0).

downside of this approach is larger amount of connections between arguments and supercombinators. The main feature of our form, the non-redundancy, still stands, as no two supercombinators in the resulting set are equal.

## VI. RELATED WORK

As our algorithm processes grammars, our work relates with the field of grammar inference. Inference methods can transform linear text into a grammar form that we can further process and convert into non-redundant supercombinator set. There exist various methods of CFG (or their subset) inference, even from the positive samples only. Although due to Gold's theorem, it is not possible to infer grammar from positive samples purely algorithmically. Hrnčíč, Merník, Bryant and Javed used evolution algorithms [13] to circumvent that problem. Another methods might include the use of minimal adequate teacher, as used by Clark [14] or a rule based system presented by Dubey, Jalote and Aggarwal [15]. There are other methods to achieve that, De Higuera presents extensive survey of various grammar inference methods in [16]. Stevenson and Cordy in [9] describe methods of inference used in the software engineering.

As our results from the section IV-D indicate, our work might contribute to grammar metrics field. Grammar metrics are formal measurements of a grammar quality. Power and Malloy in [17] describe metrics and they split them into two types, size metrics and structure metrics. Črepinšek et al. build upon that and in [18] propose new metrics based on LR parsing. However, deriving new grammar metrics is not the purpose of this paper and would require additional research. But we believe that we might contribute this field in the future.

The algorithm from our work might be used to store grammars that are processed in a data-flow manner. This relates to the field of conceptualization [19], as supercombinators might represent concepts. Data obtained by such a process [20] can be transported into grammar forms and then processed with our algorithm. As our research is grammar based, it might also prove useful to the Domain specific language (DSL) field [21]. DSLs are useful small languages that work with the abstraction rather well. They are primarily targeted for human-computer communication [22], and the structure containing data non-redundantly might prove to be useful.

## VII. CONCLUSION

We have presented an improved version of supercombinator set acquisition algorithm in this paper. As in our previous version, this algorithm is capable to convert any CFG into a set of supercombinators accompanied with the arguments (terminal symbols). By application of arguments we obtain the input grammar back. The improvements presented here include non-removal of identical terminals in the creation of a supercombinator, using more efficient data structures and the unification of a merge process. Keeping the identical terminal symbols results into more compact form with less amount of supercombinators. Only drawback is the increased number of argument references.

We have performed experiments on a set of 62 008 sentences, taken from 10 000 news articles that are included in the Groningen Meaning Bank. The goal of our experiments was to prove that the supercombinator set is upper bound. We have found that in the case of binary CFGs, the limit is a mathematical sequence called Catalan number. Should we limit the supercombinators entering the final set by a relatively low arity (we have presented results limited with the arity of 8), the growth of that set is logarithmic and never surpasses the limit posed by the Catalan number.

Another experiments showed that our process can identify most reoccurring structures in input grammars. This might be a contribution to the field of grammar metrics. The results presented here show that supercombinator set obtained from natural language sentences contains only a small fraction of supercombinators that represent majority of structures in the input set, as our final set is non-redundant.

# Labeling Source Code with Metadata: A Survey and Taxonomy

Matúš Sulír, Jaroslav Porubán  
Department of Computers and Informatics  
Faculty of Electrical Engineering and Informatics  
Technical University of Košice  
Letná 9, 042 00 Košice, Slovakia  
Email: {matus.sulir,jaroslav.poruban}@tuke.sk

**Abstract**—Source code is a primary artifact where programmers are looking when they try to comprehend a program. However, to improve program comprehension efficiency, tools often associate parts of source code with metadata collected from static and dynamic analysis, communication artifacts and many other sources. In this article, we present a systematic mapping study of approaches and tools labeling source code elements with metadata and presenting them to developers in various forms. We selected 25 from more than 2,000 articles and categorized them. A taxonomy with four dimensions – source, target, presentation and persistence – was formed. Based on the survey results, we also identified interesting future research challenges.

## I. INTRODUCTION

**D**URING their work, developers often encounter situations when they are trying to understand a program by looking at its source code, but the critical information they seek is not present in the code. Consider the following examples.

A small but tricky piece of code worked a few days ago, but now it does not. The programmer must open a web browser, navigate to the version control system (VCS) website and find the relevant commit. It refers to the issue tracking system, which is a separate website. After reading the whole, particularly long issue description and a multitude of related comments, he finally finds the reason of the malfunction.

Another programmer tries to comprehend a rather complicated algorithm. It is difficult to understand it just by looking at the code, so he decides to provide sample input data and debug the program using a built-in debugger of an IDE (Integrated Development Environment). While it is possible to display a value of any variable at any time, the debugger does not present any overview of values of a particular variable over time. Each time a program stops, the programmer must remember a value of interest and compare it with previous values in mind. As the capacity of short-term memory is very limited, the developer soon starts writing notes in a separate document. This, in turn, creates a burden of switching between two separate views (a split-attention effect [1]).

These two – at the first glance unrelated – scenarios have something in common: The information a developer needed was available *sometimes* or *somewhere*. But it was not available in the right place at the right time: in the IDE, and

associated with the particular piece of code the developer was looking at.

Many researchers have realized this problem and provided various approaches, methods and tools to partially solve some of its aspects. However, since authors use a rather large variety of terms to describe them, gaining an overview is difficult. For this reason, we decided to provide a survey of existing approaches and categorize them in a taxonomy.

Our general research questions for this survey are:

- **RQ1:** What various approaches (and tools implementing them) do exist to label parts of source code with additional metadata and present them to a programmer in order to improve program comprehension?
- **RQ2:** How can the approaches be categorized?
- **RQ3:** What observations and challenges can be concluded from the results?

## II. METHOD

We decided to conduct a systematic mapping study, which is a form of a systematic literature review (SLR). In contrast to an SLR, a mapping study has more general research questions [2] and the main goal is to classify research to categories, rather than provide precise quantitative results [3].

### A. Search Strategy

Since our view of literature through a notion of “source code labeling” is not very common and the terminology is inconsistent, we decided to try multiple different search strategies and combine their results.

1) *Manual Search:* First, we performed a manual search among all articles published in 8 journals and 4 conferences, selected by the authors’ discretion (partially inspired by a list in [4]). In this first part of the search process, arbitrary two years (2009 and 2012 in our case) were selected, as suggested by [5]. The journals of interest were:

- IEEE Transactions on Software Engineering (TSE),
- ACM Transactions on Software Engineering and Methodology (TOSEM),
- Computer Languages, Systems and Structures (COM-LAN),
- Science of Computer Programming (SCP),
- Journal of Systems and Software (JSS),

This work was supported by project KEGA 047TUKE-4/2016 Integrating software processes into the teaching of programming.

- Empirical Software Engineering (ESE),
- Information and Software Technology (IST),
- Journal of Software: Evolution and Process (JSEP), formerly known as Journal of Software Maintenance and Evolution (JSME),

and conferences:

- International Conference on Software Engineering (ICSE),
- International Conference on Program Comprehension (ICPC),
- Working Conference on Reverse Engineering (WCRE)
- and International Conference on Software Maintenance (ICSM).

A Scopus<sup>1</sup> query was constructed based on the criteria, the results list was exported as a CSV file and inspected in a spreadsheet processing program. A total of 1546 articles were manually assessed based on titles and abstracts, resulting in a list of 16 relevant articles.

2) *Keyword Search*: Continuing the methodology of Zhang et al. [5], we inspected the terminology used in articles obtained during the manual search and based on it, we constructed and tried multiple keyword-based search queries. The final Scopus query is as follows:

```
TITLE-ABS-KEY(
  ("source code" OR "program comprehension")
  AND
  ("tagging" OR "enriching" OR "augmenting"
   OR "labeling")
) AND SUBJAREA(COMP)
AND NOT SUBJAREA(bioc OR medi OR envi OR neur)
```

Basically, it searches the specified terms in titles, abstracts and keywords of computer science literature, excluding interdisciplinary research. The search yielded 85 results, of which 6 were newly found relevant ones.

The methodology by Zhang et al. [5] prescribes trying slightly different queries until one of them returns at least 80% of articles from the first (manual) phase. For the query presented above, this number was far below 20%. Broadening the terms caused the count of results to skyrocket. The number of false positives was high, without a significant positive impact on the relevant result count. For this reason, we decided to leave the methodology and continue with other techniques.

3) *References Search*: We searched for all forward and backward references of 22 articles collected so far. Again, we used Scopus.

Backward references mean all articles cited in the “References” section of particular papers. They are generally older than the article citing them. From 305 results, we considered 14 unique and relevant.

Forward references are articles for which a search engine knows they cite a particular paper. This is useful to find newer articles. Of 137 results, 3 were relevant and not yet found in previous searches.

4) *Other Sources*: Five more relevant articles were found recursively in the references of articles found during the phase of references search. Finally, we added three more papers present in the authors’ personal bibliography.

#### B. Inclusion Criteria

During the selection process, a paper was considered relevant if:

- it presented a new approach or tool to associate metadata with pieces of source code,
- the purpose of these metadata was to improve program comprehension
- and a form of presentation of these data to a programmer was described.

Examples of excluded articles are papers describing a labeling algorithm without discussing how to present results to developers, and purely empirical studies comparing existing approaches.

#### C. Final Article List

From the 47 selected articles, 17 were just descriptions of the same or similar idea in another research phase. Five were considered irrelevant after skimming or reading the full text.

The final article list thus contains 25 articles. For an overview, see Table II. Further details will be provided in section IV.

#### D. Data Extraction

The full text of 25 relevant articles was read, carefully watching for similar and distinguishing signs regarding source code labeling. Succinct notes about each article were written in a tabular form, gradually forming a taxonomy.

### III. TAXONOMY

First, we will introduce our taxonomy, answering **RQ2**. Similar to Dit et al. [6], articles (approaches) were evaluated according to multiple criteria, called dimensions. For each dimension, an article can belong to one or more attributes.

Our taxonomy has four dimensions: source, target, presentation and persistence. For an overview, see Table I. Now we will describe the dimensions and attributes in detail.

#### A. Source

A “source” dimension denotes where the metadata were originally available before they were assigned to a part of source code. The most problematic source is human mind. In order to obtain information present only in the memory of the programmer, he must manually enter these data into a system for each artifact which should be labeled. The most primitive kind of a label with a “source” of type *human* is a traditional source code comment. The developer writes the label – a natural language text easing program comprehension – above a piece of code. The assignment of the comment to a piece of code is therefore performed by its positioning.

Approaches categorized as *code* analyze the source code of a system without executing it, i.e., using static analysis.

<sup>1</sup><http://www.scopus.com>

TABLE I  
A SOURCE CODE LABELING TAXONOMY.

Dimension	Attribute	Description
<b>Source</b>	<i>human</i>	Manually entered information, previously present only in human mind.
	<i>code</i>	Results of static source code analysis.
	<i>runtime</i>	Results of the program execution; dynamic program analysis.
	<i>interaction</i>	Interaction patterns of a single developer in the IDE.
	<i>collaboration</i>	Collaboration artifacts of multiple developers like VCS commits or e-mails.
<b>Target</b>	<i>folder</i>	A directory or a package.
	<i>file</i>	A file or a class.
	<i>multi-line</i>	A multi-line part of a file, e.g., a method.
	<i>line</i>	One line in a file, such as a variable declaration.
	<i>line part</i>	A character range, e.g., a method call.
<b>Presentation</b>	<i>code view</i>	The editable source code view is augmented with metadata.
	<i>existing view</i>	Other existing views in an IDE (e.g., a package explorer) are augmented.
	<i>separate view</i>	A separate view is created just to present the information of interest.
<b>Persistence</b>	<i>internal</i>	The metadata is stored directly in the source code file (e.g., using a comment).
	<i>external</i>	A separate file, database or server is used to store the labels.
	<i>none/unknown</i>	The metadata are only presented to the user, but not stored; or a method of persistence was not mentioned in the article.

Useful metadata can be collected by execution of the program, using some form of dynamic analysis. These approaches are marked as *runtime*. The analyzed program must be buildable (which is often a problem [7]) and automated tests should be available (or the program must be executed manually).

For tools utilizing the *human* source, a programmer must purposefully enter the metadata with a sole intention that they will improve program comprehension. This is expensive on human resources. On the other hand, *interaction* data are collected automatically, possibly without the developer even knowing it (although that would be unethical). Using heuristics, these tools can infer relationships between artifacts from captured keystrokes, mouse actions, or even eye gazes [8].

As software engineering is not an individual activity, collaboration artifacts are formed naturally as the team communicates and collaborates. These artifacts include e-mails, instant messages, forum posts and VCS commit messages. These artifacts are often poorly or nowise connected with the relevant source code. The purpose of *collaboration* approaches to code labeling is to fill this gap.

Many tools use a combination of multiple methods. For example, a static analysis may be used to assign source code artifacts their documentation; then a user must manually confirm or reject the suggested links [9].

### B. Target

The purpose of source code labeling is to assign metadata to a particular piece of code. Subject of the “target” dimension is what that “piece of code” means.

This is quite a problematic question, as there are two separate views: file-based and element-based. Some tools assign metadata to files, lines and character ranges. Other assign them to classes, methods, variables, method calls, etc. These views are often mixed in one tool. Furthermore, it is not clear whether a code bookmark, labeling a line containing just a variable declaration, relates to the line or to the declaration. Therefore, we decided to mix the views in our taxonomy.

The attributes are sorted according to granularity. A *folder* represents a package in some object-oriented languages. A *file* often corresponds to a whole class. Method and function definitions are *multi-line* elements. Elements considered *line* include variable declarations. We decided to consider method calls and variable usages *line parts*.

### C. Presentation

Once the metadata were retrieved and associated with a proper source code segment, it should be presented to the developer in order to be useful.

One of the best places to show code-related data is obviously the main, editable source *code view* of an IDE. This is the place which draws the most attention of a programmer, occupies a large screen portion and offers many existing features (e.g., code completion). The code editor can be augmented by various coloring (see Fig. 1), visual overlays (like a box surrounding a piece of code) or images. Harward et al. [10] call them “in situ” visualizations. Syntax highlighting may be considered a common visual augmentation [11]. We decided to regard also gutter/ruler annotations (icons in the left or right code editor margin) as a *code view* presentation.

Fig. 1. A simple example of *code view* presentation: DepDigger [12] uses background coloring to indicate the understandability of source code parts according to the dep-degree metric.

Except for the source code editor, modern IDEs offer various supplemental views like Package Explorer, Favorites or Class Hierarchy. Plugins can augment *existing views* by additional information. For instance, packages and classes in a tree view may be augmented by colored squares according to a metric [13].

Some tools, despite associating a part of code with additional information, display the association in a *separate view*, or even window. In a better case, clicking a particular widget in this view automatically opens and focuses the code of interest in the source code editor. Otherwise, the user must manually open and find the code according to the displayed element name.

#### D. Persistence

The association between the code and the label, and sometimes also the label data themselves, can be saved to a permanent storage.

1) *Rationale*: There are three possible reasons for persistence.

First, in the case of fully automated static *code* and *collaboration*-sourced techniques, the process of retrieving and associating metadata can be resource-intensive. The storage acts as a cache<sup>2</sup>.

Second, the *runtime* and *interaction* data are partially a product of human work. Each program execution and IDE interaction can be unique. It is therefore desirable to save at least the data like traces or interaction logs. Once they are persisted, the analysis and association process can be performed every time when necessary.

Third, the persistence is an absolute requirement in the case of *human*-sourced metadata. A tool must not repeatedly ask a programmer to describe code, if exactly the same information had already been entered for the same piece of code, using the same tool.

2) *Persistence Methods*: The labels can be stored in a source code file itself. The association with the target element is thus implicit through the position of the label in the code. A typical example of *internal* persistence method is a specially formatted comment.

*External* persistence means labels are stored separately from the source code file. They can be saved in an XML file, or a

database management system (DBMS), accessed either locally or through a server.

Finally, the persistence method *none/unknown* denotes the labels are either not stored permanently, or persistence was not mentioned in a given article at all. If a tool produces only reports or exports which cannot be subsequently loaded, it was also incorporated into this category.

## IV. APPROACHES AND TOOLS

In Table II, we can see an overview of all reviewed approaches and tools, which answers **RQ1**. Now we will briefly describe each of them. The approaches will be grouped by their primary “source”.

### A. Human

A concern is a piece of information about a code element, such as a feature it implements or a design decision [32]. ConcernMapper [14] is both an Eclipse plugin and a framework to associate parts of programs with concerns, both through a GUI (graphical user interface) and an API (application programming interface).

The eMoose approach [15] allows tagging of API usage directives, like state restrictions or locking, in JavaDoc comments. Subsequent highlighting of calls to such methods in an IDE improves awareness of programmers, who then spot errors quickly.

Pollicino [16] is a plugin for collective code bookmarks, providing a more feature-rich version of classical source code bookmarks found in the majority of IDEs.

SE-Editor [17] makes it possible to embed web pages in the source code editor of the Eclipse IDE. The web page is embedded using a comment beginning with `/**`, followed by an URL. This might be useful to display code-related diagrams, tutorial videos, etc.

Spotlight [18] is an IDE plugin to tag source code with concerns. Each concern can be assigned a color, which is then displayed in the left gutter (margin) of the source code editor. Thanks to this, a programmer can more easily identify where the given concern is located in the program.

TagSEA [19] integrates waypoints and social tagging into the Eclipse IDE. Programmers note waypoints – places worth marking and sharing – into the source code as comments in the form `//@tag tagname : message`. Hierarchical tags and metadata (author, date) are also supported. Collections of waypoints can be connected into routes to create source code guides.

### B. Code

DepDigger [12] visualizes the measure (metric) dep-degree by changing the background color of source code elements – on a scale ranging from white to red – in a code view.

RegViz [20] visually augments a regular expression in-place, without a need for a separate view. For example, groups are underlined and labeled with a group number.

Stacksplorer [21] visualizes method’s callers in a column on the left of the code editor view, callees in the right one.

<sup>2</sup>Suppose collaboration artifacts are already persisted in external systems.

TABLE II  
LABELING APPROACHES AND TOOLS.

Article	Source					Target					Presentation			Persistence		
	human	code	runtime	interaction	collaboration	folder	file	multi-line	line	line part	code view	existing view	separate view	internal	external	none/unknown

Miler [28]	□	■	□	□	■	□	■	□	□	□	■	■	■	□	■	□
Rationalizer [29]	□	□	□	□	■	□	□	□	■	□	■	□	□	□	■	□
101companies [30]	■	■	□	□	□	□	■	■	■	■	□	□	■	□	■	□
Code Bubbles [31]	■	■	■	□	□	□	■	■	■	■	■	■	■	□	■	□
CoderChrome [10]	□	■	□	■	■	□	□	■	■	■	■	□	□	□	□	■

Graphical overlays may be shown to visually connect the current method definition with the left column and method calls in the source code view to items in the right column.

Traceclipse [22] and TraceME [9] are traceability management recovery tools. They link source artifacts (like documentation) to the target artifacts (usually source code). In the mentioned tools, the linking is performed based on the textual similarity, using IR (information retrieval) methods.

### C. Runtime

GUIA [23] annotates GUI-related method calls with GUI snapshots of a selected widget at the time when this method is called. This facilitates the navigation between the dynamic user interface world and the static source code world.

The next three approaches belong to a group of “in situ visualizations” – small graphical elements displayed directly in the source code editor. Impromptu HUD [11] displays a realtime clock-like visual near each scheduled function,

informing the programmer when the timing event will fire. An in-situ profiler [1] shows small diagrams with runtime performance information next to method declarations and calls. Code sparklines [24] are small charts depicting values of a particular numeric variable over time.

Senseo [13] gathers and displays dynamic information in static views of an IDE. Information like methods’ callers, callees, dynamic (overridden) argument types and return values are shown in a tooltip of a method in the code view. Selected metrics like execution frequencies, object allocation counts or memory consumption can be viewed in gutters/rulers (using heatmaps) and the package explorer (numbers). Dynamic collaborators of packages, classes and methods, and a Calling Context Ring Chart are displayed in a separate view. A controlled experiment demonstrated an improvement of maintenance correctness and speed when using Senseo [13].

#### D. Interaction

The CnP tool [25] proactively tracks, visualizes and supports editing of code clones in an IDE. Instead of a batch input of source files, the tool captures copy and paste operations in Eclipse.

HeatMaps [26] display artifacts with a background color on a scale from blue to red, according to various numeric values assigned to them. The values are, for example, the recency and frequency of browsing and modification (obtained by instrumenting an IDE), artifact age, and a version count. The blue color means “cold” (e.g., least recently browsed), red “hot”. The approach is general and can be potentially applied in many tools and to various views in an IDE.

Interaction-sourced approaches are not limited to traditional mouse and keyboard operations. iTrace [8] analyzes eye gazes (using an eye tracker) in an IDE to infer traceability links between artifacts.

#### E. Collaboration

Deep Intellisense [27] displays an interleaved list of relevant bugs, commits, e-mails, specifications and other documents for a given code element. Furthermore, a list of related people is shown. The lists are updated each time a user clicks on a code element, but they are displayed in a separate view. Rationalizer [29] integrates similar information directly into the code editor. On the right side of each source code line, it shows three columns: when this line was last modified, who, and why changed it. On the other hand, it processes only data from a VCS and an issue tracker.

Miler [28] is a toolset to retrieve, process and associate e-mail data to source code artifacts. E-mails are assigned to a source code based on textual analysis. Information about e-mails relevant to a class is displayed in the IDE’s package explorer and rulers.

#### F. Mixed Approaches

The following approaches use multiple sources of information, without any of them being dominant.

10lcompanies [30] is a software chrestomathy – a collection of many implementations of one system using various technologies, stored in a repository and linked with metadata. Metadata like an implementation language, dependence on a technology, features, and a highlighting renderer are assigned to files or file fragments using a rule-based DSL (domain specific language). The assignment can be performed according to criteria like a file extension, a regular expression for file content, or even by a separate script [30]. For example, all classes in files called “\*.java”, ending with “Listener”, could be assigned the “observer design pattern” label.

Code Bubbles [31] is a working-set based IDE using fragments called bubbles instead of traditional file-based views. It supports various forms of labeling, ranging from arrows between method calls and definitions, to small images (e.g., a literal “bug”) attachable to code bubbles.

CoderChrome [10] provides a generic framework for mapping between a metric and an in-situ augmentation. Examples

of such visual augmentations are background colors, glyphs at the beginning or end of lines, and underlining. Metrics can range from categorical to numeric ones, e.g.: a start or end of a block, the last author, the property of having a primitive type, the code age, and a line length.

### V. CHALLENGES

To answer **RQ3**, we will now present observations and lessons learned during the categorization and suggestions for future research based on these observations.

#### A. Filtering Metadata Can Be Necessary

18 of the reviewed tools display various visual annotations and overlays directly in the source code view. Although the idea of tight integration of the source code and metadata is appealing, let us perform a thought experiment: Imagine these 18 approaches are implemented as plugins of one IDE, all installed and enabled at the same time. The amount of metadata could overwhelm the developer, causing more harm than good. It would be interesting to substantiate the thought experiment and perform a real case study with actual plugins. However, since many plugins are unstable academic projects and they are implemented for various IDEs, a reimplementation of many of them would be required.

Suppose the study showed us the amount of metadata is overwhelming. One option to tackle this is to turn the plugins on and off manually each time the developer needs a particular kind of information. This interrupts the programmer and causes additional mental overhead. Therefore, we can expect the majority of tools would not be used at all.

Ideally, the relevant metadata would be shown only when it is necessary. Each tool should formally provide a list of source code characteristics, task kinds and other relevance indicators – in which situations and contexts is this tool useful. The IDE would then calculate numerical relevance based on these characteristics and display only metadata with a relevance higher than a given threshold.

#### B. Evolution Needs to Be Taken into Account

Both the source code and metadata evolve over time. Each “persistence” type has its advantages and disadvantages regarding evolution.

If a piece of metadata is stored using *internal* persistence, it is pushed to a VCS each time it is updated. This can cause unnecessary overhead during collaboration – e.g., during merging. On the other hand, if the source code itself changes (and the metadata remains valid), there is no referencing problem.

When using *external* storage, the target code part must be explicitly referenced. The most primitive example is referencing by a line number. However, as the source code file content changes with each revision, the original line number may no longer contain the same element. Reiss [33] compared various methods for tracking source code locations, e.g., storing an exact line content, a context of a few lines around the line, AST matching, a diff-based approach, and their combinations.

While some combinations of methods achieve correctness above 97%, none of them is 100% accurate. Furthermore, the performance (space to store the reference and time to compute it) must be taken into account.

Using neither internal nor external storage solves the problem with evolution. However, it is generally advisable only for the *code* source (static analysis). For example, not storing metadata from dynamic analysis causes data loss as soon as the tool is closed.

In the reviewed articles, the effects of evolution, especially what happens if the source code itself changes, were rarely discussed. Empirical evaluations of tools taking evolution into account are necessary.

### C. What If Source Code Was Updated by Tools?

One particularly interesting observation can be made by looking at patterns in Table II. All approaches using *internal* persistence use purely *human* source of information. This means that automated tools do not write metadata to the source code files themselves.

We investigated this matter and described preliminary approaches which write the results of dynamic and static analysis directly into the source code, e.g., in a form of Java annotations [34], [35]. Another example is our recent prototype of a tool writing automatically generated Javadoc comments directly into source code files [36]. The mentioned approaches have advantages and drawbacks already mentioned in section V-B.

An interesting way to utilize *internal* persistence for non-human sources would be for IDE-independent program comprehension tools. A tool would temporarily annotate the source code with metadata, using annotations or comments. Therefore, they will be viewable with any IDE or even a simple text editor. Then, just before committing the modified source code to a VCS (or even sooner, when the developer would not need the metadata for comprehension anymore), the tool would remove the metadata, so the source code would remain clean. A disadvantage of this approach is its limitation only to textual metadata.

## VI. THREATS TO VALIDITY

The set of articles included in this study is by no means complete. Nevertheless, due to a large number of papers pertaining to a research area, collecting all related articles is often unrealistic and it is just important for the selected subset to be representative with respect to the research field [2]. We did not attempt to collect all available evidence – our main goals were to present at least a portion of approaches and tools using a preliminary mapping study, construct the taxonomy, and portray future challenges.

One could argue that the whole search process relies on one search resource – Scopus. However, during backward references search, also papers not indexed by Scopus were returned (secondary documents in their terminology).

Although the oldest included articles are from 2005, the selection was not artificially limited to any specific date.

Article selection and data extraction were performed by a sole researcher, which could produce biased results based on subjective decisions. Brereton et al. [37] suggest either independent extraction by at least two researchers and then a comparison of results, or checking the data afterward. In case of the lack of resources, a random sample of data may be cross-checked [3].

This paper is focused on tools presented in academic articles. However, there exist many industrial tools not described in papers, which could be also worthwhile to describe.

## VII. RELATED WORK

The research area of feature location partially overlaps with source code labeling – features can be considered one of possible source code labels. Dit et al. [6] reviewed 89 feature location techniques and classified them into a taxonomy. Our “source” dimension is similar to their “type of analysis”; and “target” to “output”. On the other hand, we were more concerned about the presentation and persistence.

The *runtime* source in our taxonomy indicates a use of various dynamic analysis approaches. Cornelissen et al. [38] reviewed 176 articles related to dynamic source code analysis. However, labeling parts of source code with obtained information was out of the scope of the mentioned survey.

The goal of traceability research [39] is to allow following links among various forms of software artifacts. Often the target artifact is source code, just as in the case of source code labeling. Two traceability tools, Traceclipse [22] and TraceME [9], were included in this mapping study.

In software engineering, recommendation systems [40] suggest relevant information based on the developer’s context. The context can be implicit (e.g., IDE history), explicit (a query) or a combination of them. Robillard et al. [41] recognized multiple design dimensions of recommendation systems. Their “data” dimension is similar to our “source”. They also recognized the “presentation” dimension, but in their case, it has values *batch* and *inline*.

Software artifact summarization [42] aims to create shorter descriptions from longer pieces of code, bug reports, mailing lists and discussions. In this sense, summaries can be considered source code labels obtained from the *code* and *collaboration* sources.

Source code labeling with the *collaboration* source often seeks to improve workspace awareness [43] – knowledge of the tasks and artifacts of others in a distributed software development team.

## VIII. CONCLUSION AND FUTURE WORK

In this systematic mapping study, 2,091 articles were assessed in total (including duplicates), from which 25 unique and relevant articles were selected and briefly described. A taxonomy of source code labeling containing four dimensions was created by the analysis of the articles.

Thanks to this survey, researchers can both get a quick overview of many source code labeling approaches, and find interesting future research directions by analyzing the gaps.

IDE developers can use it as an inspiration about which features to implement in their product. Practitioners struggling to analyze existing large codebases may find information about available tools and approaches here.

We identified three main challenges in the area of source code labeling. First, it will be necessary to filter the metadata displayed directly in the source code view only to the most relevant information – to prevent visual clutter. Second, the evolution of both source code and metadata need to be taken into account when designing tools. Finally, writing the metadata directly into source code files could be promising if implemented properly.

Note that some of the approaches described here are already implemented in industrial IDEs. Furthermore, there exist some features of commercial IDEs not described here. It would be interesting to compare code labeling features of common IDEs and academic tools.

This paper provided only a high-level qualitative overview of the topic. More in-depth analysis, like the quantification of the amount of necessary human work for each approach, is left as future work. We can also introduce more taxonomy dimensions and attributes.

# 9<sup>th</sup> Workshop on Scalable Computing

**T**HE Workshop on Scale Computing (WSC) is a result of evolution in the world of computing. It originated (as Workshop on Large Scale Computing in Grids; LaSCoG) in 2005. Next, cloud computing became popular and, in response to this new trend, Workshop on Scalable Computing in Distributed Systems (SCoDiS) emerged. The two workshops (under a joint name LaSCoG-SCoDiS) have been organized till 2014 (information about past events can be found here). However, the world of large-scale computing continuously evolves. In particular, data-intensive computations (known as “Big Data”) brought a completely new set of issues that have to be solved (in addition to those that exist since late 1990th and that still deserve our attention). Therefore we have decided to refresh the name of the event (to better represent the scope of interest). This is how the Workshop on Scalable Computing (WSC) came to being.

## TOPICS

- General issues in scalable computing
  - Algorithms and programming models for large-scale applications, simulations and systems
  - Large-scale symbolic, numeric, data-intensive, graph, distributed computations
  - Architectures for large-scale computations (GPUs, accelerators, quantum systems, federated systems, etc.)
  - Data models for large-scale applications, simulations and systems
  - Large-scale distributed databases
  - Security issues for large-scale applications and systems
  - Load-balancing / intelligent resource management in large-scale applications, simulations and systems
  - Performance analysis, evaluation and prediction
  - Portals, workflows, services and collaborative research
  - Data visualization
  - On-demand computing
  - Virtualization supporting computations
  - Self-adaptive computational / storage systems
  - Volunteer computing
  - Scaling applications from small-scale to exa-scale (and back)
  - Computing for Big Data
  - Business applications
- Grid / Cloud computing
  - Cloud / Grid computing architectures, models, algorithms and applications

- Cloud / Grid security, privacy, confidentiality and compliance
- Mobile Cloud computing
- High performance Cloud computing
- Green Cloud computing
- Performance, capacity management and monitoring of Cloud / Grid configuration
- Cloud / Grid interoperability and portability
- Cloud / Grid application scalability and availability
- Economic, business and ROI models for Cloud / Grid computing
- Big Data cloud services

# Techno-economic framework for cloud infrastructure: a cost study of resource disaggregation

Mozhgan Mahloo, João Monteiro Soares and Amir Roozbeh  
Cloud Technologies Department, Ericsson Research, Ericsson AB  
Stockholm, Sweden

{mozhgan.mahloo, joao.monteiro.soares, amir.roozbeh}@ericsson.com

**Abstract**—The rapid growth of data and high-dependency of industries on using data put lots of focus on the computing facilities. Increasing the efficiency and re-architecting the underlying infrastructure of datacenters, has become a major priority. The total cost of owning and running a datacenter (DC) is affected by many parameters, which until recently were ignored as their impact on the business economy was negligible. However, that is not the case anymore, as in the new era of digital economy every penny counts. The market is too aggressive to ignore anything. Hence, the economic efficiency becomes vital for cloud infrastructure providers despite their size. This article presents a framework to assess cloud infrastructure economic efficiency, taking into account three main aspects: application profiling, hardware dimensioning and total cost of ownership (TCO). Moreover, it presents a cost study of deploying the emerging concept of disaggregated hardware architecture in DCs based on the proposed framework. The study considers all the major cost categories incurred during the DC lifetime in terms of both capital and operational expenditures. A thorough cost comparison between a DC running on a disaggregated hardware architecture with one running on a traditional server-based hardware architecture is presented. The study demonstrates the evolution of the yearly cost over DC lifetime as well as a sensitivity analysis, allowing to understand how to minimize the cost of running cloud. Results show that, lifecycle management cost is one of the main differentiators between two technologies. Moreover, it is shown that in the presence of heterogeneous workloads, having a DC based on a fully disaggregated hardware brings high savings (more than 40% depending on the applications) compared to the traditional hardware architectures independent of the hardware set-up.

**Index Terms**—datacenter cost, disaggregated hardware, total cost of ownership, hardware pools, reconfigurable hardware

## I. INTRODUCTION

The rapid digitalization of industries, combined with the rise of the Internet of Things (IoT) concept, are just a few factors forcing a vast increase of Information Technology (IT) capacity, such as compute, storage and networking in datacenters [1]. In consequence, global spending on datacenter (DC) systems and cloud computing is growing [1]. However, as current ratio between IT capacity and its related cost is already high, it will not be easy to deliver the required capacity in the future using current datacenter technologies and strategies, even by increased spending. Hence, decreasing the total cost of owning and running datacenters is of high interest.

These facts have led the IT community to search for ways to scale DC infrastructures beyond the cost and capacity limitations of today's architecture [2]. This requires technical advancements to be brought to life along with a perception of their financial impact. Any new technology should be

financially viable to survive in the competitive markets despite its technical excellence. Vendors must assure business profitability before investing on new technologies. Although we have been witnessing several significant IT's technological advancements in cloud area, there is very little insight on the financial impact of those advancements. In that sense, we argue that a methodology and framework for assessing the cloud infrastructure economic efficiency should be available.

From a technical perspective, we are seeing the DC architecture being fundamentally rethought to become more modular, flexible and smart. In the center of this architecture change is the concept of hardware resource disaggregation [4], whose flexibility not only brings new functional opportunities, but it is also seen as a promising step towards reduced total cost of ownership (TCO). There have been a set of early studies looking to application performance under this new architecture [4][5]. Although these studies showed that migrating certain applications can result in a decrease in performance, they have also pointed out that redesigning of applications with this architecture in mind could boost back application performance. While performance aspects will define/limit to some degree the exact shape of a disaggregated system, the cost will as well. However, there is limited work exploring the cost dimension of this paradigm.

To cover the gap in the current studies, in this paper, we present a methodology and a generic framework to assess cloud infrastructure economic efficiency, considering three main aspects: application profiling, hardware dimensioning and TCO. Moreover, using a simulation tool that implements the proposed methodology and framework, we present a comprehensive cost study of deploying the emerging disaggregated hardware architecture in DCs in comparison with the counterpart alternative of having traditional servers. We analyze the TCO of a DC, considering all the major costs categories incurred during the DC lifetime, both in terms of capital expenditures (CAPEX) and operation expenditures (OPEX). The results of our cost study show considerable cost benefits of deployments of disaggregated hardware architecture compared to the traditional server-based architectures (i.e., more than 40% depending on the applications type).

The remainder of this paper is organized as follows. Section II presents the related work. Section III details the methodology and framework used for the cloud infrastructure economic efficiency assessment. Further, Section IV introduces the different architecture deployment scenarios along with the case studies and assumptions considered in our study. Section

V discusses the cost study results of the different scenarios. Finally, Section VI presents final conclusions and future work.

## II. RELATED WORK

The extensive amount of studies addressing cost (in)efficiencies in DCs confirms the high importance of this aspect for DC and cloud providers. [6] evaluates the impact of data-centric workloads on the design of DC. Their observation suggests heterogeneity in the DC, in which running a job on the most cost-efficient server reduces the overall cost. In [7], the cost benefits of software-defined DCs over the traditional hardware dependent design are presented. [8] compares the TCO of a private cloud (based on the dynamic infrastructure) with public cloud alternatives and conventional server models. Their results show that the considered private cloud implementations can be up to 80% less expensive than public cloud options over a five-year period and nearly 90% less than a traditional server approach.

The concept of hardware disaggregation has been increasingly explored in the recent years. The authors of [4] were one of the first to discuss resource disaggregation on a broad perspective. Lately, further work has been done to understand required technical components to realize resource disaggregation, such as [5][10][11]. Today's most tangible realization of a disaggregated system is seen in Intel's rack scale design (RSD) [12] which is part of the foundation of the first disaggregated system available in the market [13]. However, it is important to highlight that today there is not (yet) a complete disaggregated environment, hence it is essential to have a clear and thorough understanding of the ultimate cost and business impacts of this new model to assure vendors of the return on their investment.

Although there is an extensive list of articles analyzing DC TCO considering some specific scenarios, there is lack of a more complete model to assess cost. Moreover, studies on the cost impact of a disaggregated architecture model have been limited. Cost benefits of rightsizing DCs, which is a natural outcome of disaggregated architectures, is shown in [14]. In [15], TCO is analyzed for different processor types confirming benefits of having a new scale out processors. [16] presents the cost benefits of having shared infrastructure in DCs through the comparison of a four-server chassis with shared resources with the single server case showing substantial cost savings even on a small scale.

The work presented in [17] was one of the first to provide initial insights into the cost of disaggregated systems. The authors focused on the impact of memory disaggregation on CAPEX, and ignored the OPEX. [18] goes beyond [17] by providing an overall perspective on the cost impact of full resource disaggregation. However, it does not provide thorough insights on the assumptions nor the models.

None of the aforementioned studies offers a comprehensive framework for estimating cost of ownership of running a datacenter. The available frameworks lack the possibility of comparing TCO of different technologies, architectures, hardware configurations as well as the ability to evaluate the impact of running different application types.

## III. METHODOLOGY AND FRAMEWORK

To have a comprehensive techno-economic evaluation, a complete framework is required. DC planning consist of several stages that should be considered in a techno-economic model. This section introduces a high-level view of the main modules of the proposed framework, which contains three main modules; application profiling, hardware dimensioning and TCO calculator (see Fig. 1). Table 1 briefly describes each box of the framework shown in Fig. 1.

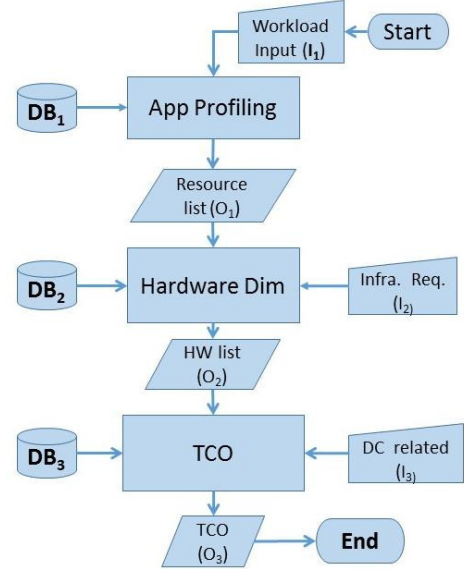

Fig. 1. Flowchart of proposed framework for cost evaluation of DC

### A. Application profiling

Knowledge of the types of applications that are planned to be served by the DC and their workloads, as well as their projected yearly growth are essential for dimensioning and defining how much and what type of IT hardware needs to be purchased. For example, some applications are compute-intensive, while others might be considered as memory-intensive or network-intensive. Therefore, this module is responsible for taking the applications and their workload requirements as input and estimate the minimum amounts of IT resources needed to serve those applications using the available information in the database (i.e., DB<sub>1</sub> in Fig. 1). The output of this module is in terms of the unit of various components, such as the number of CPU cores or MIPS, the volume of RAM or storage, and the amount of bandwidth to/from computing nodes. However, due to the diversity of existing applications, proposing a detailed application profiling model is outside of the scope of this paper.

### B. Hardware dimensioning module

Hardware dimensioning engine has access to the list of hardware that can be purchased, such as CPU types, RAM volumes, switch models and their specifications (stored in DB<sub>2</sub>). It takes the resource requirements generated by the application profiling module as an input to produce the shopping list containing the hardware and software that need to be purchased. It also defines supporting hardware required to run the cloud related equipment such as the number of chassis, racks, power supplies and so on.

For example, if parts of the output of application profiling modules show that 800 CPU cores are needed, then hardware dimensioning module tries to find the best CPU type to cover such requirements considering the cost and other criteria. The answer could be to purchase, 100 CPUs with 8 cores each, or 50 CPUs with 16 cores each, depending on their frequencies, speed, cache size, and so on. The most cost efficient option can be defined through the interaction with the TCO engine.

Table 1. Description of the boxes related to our framework

Box	Description
Workload Input ( $I_1$ )	Requirement related to applications to be run on the datacenter, e.g. applications type and load
Database 1 (DB1)	Keeps mapping between application type, load and amount of related hardware resources
Application profiling	Module for estimating amount of hardware resources based on workload input.
Resource list ( $O_1$ )	Estimated resource list based on workload input
Infrastructure request ( $I_2$ )	Requirement related to DC infrastructure which can affect hardware dimensioning and planning, e.g. power density limit
Database 2 (DB2)	List of available hardware resources to be purchased such as CPU types, etc.
Hardware dimensioning	This module will calculate the list of hardware resources to be purchased
Hardware list ( $O_2$ )	Output calculated by the hardware dimensioning which be used for cost calculation
DC related input ( $I_3$ )	DC related input which can impact the cost and should be given by the user to TCO calculator module, e.g. the location or size of DC
Database 3 (DB3)	Contains hardware related information, such as cost, their power consumption, failure rate, etc.
TCO calculator	Module for estimating TCO for DC
TCO results ( $O_3$ )	Ultimate results showing the estimated cost factors and total cost in details

### C. TCO module<sup>1</sup>

The results of hardware dimensioning will be sent to the TCO module, to estimate the TCO (i.e., including both CAPEX and OPEX aspects) of the DC for a lifetime of  $L$  years. The TCO model includes all the major costs categories incurred during the datacenter lifecycle (i.e., from the deployment phase, when a huge upfront investment is required, up to all cost aspects related to each operational process). Fig. 2 presents the generic TCO cost classification. If there is more than one set of hardware list fulfilling the application requirements, the most cost efficient option can be selected based on the results of TCO module.

#### 1) Pricing model

The price of equipment especially when they are recently introduced to the market is normally decreasing as a result of the increase in the production volume and the market purchase, as well as, maturity of the technology. On the other hand, the expenses related to the human resources such as technician salaries are increasing each year. Therefore, price erosion should be considered while calculating the TCO.

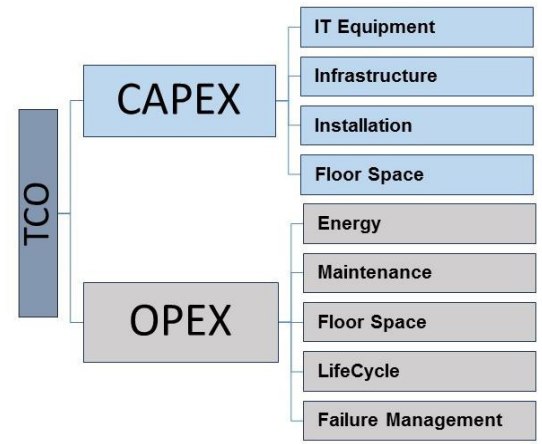

Fig. 2. Cost classification of TCO module

Price erosion during time can be calculated via learning curve used in the industry to predict the reduction/increase of the product cost [19]. However, finding the right learning curve for each product is hard. Hence, in this paper, a simple formula is considered for calculating the cost erosions (Eq. 1).

$$Pr_i = (1 + \alpha) Pr_{i-1} \quad (i \geq 1) \quad \text{Eq. 1}$$

$Pr_i$  represents the price in year  $i$  of DC lifetime, where  $Pr_0$  is the price of the component or starting charge in year zero. The coefficient of  $\alpha$  denotes the cost change factor in time. This parameter has a negative value when calculating the hardware prices and a positive number for human related resources such as salaries or energy cost. In reality  $\alpha$  might vary in time.

#### 2) Capital expenditures (CAPEX)

Th CAPEX covers the initial investment to set-up and run the DC and can be divided into three main parts, i.e., *IT equipment*, *Infrastructure* and *Installation* cost (see Fig. 2).

##### a) IT Equipment cost

The IT equipment cost is the sum of all expenses related to purchasing the IT related hardware such as servers, switches, CPUs, chassis, rack. This number can be calculated by multiplying the estimated volume of each hardware (i.e., output of hardware dimensioning module) by their prices (Eq. 2).

$$IT_{eq} = \sum_{k=0}^n V_k Pr_k \quad \text{Eq. 2}$$

Where  $n$  denotes the number of component types (e.g., CPUs, disks, servers).  $V_k$  and  $Pr_k$  represent the volume (i.e., number of units) and the price of equipment  $k$ , respectively.

##### b) Infrastructure (Cooling and Power) cost

A major part of any DC are the cooling and powering related facilities which their capacities need to be estimated based on the required workload in the upcoming years [20]. Some examples of such systems are; chillers, uninterruptible power systems (UPSs), heating, ventilation, air conditioning (HVAC), power distribution units (PDUs).

The infrastructure cost, which is a one-time investment, covers the expenses needed to purchase and install the cooling and powering facilities, and can be estimated by Eq. 3.

<sup>1</sup> It should be noted that the formulas presented here are simplified version of the versions used and implemented in the simulation tool.

$$P\&C_{in} = PUE \times P_{IT} \times Pr \quad \text{Eq. 3}$$

Power utilization efficiency (*PUE*) measures how efficiently energy is used, considering total energy including the power used for IT components, cooling, lighting and other overheads compared to the power consumed by the IT loads. *PUE* varies between 1 and 2, where the ideal value is 1. *P<sub>IT</sub>* represents the estimated total energy consumption of IT hardware, and *Pr* is the investment for power and cooling infrastructure for each kilowatt (KW) of consumed power.

#### c) Installation cost

The purchased IT equipment, needs to be installed in the appropriate location within the DC, with proper connectivity both to the network devices and power distributions units. The installation cost depends on the number of technicians required for the installation, their hourly salary rate, as well as time to install each equipment and can be calculated via Eq. 4.

$$IT_{Ins} = Tech_{sal} \sum_{k=0}^n V_k T_k \quad \text{Eq. 4}$$

Where *Tech<sub>sal</sub>* reflects the hourly salary of technicians who are installing the components and *n* denotes the number of component types (e.g., CPUs, memory slots, disks, servers) that need to be installed. *V<sub>k</sub>* and *T<sub>k</sub>* represent the volume (i.e., the number of units) and the installation time in hour for equipment type of *k*, respectively.

#### d) Floor space cost

The real state cost is covered in this category. In some cases, cloud infrastructure provider buys the DC's building or it has to make some initial investment to restructure the building to be suitable for its special purpose. In this case, any related investment is considered as part of the CAPEX, and should be added to the estimated cost of factors mentioned above. However, in the cases which building is rented, floor space cost can be considered zero in the initial year, and be added to OPEX as we discuss later.

### 3) Operational expenditures (OPEX)

OPEX refers to the expenses occurs during DC operation over a predefined time interval. The main OPEX components considered in this study are indicated in Fig. 2.

#### a) Energy cost

The energy cost which is one of the major challenges of DC owners can be obtained by summing up the energy cost of all the IT equipment during the project lifetime (*L*). Moreover, an estimation of the overhead power consumption (energy consumed by the lighting and cooling facilities) should be included in the calculation of energy cost using *PUE* coefficient, as shown in Eq. 5.

$$E_n = H_{year} \times PUE \sum_{i=0}^L Pr_i \sum_{k=0}^n V_{ik} P_{ik} \quad \text{Eq. 5}$$

*H<sub>year</sub>* and *Pr<sub>i</sub>* denote number of hours per year and energy price per kilowatt-hour in year *i*, respectively. Number of component types, the volume of each type and their power consumption in kilowatt in year *i*, are shown by *n*, *V<sub>ik</sub>* and *P<sub>ik</sub>*.

#### b) Hardware lifecycle management cost

IT equipment needs to be replaced as their performance degrades with time, or new generations of same hardware

comes to the market with better performance. These expenses are considered in this cost category and reflect the investment required to procure and install new equipment during DC lifetime. The number of equipment to be replaced is calculated based on their current volume as well as their lifetime. Lifecycle management cost can be calculated via Eq. 6.

$$LC = \sum_{i=0}^L \sum_{k=0}^n r_{ik} V_{ik} (Pr_{ik} + Tech_i^{sal} T_k) \quad \text{Eq. 6}$$

$$r_{ik} = \begin{cases} 1 & \text{if } i = x \times lc_{ik} \\ 0 & \text{otherwise} \end{cases}$$

Where *L* and *n* denote DC's lifetime and the number of component types (e.g., CPUs, disks, servers), respectively. *r<sub>ik</sub>* is the coefficient defining if a component of the type *k* reached the end of its lifecycle in year *i* and needed to be replaced in the current year of DC lifetime (*i*). If *i* is equal to a factor of component *k* lifecycle (*lc<sub>ik</sub>*), *r<sub>ik</sub>* is equal to one, and zero otherwise. *V<sub>ik</sub>* and *Pr<sub>ik</sub>* represent the volume (i.e., the number of units) and the price of equipment *k*, in year *i*. *Tech<sub>i</sub><sup>sal</sup>* reflects the technician salary in year *i*, and *T<sub>k</sub>* presents the number of hours needed to install equipment *k*.

#### c) Maintenance cost

A regular maintenance routine is needed to keep the DC's equipment and infrastructure up and running. This includes monitoring and testing the equipment, updating the software (including renewing licenses when needed), and the renewal of supporting components such as batteries. Maintenance cost consists of the human resource expenses as well as cost of supporting components. However, as it is hard to estimate this expenses with such a fine grain approach, we have considered a linear relation between cost of maintenance and CAPEX.

#### d) Floor space

As discussed, the cloud providers have two options to secure their floor space, i.e., buy/build the building or lease one. In the later case, the floor space cost is a yearly rental fee paid by DC owner to house its equipment<sup>2</sup>. It also includes the area required for placing the infrastructures. In this study, we first calculate the required area by estimating the total number of racks needed to serve the defined workloads, in addition to the space for placing cooling and power facilities. Then, this number is multiplied by an average rental fee per year to estimate floor space cost (see Eq. 7).

$$FS = \sum_{i=0}^L Pr_i (\alpha A_{rack} N_i^{rack} + A_{of}) \quad \text{Eq. 7}$$

Where *Pr<sub>i</sub>* denotes the yearly rental fee per square meter of DC in year *i*. Parameter *α* reflects the working area for technicians or corridors in front of racks. Moreover, *A<sub>rack</sub>* and *N<sub>i</sub><sup>rack</sup>* denote area needed for a rack in a DC and number of racks in year *i*, respectively. Finally, an extra area for placing the infrastructures, control systems and offices are also considered by adding *A<sub>of</sub>* to the equation.

<sup>2</sup> In this article, the DC owner is considered to be the entity owning all the IT related equipment. The facility/building where the data center is hosted is owned by a separate entity that charges a certain fee for the rental of the space.

#### e) Failure management cost

The cost of fixing the failures, such as replacing faulty components, or repairing them when possible is also part of the OPEX. However, estimating failure management cost is a very complex task and deserves a separate study.

### IV. DEPLOYMENT SCENARIOS

In this section, the two DC architecture scenarios considered in this paper are presented; the traditional server-based model, and the disaggregated-based model. Moreover, we present the DC workload case studies considered and detail the assumptions and parameters used in our study.

#### A. Server-based model (Hardware-Defined Infrastructure)

Traditional DC architectures follow server-oriented model, composed of pools of servers with fixed configuration. The fixed configuration offers limited sharing capabilities among resources, preventing them from being able to adapt to different workloads. Hence, DCs are usually planned to serve the peak demand. DC providers employ server virtualization technologies to implement resource sharing and improve utilization, while reducing their costs. However, still DCs operate at very low utilization rate [21] that means the resources paid for are not being utilized to their full capacity.

In this model, DC's lifecycle management becomes tightly bound to the lifecycle of a server. This causes problems (e.g. high cost) for providers who wish to upgrade part of their infrastructure for higher performance as the resources composing a server have different lifecycles. For example, if a DC provider wants to upgrade or increase capacity by using new memory type or CPU technology, in most cases, it ends up with replacement of the entire server, even though not all components need to be upgraded.

#### B. Disaggregated-based model

The hardware disaggregation principle breaks traditional physical server boundaries and considers resources as individual and modular components. Resources tend to be organized in a pool-based way, i.e. pool(s) of compute units, memory units, storage units, network interfaces, and other resources like accelerators. This brings greater modularity to a DC's lifecycle, which in turn allows the operators to optimize their resources in a more efficient way. In such environment, hosts are logically composed on top of hardware pools. Each resource pool can serve multiple hosts, and a single host can consume resources from multiple resource pools. This approach is allowing to maximize resource utilization by increasing the degree of resource sharing [5].

#### C. Case studies

We have considered three different type of applications, namely: systems applications and products (SAP) HANA, video on demand (VoD), and Mesos. These were chosen due to their different requirements, in terms of CPU and memory resources [22][23][24]. Each application is considered to have a different amount of load during day and night (See Table 2). The load variations of applications are adjusted in a way that total CPU and RAM requirement during day and night are nearly the same aiming to maximize the resource utilization at all the time.

We define three different scenarios based on the hardware architecture and technology used in the DC related to IT equipment: fully disaggregated architecture (DisAgg), server-based architecture with homogeneous set of hardware (Agg\_1Pod), and server-based architecture considering (three) different and specialized hardware silos, one per application (Agg\_3Pod). In the first two scenarios, the same type of IT equipment is dimensioned for all the applications meaning that resources can be shared among applications during different time of the day/night, while in the third scenario, each application has its own server type based on its needs.

Table 2. Application load profiles during day and night.

Application	Load unit	Day load	Night load
SAP	Server	42	30
VoD	Streams	1000000	400000
Mesos	Jobs	8000	12000

#### D. Input parameters and assumptions

##### 1) Application profiling

Table 3 presents the maximum amount of required CPU cores and memory volume (GB) per scenario for each application using the following methods. SAP HANA standard specification consists of one or more very large servers, where individual server configuration is equal to four CPUs (minimum 15 cores) and 1.5 TB of Memory. So, the hardware for the required workload can be calculated using Eq. 8 and 9 [22].

$$\text{CPU}_{\text{core}} = N_s \times 4 \times N_c \quad \text{Eq. 8}$$

$$\text{RAM}_{\text{volume}} = N_s \times 1500 \quad \text{Eq. 9}$$

Where,  $N_s$  represents the number of running servers (42 servers during day time and 30 servers during night hours, according to Table 2), and  $N_c$  is the number of cores per CPU (15 in this example). VOD requirements are calculated based on Eq. 10 and 11 [23], where  $S$  represents the number of simultaneous streams (see Table 2).

$$\text{CPU}_{\text{core}} = S \times 0.013 \quad \text{Eq. 10}$$

$$\text{RAM}_{\text{volume}} = S \times 64 \quad \text{Eq. 11}$$

In case of Mesos, there is a 1 to 8 relation between CPU core and RAM volume, meaning that for each CPU core, 8 GB of memory are required. Mesos needs at least three servers (or VMs) as follows; one bootstrap node (2 cores and 16 GB RAM), one master node (4 cores and 32 GB RAM) and one agent node (2 cores and 16 GB RAM). However, the recommended configuration is to have three master nodes which can support many agent nodes [24]. The number of agent nodes grows with the amount of jobs planned to be executed. We consider one job per agent node at each point of time, where a job can have many tasks [24].

Table 3. CPU, memory and storage requirement per scenario

Scenario		CPU cores	RAM (GB)	Storage (GB)
DisAgg		31534	262712	300000
Agg_1Pod				
Agg_3Pod	Pod 1	2520	63000	120000
	Pod 2	13000	64000	140000
	Pod 3	24014	192112	40000

## 2) Hardware dimensioning

Table 4 presents the results of hardware dimensioning for each scenario in first year based on the application loads in Table 2 and application's requirements in terms of hardware resources [22][23][24]. A ten percent increase in the load per year is also considered, which means new hardware needs to be purchased to accommodate the growth each year.

In the case of fully disaggregated architecture, compute, memory, network and storage sleds are used to accommodate the components such as CPU, memory (e.g. RAM), NIC cards and storage disks (e.g. HDD, SSD). Server-based scenarios are dimensioned based on commercially available servers ([25][26][27]) which can fulfill applications requirement with the lowest amount of wasted resources. For example, as the minimum requirement for SAP server is 4 CPUs and 1.5 TB of memory, a server with 4 CPU sockets and a large amount of memory slot should be selected (in this case [25]).

Table 4. Hardware dimensioning results

Component/Item	Lifecycle (years)	Volume in number		
		DisAgg	Agg_1Pod	Agg_3Pod
Rack	7	32	50	56
Compute sled (4 socket)	5	359	0	0
Memory sled (48 DIMM)	5	86	0	0
Network sled (4 NICs)	5	359	0	0
Storage sled (20 SSD)	5	10	10	10
Server (4 socket-48 DIMM)	3	0	500	44
Server (2 socket-24 DIMM)	3	0	0	670
Server (2 socket-12 DIMM)	3	0	0	325
CPU (16 cores)	3	0	2000	174
CPU (18 cores)	3	0	0	1339
CPU (20 cores)	3	0	0	650
CPU (22 cores)	3	1436	0	0
RAM (64 GB)	4	4128	0	0
RAM (32 GB)	4	0	14300	6012
RAM (16 GB)	4	0	0	16080
SSD (960 GB)	5	200	200	200
NICs (2*25 GB ports)	4	1436	2000	2163

In the case of Agg\_1Pod scenario, since workloads can share servers, all applications should be dimensioned based on highest requirements, meaning that all applications will use the model of [25]. While, in the case of Agg\_3Pod, servers with 2 CPU sockets are enough for serving VoD and Mesos workloads. However, due to their different CPU core to memory proportion, different servers with 24 and 12 DIMMs are selected for them. The storage is considered the same for all scenarios because it is already separated from servers even in today's DCs. Except one of the server models from [25] which needs two rack units (RUs), the rest of the servers/sleds fit in one RU of a two RUs chassis inside rack.

The number of racks are calculated based on the number of required chassis to accommodate servers/sleds. In many cases, DCs are limited in the amount of watt per square meters they can offer, due to a variety of reasons such as safety or existence of power infrastructure facilities. This is reflected in our assumptions by filling up only half of the racks (42 RUs).

The networking equipment, e.g. top of rack switches, aggregation switches, etc. are not considered in this study. However, high capacity connectivity requirement between compute and memories in disaggregated scenario, are added to the price of compute sleds.

Components lifecycles are calculated based on the architecture types, i.e. in case of server-based scenario, replacement window of a server is equal to the lifetime of the server's component with the shortest lifecycle, while in the case of disaggregated architecture each component has its own independent replacement window. Furthermore, the coefficient of cost change factor (i.e.,  $\alpha$  in Eq. 1) is considered to be constant (3 percent) for the whole DC lifetime. The  $H_{year}$  is equal to 8760 (i.e., hours per year) and  $Pr_0$  in Eq. 5 assumed to be 0.2 \$ in this study. A predefined lifetime of 3 to 5 years are considered for various components based on component warranty (CPU, SSD [28], and NIC [29][30]), known refreshment lifecycles (four years for RAM [31] and hard disk) (see Eq. 6). Moreover, in Eq. 7,  $Pr_0$  (i.e., yearly rental fee per square meters of DC) assumed to be 500 \$ and the coefficient  $\alpha$  (working area for technicians) is equal to 2. The failure management cost is excluded and not addressed here and we assumed that the maintenance cost per year is equal to 5 percent of the CAPEX.

Component prices used for cost calculations are selected and/or estimated based on the values in [25][26][27][32][33][34][35]. Since the hardware related to disaggregated scenarios is not commercially available, we derived the prices based on equations 12, 13 and 14.

$$P_{ComSl} = \alpha P_{ser} \quad \text{Eq. 12}$$

$$P_{MemSl} = \beta P_{ser} \quad \text{Eq. 13}$$

$$P_{NetSl} = \delta P_{ser} \quad \text{Eq. 14}$$

Where  $P_{ComSl}$ ,  $P_{MemSl}$  and  $P_{NetSl}$  represent price of compute, memory and networking sleds excluding the CPU, RAM or NIC, and  $P_{ser}$  reflects price of conventional server with similar configuration (e.g. same number of CPU sockets, RAM slots, etc.).  $\alpha$ ,  $\beta$  and  $\delta$  reflect the relation between the price of compute, memory and networking sleds, with the price of the server with the same capacity, respectively. Due to the need of high-speed networking in the disaggregated architecture, the prices are derived based on the cost of current servers plus added value of new boards and high performance networking (i.e.  $\alpha+\beta+\delta>1$ ). Due to the high demanding communication requirements between CPUs,  $\alpha$  has a relatively large value (1.3), while  $\beta$  and  $\delta$  are 0.3 and 0.2, respectively. This means that the price of a disaggregated setup is 1.8 higher than a server with the same capacity.

## V. COST ANALYSIS

We have developed a tool implementing the proposed framework based on the Java language, to be able to study and understand the cost impact of various technologies, infrastructures, and architectures while planning a DC. This tool is used to present some case studies, comparing TCO of new disaggregated hardware architectures and the conventional server-based hardware model for a DC. This section details the cost study results based on the assumptions discussed in the previous section.

### A. Total cost of ownership (TCO)

Fig. 3 illustrates the accumulative TCO for the three scenarios for a DC lifetime of ten years. The disaggregated scenario offers much lower TCO compare to two other

scenarios. The cost difference grows over time due to the impact of OPEX reduction in the disaggregated scenario.

Fig. 3. Accumulative TCO per year for all scenarios

Fig. 4 shows the TCO for the three scenarios for ten years of lifetime. It can be seen that using disaggregated hardware is possible to save around 40 percent in cost after ten years. The figure also highlights the importance of OPEX, as it is twice as big as the initial investment (CAPEX).

Fig. 4. Total cost for 10 years

### B. Cost breakdown and value argumentation

Fig. 5 presents the cost breakdown to assess the impact of each cost category described in Section III on the total cost for each scenario. These numbers allow identifying the main contributors of DC's TCO, which is essential for understanding where the reductions presented above come from. It becomes evident that lifecycle management (around 35%), IT equipment (around 30%) and energy cost (around 20%) are the most expensive elements of TCO. This means that reducing any of this cost factors can lead to a considerable saving in TCO for DC owners, while focusing on improving in other categories such as having less number of technicians, has a more negligible impact on the total cost reduction.

Fig. 5. Normalized TCO breakdown

Fig. 6 illustrates the expenses per cost category for three scenarios. The IT equipment cost is around 35 to 40 percent lower for disaggregated architecture. This is due to the lower amount of IT equipment purchased (32 racks compared to 50 and 56 in other two cases). A large reduction of the amount of required hardware comes from the increased hardware utilization of resource pooling (above 90% for both CPU and memory) shown in Fig. 7 and Fig. 8.

Fig. 6. Expenses per cost element for all scenarios

Though amount of assigned CPU cores is nearly the same in all scenarios, around 20 percent of CPU cores are wasted in the Agg\_3Pod scenario. This is caused by the overprovisioning of resources to accommodate peaks when the sharing of resources is not possible.

Fig. 7. Amount of allocated and wasted CPU cores during peak

Under-utilization percentage for memory increases to around 40 and 35 percent for Agg-1Pod and Agg-3Pod scenarios, respectively. This is both because servers are dimensioned for highest CPU utilization instead of memory, as well as the coarse granularity in the server's configurations and the limited boundaries for sharing the resources. This means that, when all CPUs are used in a server, residue memory is wasted and cannot be used by neighboring servers.

Fig. 8. Amount of allocated and wasted memory during peak

Fig. 9 shows an example of VM/server assignment to physical resources aiming to clarify increased utilization and fewer resource requirements of DisAgg scenario compared to Agg-1Pod. Two types of VM are considered, with 8 and 4 CPU cores as well as 32GB and 48GB of memory, respectively. Considering a homogeneous set of hardware, the minimum amount of resources to serve 2 VMs of each type is shown in Fig. 9. As shown, 4 RAM slot (8GB each) and 8 CPU cores are wasted in the Agg\_1Pod, while in DisAgg case, resources are fully utilized and the demand could be satisfied with less hardware (25% fewer cores and 16% less memory).

Fig. 9. VM allocation example for two scenarios

Lower amounts of components lead to the reduction of installation cost, as less time is needed to install, test and operate the resources. Increased utilization and less amount of IT resources can be translated to lower power consumption (around 35% to 40% based on Fig. 6). This leads to a lower power and cooling capacity, which reduces datacenter infrastructure cost in case of disaggregated architecture. Lower number of racks and hardware, as well as infrastructures brings around 20% and 40% of the reduction in the floor space and maintenance expenses for ten years of operation.

As shown in Fig. 5 and Fig. 6, one of the main contributors of cost reduction in case of disaggregated architecture is lifecycle management cost. Currently the lifetime of a

traditional server is equal to the lifetime of the component with shortest life (i.e. CPUs with 3). This leads to more frequent and unnecessary replacements of hardware for the rest of components with longer life. However, while managing independent pools of resources, hardware refreshment process is more efficient, as each part will be replaced at the end of its own lifetime. This means that, in the two server-based scenarios, motherboard, memories, NIC cards and CPUs need to be replaced every  $X_1$  years (CPU lifetime), while in case of disaggregation, CPUs are replaced after  $X_1$  years and memories after  $X_2$ , and NICs after  $X_3$  years (where  $X_1 \leq X_2, X_3$ ). Therefore, 50% reduction in lifecycle cost of DisAgg scenario comes from both having lower amount of hardware to replace, and more efficient replacement process.

The same argumentation is valid for hardware failure management, meaning that in case of failure of one component (e.g. CPU), the entire server needs to be replaced and will not be operable in case of server-based scenarios, while in disaggregated case, only the failed component need to be replaced, and the rest of hardware remains operational. Note that due to complexity and tight relation of failure management cost with software and platform layers, it is not assessed as part of the TCO in this article.

Fig. 10 illustrates the TCO evolution for all the scenarios showing the cost in a given year. The amount of yearly investment varies a lot from year to year, which is mostly due to the hardware refreshment windows. There is a jump in OPEX every three years when the CPUs (entire server in Agg-1Pod and Agg-3Pod) need to be replaced.

Operational cost of datacenter is always lower in case of disaggregated scenario, though the difference varies year by year. The other two scenarios are very similar both in terms of variation trend and exact cost values.

### C. Sensitivity analysis

The impact of variations in some input parameters and assumptions such as datacenter size and lifetime on the TCO fluctuation and savings are analyzed in this section. Fig. 11 shows the impact of increase in the price of disaggregated hardware, such as compute, memory and networking sled on the total cost of ownership of DC compared to the server-based scenario (see Eq. 12,13,14).

Fig. 10. TCO evolution per year for three scenarios

Red (DisAgg1) and yellow (Agg\_1Pod) lines are considered as the baseline of the comparison, as they depict the results presented earlier in Fig. 3. The green and blue lines depict the yearly TCO considering a 5 and a 10 time increase in the price of compute, memory and networking sled ( $\alpha, \beta$  and  $\delta$  in Eq. 12, 13, and 14) in case of disaggregated hardware architecture. As it can be seen, with up to 10 times increase in the hardware cost the TCO can still be compensated with the improvement in the utilization rate of server systems.

Fig. 11. Accumulative TCO for various disaggregated hardware prices

Fig. 12 shows the average yearly investment on datacenter for disaggregated and server-based scenario with homogeneous hardware (Agg\_1Pod) considering variation in datacenter lifetime. As shown, the average spending per year decreases by spanning the datacenter lifetime. This is caused by the fact that the initial onetime investment (CAPEX), which represents a large part of TCO, is spanned over a larger time period.

Fig. 12. Average yearly cost for different datacenter lifetime

Fig. 13 represents the cost savings in TCO by using disaggregation architecture compare to two other scenarios for a lifetime of 10 years for 3 different datacenter sizes; Small, Medium and Large. The large case is as the same size as the scenario presented in the previous section, while the workload requirement and IT equipment's are downsized by a factor of 5 and 10 for Medium and Small scenarios, respectively. It is evident that the larger the datacenter the higher the savings, due to better utilization which is the result of the increased level of resource sharing and economy of scale.

Fig. 13. Saving percentage when having disaggregation

The last part of our sensitivity analysis addresses the impact of having a single application on TCO (see Fig. 14). The TCO difference is much smaller when running only one application in a datacenter, as the hardware configuration can be optimized in both scenarios, and there is no benefit of sharing where disaggregated architecture has the most leverage. This can be translated as the benefits of multi tenancy in datacenters. The saving for single application scenarios is around 16% compared to 40% when having 3 distinct types of applications.

Fig. 14. Datacenter TCO for single application type

## VI. CONCLUSIONS

This paper presents a comprehensive techno-economic framework for estimating the cost of ownership of running a datacenter. The proposed framework supports a detailed cost comparison of different technologies, architectures, and hardware configurations. Moreover, it also allows to evaluate the impact of running different application types.

The first part of the paper focuses on detailing the framework and presenting the rationale behind it. The second part takes as a case study the prominent case of disaggregated hardware datacenter architectures and evaluates it towards the proposed framework. The study comprises a comparison of having separate pools of resources in a datacenter (as in a disaggregated architecture) towards having currently available server-based architectures with homogeneous and heterogeneous hardware configurations. The results show that cost savings of around 40% are achieved using disaggregated hardware for a 10 years' period of datacenter operation. The savings are a result of better utilization in disaggregated architecture as well as independent lifecycle management of components (due to components being arranged by pools instead of mixed as in traditional servers). Moreover, a detailed TCO breakdown is presented which allows datacenter operators to have a better understanding of their TCO dynamics to act upon minimization of CAPEX and OPEX during deployment and operational phases.

Finally, the impact of uncertainty in some input parameters and assumptions on the cost results is evaluated. It was shown

that the longer the datacenter lifetime, the lower the investment per year. Moreover, amounts of cost savings increases slightly by expanding the size of datacenters. Our results also show the importance of sharing the resources among multiple applications or tenants to maximize the benefit from disaggregated hardware architectures.

TCO assessments can give an idea of the cost associated to deploying and operating a datacenter. However, a thorough business viability assessment is needed to understand the return on investment and revenue stream. Therefore, a possible future direction for this study would be to include cash flow analysis considering various business models to guide the operators on how much investment should be done at which time for each technology to have the greatest profit

**Abstract**—Modelling of a database performance depending on numerous factors is the first step towards its optimization. The linear regression model with optional parameters was created. Regression equation coefficients are optimized with the Flower Pollination metaheuristic algorithm. The algorithm is executed with numerous possible execution parameter combinations and results are discussed. Potential obstacles are discussed and alternative modelling approaches are mentioned.

## I. INTRODUCTION

THIS article presents advances in the research introduced at FedCSIS 2015 DS-RAIT [1] and then presented at FedCSIS 2016 8th WSC [2]. The research relies on benchmarking the column-oriented database management system CODB. Model coefficients (weights) are optimized by the Flower Pollination Algorithm (FPA) [3]. Section II presents a sequence of steps that result in two regression equations without concrete weight values. Section III discusses how a model performance varies as a result of selecting different combinations of algorithm execution parameters in both variants. It also contains both model regression equations after supplying coefficients that achieved the highest accuracy. An outcome of the research is a mathematical model that expresses a database performance. It is created on the basis of empirical data collected by benchmarking the CODB database. In contrary to the previous study [2], technology-oriented factors were not covered. Study has shown that such components have low impact on overall performance. Thus, further research is focused on data features and features of request sequence issued against a database management system.

## II. MODEL CONSTRUCTION

The modelling process was conducted as a sequence of activities described in next paragraphs. Firstly, a database benchmark was executed numerous times with different, but regular, settings in order to isolate data about specific factors' influence on overall performance. Then, a data concerning specific factors was visualised as a scatter plot and curves in a three-dimensional space. Function shapes for specific factors are recognized by a manual visual graph assessment. The model has been split into two variants at this stage. The second variant enriches the first one by including an information about proportion between database operations. The first variant

skips this feature, whereas a second one uses it, in a form of a compositional variable components supplied directly to the regression equation. Both variants are compared to each other in terms of model accuracy. Second benchmarking round used random values obtained from the uniform distribution as input variables. Splitting the empirical data collection onto two stages was intended to ensure high quality of input data. A model formula with coefficients (weights) was coined as the result of both stages. Coefficients are optimized for the minimum error, i.e. the higher accuracy.

Model is created with the multiple regression technique with a priori known explanatory variable distributions. This method is based on a well-known and widely used linear regression model [4], with multiple input variables and a single output variable. Input parameters are called independent or explanatory variables, whereas an outcome is a dependent or explained variable. Created model is linear, although the explanatory variables are handled with polynomial functions. The linearity relates to the linearity of model coefficients in the model equation. The regression analysis has been chosen for the analysis because of its simplicity and straightforwardness.

The general regression formula for  $n$ -dimensional independent variables vector  $X$  and dependent variable  $Y$  is:

$$Y = w_n X_n + w_{n-1} X_{n-1} + \dots + w_1 X_1 + w_0 + \epsilon, \quad (1)$$

where  $\epsilon$  denotes an error term,  $w$  is a  $n + 1$ -dimensional coefficient vector, especially with the random term  $w_0$ . The error term is discussed in section III.

Model construction started from two fundamental factors acting as independent variables: a number of values ( $v$ ) and a number of columns ( $c$ ). Benchmark execution time  $t$  was set as an explained variable. Database benchmarking, that is a source of training data used for a model coefficient optimization, was limited by a number of constraints, such as maximum values for a number of columns and a number of values. A number of columns and a number of values both must be higher than 0 for obvious reasons. Both parameters are integers. A polynomial that expresses time depending from number of values will be referred to as  $t(v)$ , whereas time from number of columns will be  $t(c)$ . In this research,  $t$  was measured as a time of execution of 20 000 database operations. Initial column family state was 20 000, 30 000 or 40 000

tuples already existing at a start of measurement. A number of initially existing records depend on the ratio between different types of database operations, described in the next part of this paper. Regardless of parameters, each test has been executed 4 times. Values used for testing are randomly generated strings with lengths randomized from range [100, 10000] with unified distribution. The formula 1 with supplied parameters is:

$$\begin{aligned} t &= t(v) + t(c) + w_0 + \epsilon \\ &= w_n v^{dv} + w_{n-1} v^{dv-1} + \dots + w_{n-dv} v \\ &\quad + w_{n-dv-1} c^{dc} + w_{n-dv-2} c^{dc-1} + \dots + w_1 c \\ &\quad + w_0 + \epsilon, \end{aligned} \quad (2)$$

where  $n + 1$  is a number of coefficients,  $w_i$  constitute model coefficients, especially with the  $w_0$  random term.  $dv$  and  $dc$  are polynomial degrees for  $t(v)$  and  $t(c)$  polynomial functions, respectively.

The first variable, a number of values, denotes how many values are read or written while working with database. Although it may appear that usually this number is indefinite, this is not true for each case. There are many cases that have not only definite, but really low number of possible values. Such cases include, among others, gender, city or country, which are usually taken from dictionaries. The model assumes that in case of analysed field there is a finite value set. For the sake of model construction, a range of [1, 500] was used as the  $v$  parameter domain.

The second factor,  $c$ , denotes a number of columns involved in given request. For the write or delete requests it is a number of columns that are modified, whereas for the read request it is a number of columns that consists of a read tuple. Similarly as in case of number of values, a range of [1, 500] was used as a domain with similar assumptions. This range is supposed to handle most of typical Create-Retrieve-Update-Delete (CRUD) use cases.

In order to assess a general shape (a polynomial function degree) of functions for each parameter, an intermediate value within presumed domains were chosen and benchmarked extensively. Research started with the following values:

$$c, v \in \{1, 100, 200, 300, 400, 500\}.$$

A ratio between read and write operations was  $\frac{2}{1}$ , that is 67% of operations were read, and 33% were write. The very early result examination displayed that a shape varies more for lower values, than for higher values of  $c$ , so for the sake of a shape assessment, a value density has been increased in the lower part of the range:

$$c \in \{1, 5, 10, 30, 50, 100, 200, 300, 400, 500\}.$$

The first graph lets to extract first conclusions about the shape. The general trend is that a performance improves as the number of different values increase. But it is not the only observable trend. Results are more stable when the number of values increase. Standard deviation for  $v = 1$  is 10.10 (including values that are hidden on the graph), for  $v = 200$  it falls down to 0.22 and for  $v = 500$  it is only 0.11. When

it comes to a number of columns, operations time decreases as a number of columns grows, but does not approach 0 asymptotically. Somewhere between 200 and 300 columns (depending on  $v$ ) it starts to grow again. Probably this marks a moment when there is too many columns to be handled by operating system I/O smoothly and jumps between numerous files starts to be a visible cost. For lower  $v$  values, a higher dispersion for low  $c$  values is observable, than for higher ones. However, the impact is lower than in case of low  $v$  values.

Fig. 1. A scatter plot of  $t(v, c)$  with  $\frac{R}{W_i} = \frac{2}{1}$  with 3rd order polynomial regression curves and points for chosen  $v$  values ( $v = 1$  removed for clarity)

Fig. 2. A scatter plot of  $t(v, c)$  with  $\frac{R}{W_i} = \frac{2}{1}$  with 3rd order polynomial regression curves and points for chosen  $c$  values ( $c = 1$  removed for clarity; please note the reversed graph orientation)

Figure 1 presents data points for  $t(c)$  for constant  $v$  values with curves that present a supposed function shape for each value. Just as the main model, these functions were constructed using simple regression with FPA-optimized weights but they are used exclusively for presentation purposes. The trend is visible, with growing  $v$  values curves are smoother and almost linear near the end of the scope. This is an indication of a

higher result stability for higher values. The same was repeated for different  $v$  with constant  $c$  values and presented on Figure 2. Conclusions are similar to those for Figure 1.

Fig. 3. A  $t(v, c)$  with  $\frac{R}{W_i} = \frac{2}{1}$  plane with weights ( $c \in \{1, 5\}$ ) removed from graph for clarity; please note the reversed graph orientation)

On the basis of presented plots, a polynomial degree for both  $t(c)$  and  $t(v)$  was heuristically estimated as 3. This results in 7-dimensional optimization task for the algorithm, because the refined regression formula has 7 coefficients:

$$t = w_6v^3 + w_5v^2 + w_4v + w_3c^3 + w_2c^2 + w_1c + w_0 + \epsilon. \quad (3)$$

Besides number of columns and number of values, a very important performance determinant is a ratio between a different kinds of database operations. Three different kinds of operations were identified:  $O_R$  - read (fetching a tuple of values identified by a common key),  $O_{W_i}$  - insertion and  $O_{W_d}$  - deletion. These values compose a typical compositional data [10], which is a set of variables linked together so that they sum up to a constant value. The most intuitive representation for a ratio between different exclusive values of the same feature is a percentage, so a constant sum constraint is  $O = O_R + O_{W_i} + O_{W_d} = 100$ . Using a compositional data in regression model has a serious drawback. In order to ensure that regression model will be free from a noise, explanatory variables should be linearly independent from each other. This is not true for composite elements. When compositional data is to be used in regression model, it should be transformed to a set of abstract components that are not correlated, for example with the principal component analysis (PCA) or its' internal dependence should be weakened by removing one or more components. However, for the sake of this research, composite components were put directly into model, because there are only three components and removing even one of them would cause a model to infer on incomplete data. In order to monitor and control potential model accuracy degradation, results from model variants with and without compositional variable was compared.

In the first data discovery phase, 10 permutations of  $R/W_i/W_d$  values were considered, with each component

$\in \{0\%, 33.(3)\%, 66.(6)\%, 100\%\}$  so that the sum was always 100%. Assuming 240 tests executed for each of 10 proportions, it gives 2400 data points in total. For the majority operation ratios a plane has more or less common shape, similar to the one presented on the Figure 3. Rapid execution time growth in the lower parts of both crucial parameters is clearly visible as a red peak in the back right graph corner. There are areas of significantly higher results in the central and higher part of value number range. They have one feature in common: delete operation has dominated in these benchmark executions (100% or 67%). This is is unintuitive given the CODB storage architecture [2]. However, for a low column count (as in discussed cases), this may require to rewrite a high number of identifiers in order to move free space to the end of the area occupied by the value record. This is the most probable reason for exceptionally high execution times for test cases with high deletion ratio.

As it was mentioned previously, operation sorts ratios are expressed in percents, so their domain are integers from range  $[0, 100]$ . The  $O$  components were put directly into model equation:

$$\begin{aligned} t &= t(O) + t(v) + t(c) + w_0 + \epsilon \\ &= w_9O_R + w_8O_{W_i} + w_7O_{W_d} + w_6v^3 + w_5v^2 + w_4v \\ &\quad + w_3c^3 + w_2c^2 + w_1c + w_0 + \epsilon. \end{aligned} \quad (4)$$

### III. MODEL OPTIMIZATION AND RESULTS

In this section, the main optimization goal is to minimize an error. The residual sum of squares (RSS; also known as sum of squared error, SSE) [11] metric has been chosen to measure error value. It is calculated as a sum of error term values from each sample:

$$RSS = \sum_{i=0}^n (\epsilon_i) = \sum_{i=0}^n (t_i - m_i)^2, \quad (5)$$

where  $t_i$  is actual value of  $i$ -th benchmarked case,  $m_i$  is a corresponding model value and  $n$  constitutes a number of benchmark results. The residual standard error (RSE) is presented as an auxiliary error metric. Its advantage over the RSS metric is that it is expressed in similar orders of magnitude as the original data which makes it directly comparable to actual results. The RSE can be calculated on the basis of the RSS:

$$RSE = \sqrt{\frac{RSS}{n - p - 1}}, \quad (6)$$

where  $n$  is a number of samples (2400 and 4800 for the first and second modelling round) and  $p$  is number of parameters in each sample (7 and 10, for model without and with operations component, respectively). The  $n - p - 1$  value is called degrees of freedom and is commonly used metric in statistics.

The FPA [3] was used to optimize model coefficients. The optimization goal was to minimize the RSS. Execution parameters include a number of iterations, a number of flowers (solutions) and a switch probability. Number of iterations denote how many times a simulated pollination will be performed. Number of solutions defines how many solutions will

TABLE I  
MODEL COEFFICIENT SEARCH RANGES

Coefficient	Initial range	Refined range
$w_0$	$[-100, 100]$	$[-100, 100]$
$w_1$	$[-100, 100]$	$[-10, 10]$
$w_2$	$[-100, 100]$	$[-2, 2]$
$w_3$	$[-100, 100]$	$[-1, 1]$
$w_4$	$[-100, 100]$	$[-10, 10]$
$w_5$	$[-100, 100]$	$[-2, 2]$
$w_6$	$[-100, 100]$	$[-1, 1]$
$w_7$	$[-100, 100]$	$[-100, 100]$
$w_8$	$[-100, 100]$	$[-100, 100]$
$w_9$	$[-100, 100]$	$[-100, 100]$

be handled in each iteration. Just like in case of the number of iterations, the bigger the value is the better performance is. A switch probability defines a probability of the random long pollination. This parameter defines a compromise between a local-optimum protection and a close result space exploration.

For each model coefficient, search range was initially defined as  $[-100, 100]$ . Initial results displayed that particular coefficients tend to converge to specific order of magnitude. A rule of thumb is that the order of magnitude is reversed proportional to given coefficient's degree, for example a random term is expressed in unities or at most tens, whereas  $v^3$  weight always felt into  $10^{-6}$ . Table I presents refined ranges.

After search range refinements, the model coefficient optimization phase has been performed. Table II presents results from the first phase for a Cartesian product of three algorithm execution parameters value sets: number of iterations in  $\{1000, 2000, 3000\}$ , number of solutions in  $\{100, 200\}$  and switch probability in  $\{0.2, 0.5\}$ . These values were chosen arbitrarily on the basis of previous tries. Besides these basic execution parameters, FPA has other parameters that were not modified, default values are used. Their impact on model performance has been analysed in [12]. The *RSS* and *RSE* columns present the best (the least), error value achieved in algorithm executions with given parameter values. The *RSS diff* and *RSE diff* columns present how the error value has changed after compositional variable insertion to the regression equation. Difference is calculated as:

$$d = 100\% \cdot \frac{v_2}{v_1} - 100, \quad (7)$$

where  $v_1$  and  $v_2$  before and after values. A positive number indicates error growth, and a negative indicates a decrease, so that the lower value the better.

Table III presents the model performance after coefficients recalculation with randomly collected data set. For each parameters combination, a percentage improvement or regression in relation to performance from the corresponding row from Table II is presented in brackets in the same cells as *RSS* and *RSE* values. In both tables and both variants, a reversed dependency of the error from a number of iterations is visible yet weak. This conforms intuitive predictions that the more iterations the better, as the FPA algorithm is by design protected from result degradation. As  $p$  is growing, model accuracy falls down dramatically. For the simpler variant 1 the best results were obtained with almost all the parameter combinations, regardless of iterations or solutions number. The

more complex variant 2 required at least 2000 iterations to get the best result. In most cases, variant 1 is less accurate than variant 2. This happens despite theoretical risk of disturbances caused by mutual correlation of three variables. It is likely that a disturbance introduced by the correlated compositional variable components into the regression model makes less damage to the accuracy than a partial lack of information. A difference between phases 1 and 2 is much higher than anticipated and requires further investigation, because there are many possible reasons. More evenly distributed data than in the 1st phase was expected to increase model accuracy, but such a low *RSE* may indicate overfitting to the train data caused by a lack of a cross validation.

Coefficients obtained with the best solution from table III were put into equations (3) and (4) resulting with:

$$\begin{aligned} t = & -4.586E - 8 \cdot v^3 + 2.873E - 5 \cdot v^2 - 1.873E - 3 \cdot v \\ & + 4.674E - 9 \cdot c^3 + 4.536E - 6 \cdot c^2 - 6.034E - 4 \cdot c \\ & + 0.544 + \epsilon \end{aligned} \quad (8)$$

as the model variant 1 and:

$$\begin{aligned} t = & t(O) + t(v) + t(c) + w_0 \\ = & -0.301 \cdot O_R - 0.304 \cdot O_{Wi} - 0.286 \cdot O_{Wd} \\ & - 5.004E - 8 \cdot v^3 + 2.883E - 5 \cdot v^2 - 1.460E - 3 \cdot v \\ & + 3.513E - 9 \cdot c^3 + 5.398E - 6 \cdot c^2 - 7.249E - 4 \cdot c \\ & + 29.800 + \epsilon \end{aligned} \quad (9)$$

for the variant 2. Both weights vectors were taken from 3000/200/0.2 executions with *RSS* = 2478 and *RSS* = 2179 for variant 1 and 2, respectively.

#### IV. SUMMARY

This paper presents a mathematical model of a column-oriented database performance. Mandatory explanatory variables of the model are a number of columns and a number of different values present in a database and requests issued against it. As an optional component, explanatory variables set includes information about percentage share of different kinds of database CRUD operations. Data was collected in two phases. The first stage collected data necessary to assess function shape for particular factors whereas the second increased statistical value of the model input data. Number of columns and values explanatory variables model were assessed as third-order polynomial, which resulted in regression equation with 7 coefficients. A variant with operation ratios increased a number of coefficients to 10. Both problems were optimized with the FPA for minimal *RSS*. The switch probability parameter  $p$  turned out to have a significant impact on the model accuracy, making a model generated with  $p > 0.5$  much less accurate, especially with lower iteration counts. The best results were obtained with  $p = 0.2$ . An impact of the remaining parameters, iteration and solution counts, turned out to be lower, but still observable.

In the future, the model may benefit from trying out other metaheuristic algorithms, such as the Krill Herd Algorithm

		0.5	2478 (-95.94%)	0.72 (-85.75%)	2181 (-96.18%)	-11.99%	0.67 (-86.30%)	-6.94%

[13] [14]. Numeric optimization is also one of the most typical appliances of evolutionary and genetic algorithms [5]. A compositional value transformation such as Additive/Centered/Isometric Log ratio Transformation (ALR, CLR, ILR) [15] should be used against the operations compositional variable. This should improve model accuracy and let to perform analysis without comparing both model variants. Trying out different modelling techniques, like non-parametric methods [8] [9] and other prediction models, such as Radial Basis Function neural networks [6] [7], may improve accuracy. The model is intended to be a foundation for a database performance optimization, which means it should be as accurate and sophisticated as possible. However, it needs to maintain simplicity to be executed with satisfying performance. This balance between accuracy and execution time is crucial for the considered application.

**Abstract**—The increasing heterogeneity of cloud resources, and the increasing diversity of services being deployed in cloud environments are leading to significant increases in the complexities of cloud resource management. This paper presents an architecture to manage heterogeneous resources and to improve service delivery in cloud environments. A loosely-coupled, hierarchical, self-adapting management model, deployed across multiple layers, is used for heterogeneous resource management. Moreover, a service-specific coalition formation mechanism is employed to identify appropriate resources to support the process parallelism associated with high performance services. Finally, a proof-of-concept of the proposed hierarchical cloud architecture, as realized in CloudLightning project, is presented.

**Index Terms**—Hierarchical architecture, heterogeneity, cloud computing, resource management, coalition formation

## I. INTRODUCTION

OVER the last decade, large scale cloud services have been created by service providers such as Amazon, Microsoft, Google and Rackspace. In order to meet the needs of their consumers, cloud service providers have built data centers at unprecedented scales. In 2013 Steve Ballmer estimated that Google, Microsoft and Amazon are running roughly one million servers each [1]. These data centers are large industrial facilities containing computing infrastructure: servers, storage arrays and networking equipment. This core equipment requires supporting infrastructure in the form of power, cooling and external networking links. Reliable service delivery depends on the holistic management of all of this infrastructure as a single integrated entity: the warehouse-scale computer (WSC) [2].

The WSC design suggests that a **hierarchical** top-down model is used to manage large-scale cloud infrastructures. Meanwhile, the growth in cloud raises the question of how far we can push the limits of computing and communication

systems, while still being able to support effective policies for resource management and their implementation mechanisms. Software running on cloud environments is becoming increasingly complex, consisting of more and more layers. Thus, the challenge of controlling these large-scale systems is exacerbated. Control theory tells us that accurate state information, and a tight feedback loop, are critical elements for effective control of a system. In a traditional hierarchical organization, the quality of state information degrades as it is propagated from the bottom to the top; only local information about the state of a server is, by definition, accurate. Moreover, the value of this information is time sensitive, it must be acted upon promptly because the state changes rapidly. WSC-like architectures employ centralized resource management associated with the upper layers of the hierarchy. These models, based on monitoring, are costly, since the communication overhead can be more than two orders of magnitude higher than that required by decentralized resource management strategies as illustrated in [3].

The increasing **heterogeneity** of cloud servers, and the diversity of services demanded by the cloud user community, including access to High Performance Computing (HPC), are some of the reasons why it is imperative to devise new resource management strategies. These strategies should aim to significantly increase the average server utilization and the computational efficiency measured as the amount of computations per Watt of power, make cloud computing more appealing and lower the costs for the user community. Finally, they should simplify the mechanisms for cloud resource management.

Current cloud infrastructures are mostly homogeneous, centrally managed and made available to the end user through the three standard delivery models: Infrastructure as a Service

(IaaS), Platform as a Service (PaaS) and Software as a Service (SaaS). In the traditional PaaS and SaaS models, the user is completely unaware of the physical resources being used to run services. This is also the case for IaaS (if bare metal offerings are ignored), since the infrastructure offered is most often virtualized on top of commodity hardware. The drive towards connecting specialized hardware to the cloud (such as dedicated HPC machines and servers clustered on dedicated high-speed networks) and towards augmenting servers with specialized accelerators (such as Graphics Processing Units - GPUs, Many Integrated Cores - MICs, and Field Programmable Gate Arrays - FPGAs) has the potential to shift the operational dynamics of the cloud. By incorporating diverse hardware, the cloud becomes heterogeneous and an opportunity is created for offering discriminated services based on the operational characteristics of these different hardware types. Thus, the possibility exists for realizing the same service at different costs and at different performance levels. However, exploiting different architectures poses significant challenges. To efficiently access heterogeneous resources, to exploit these resources to reduce application development effort, to make optimizations easier and to simplify service deployment, requires a re-evaluation of our approach to service delivery.

In this paper, a hierarchical cloud architecture is proposed to address heterogeneous resource management and advanced service delivery. The remainder of the paper is organized as follows. Section II reviews the related work from the literature, while Section III introduces the hierarchical cloud architecture for heterogeneous resource management and service delivery. A self-organizing self-managing system is presented as a proof-of-concept of our proposed hierarchical cloud architecture in Section IV, and concluding remarks and future work are presented in Section V.

## II. RELATED WORK

### A. Hierarchical frameworks in cloud

Warehouse Scale Computers (WSCs) consist of thousands of commodity parts including processors, memory, disk, network, servers, etc., which are attached together to form a warehouse of interconnected machines [4]. The WSC is widely used as large-scale datacenter by Google, Yahoo, Amazon, Facebook, Microsoft and Apple [5]–[7].

In a WSC the hierarchical architecture is formed from a collection of physical machines and interconnects. A server is composed of a number of processor sockets, local shared and coherent DRAM, and a number of directly attached disks. The DRAM and disk resources within a rack are connected via a first-level rack switch, and all resources in all racks are connected through a cluster-level switch.

Within the physical hierarchy of a WSC, control theoretic feedback loop techniques are often used to enable system stability [8] and effective resource allocation [9], as well as to improve system performance [10] and power efficiency [11], [12]. The previous study [8] of using queuing theory with feedback control theory for performance guarantees in QoS-aware systems shows that the combined schemes perform

significantly to achieve QoS specifications in highly unpredictable environments. Performance control of a web server by using classical feedback control theory was studied in [10], achieving overload protection, performance guarantees, and service differentiation in the presence of load unpredictability. Wang et al. [11] proposed a cluster-level control architecture that coordinates individual power and performance control loops for virtualized server clusters. The higher layer controller determines capacity allocation and VM migration within a cluster, while the lower layer controllers manage the power level of individual servers.

### B. Heterogeneity in cloud

Limitations on power density, heat removal and related considerations require a different architecture strategy for improved processor performance by adding identical, general-purpose cores [13]. Unlike traditional cloud infrastructure built on an identical processor architecture, heterogeneity assumes a cloud that makes use of different specialist processors that can accelerate the completion of specific tasks or can be turned off when not required, thus maximizing both performance and energy efficiency [14]. Another previous study [15] proposes a resource allocation strategy in a heterogeneous cluster (integration of core nodes and accelerator nodes) to realize a scheduling scheme that achieves high performance and fairness.

Very recently, larger cloud infrastructure providers have been offering commercial heterogeneous cloud services, e.g. Amazon Web Services offers a variety of GPU and FPGA services [16]. Similarly, OpenStack also supports GPU and FPGA accelerators on provisioned VM instances [17]. As demand for better processor price and power performance increases, it is anticipated that larger infrastructure providers will need to cater for several of these processor types and specifically for the emerging HPC public cloud market [18].

Currently, many EU-funded projects are attempting to bring heterogeneous resources into cloud environments. The Hardware- and Network-Enhanced Software Systems for Cloud Computing (HARNES) project [19] brings innovative and heterogeneous resources (such as FPGAs, GPUs) into cloud platforms by improving performance, security and cost-profiles of cloud-hosted applications. Heterogeneous Secure Multi-level Remote Acceleration Service for Low-Power Integrated System and Devices (RAPID) [20] proposes the development of an efficient heterogeneous CPU-GPU cloud computing infrastructure, which can be used to seamlessly offload CPU-based and GPU-based (using OpenCL API) tasks of applications running on low-power devices (such as smartphones, tablets, portable/wearable devices, etc.) to more powerful devices over a heterogeneous network (HetNet).

Managing different architectures independently and integrating with an existing general purpose cloud architecture can be very challenging. The adoption of heterogeneous resources dramatically increase the complexity of an already complex cloud ecosystem.

### C. Resource management frameworks in cloud

Apache Mesos [21] is a platform for abstracting compute resources (e.g., CPU, memory, storage) away from machines (physical or virtual) and sharing commodity clusters between multiple diverse applications (e.g., Hadoop, Spark and MPI). Aiming to share clusters efficiently between different applications, Mesos introduces a two-level scheduling mechanism called resource offers. Over a series of resource allocation steps, the Mesos master decides how many resources to offer each application, while applications decide on which resources to accept and which computations to run on them.

Google Borg system [22] is a cluster manager running hundreds of thousands of jobs, from many thousands of different applications, across a number of clusters each with up to tens of thousands of machines. The Borg system consists of a logically centralized controller called the Borgmaster and an agent process called the Borglet that runs on each machine.

Mesos and Borg share the same fundamental approach of a centralized resource manager and multiple application frameworks are supported. Borg and Mesos work with bare-metal machines and, as such, are not directly concerned with virtualization. Furthermore, being monolithic schedulers, scalability is an issue.

Google Omega [23] introduces a new cluster manager scheduling architecture using shared state and lock-free optimistic concurrency control mechanisms.

Kubernetes [24] is an open-source platform for placing applications in Docker containers onto multiple host nodes, which runs both physical and virtual resources. The Kubernetes architecture is defined by a master server and multiple minions (nodes). The command line tools connect to the API endpoint in the master, which manage and orchestrate all the minions, and Docker hosts that receive the instructions from the master and run the containers.

Omega and Kubernetes have been developed to support multiple parallel schedulers and to place applications in Docker containers separately. However, there are still many outstanding issues with Omega and Kubernetes, such as massive message passing between the parallel schedulers, many house-keeping activities within each scheduler, without reference to server utilization.

### D. Self-organization self-management approach

Self-organization is a powerful technique for addressing complexity and borrows heavily from the natural sciences and the study of natural systems [25] [26]. It has been applied successfully in complex engineering projects [27] [28]. In the computing context, Heylighen and Gershenson [29] define organizations as structure with function and self-organization as a functional structure that appears and maintains spontaneously. Alan Turing [30] once observed that global order arises from local interactions. In this context, global order is achieved through propagation and adaptation. Components in a self-organizing system are mutually dependent and typically only interact with nearby components. However, the system is dynamic and therefore the components can change state to

meet mutually preferable, satisfactory or stable states [29]. As they meet these states, they adapt and achieve *fit* and this propagation of *fit* results in system growth. Structural complexity is driven by increasing the interchangeability and individuality of components capable of achieving *fit*. As more and more components adapt and become assimilated within the system, complexity increases to incorporate the individual characteristics of components. Growth only stops when resources have been exhausted and self-maintenance is the *de facto* purpose of the system. As such, self-organizing systems are defined by their robustness, flexibility, and adaptivity [31].

Self-management has been posited as a solution to complexity in IT infrastructure development generally and cloud computing specifically [32] [33]. It has its roots in autonomic computing. Such systems are designed to react to internal and external observations without human intervention to overcome the management complexity of computer systems [34]. As such, self-managing systems are described in terms of four aspects of self-management, namely, self-configuration, self-optimization, self-protection and self-healing [35].

The application of self-organization and self-management principles to cloud computing is at an early stage. Zhang et al. [34] posit that cloud computing systems are inherently self-organizing and while they exhibit autonomic features are not self-managing as they do not have reducing complexity as a goal. Marinescu et al. [36] argue that cloud computing represents a complex system and therefore self-organization is an appropriate technique to address this complexity. They propose an auction-driven self-organizing cloud delivery model based on the tenets of autonomy of individual components, self-awareness, and intelligent behavior of individual components. Extending work on self-manageable cloud services by Brandic [37] at an individual node level, Puviani and Frei [33] propose self-management as a solution for managing complexity in cloud computing at a system level. They propose using a catalog of adaptation patterns based on requirements, context and expected behavior. These patterns are further classified according to the service components and autonomic managers.

## III. HIERARCHICAL CLOUD ARCHITECTURE

An overview of a hierarchical cloud architecture for heterogeneous resource management and service delivery is shown in (see Fig.1). The resource management framework is composed of a logical hierarchy and is described in Section III-A. At the bottom level of this hierarchy a service-specific coalition formation mechanism is used to support the process parallelism of high performance services and this is presented in Section III-B.

### A. Hierarchical resource management

Our resource management framework is based on a loosely coupled, logically hierarchical, decentralized management model across multiple layers. Each layer can be considered as a self-contained system/component, which may be influenced

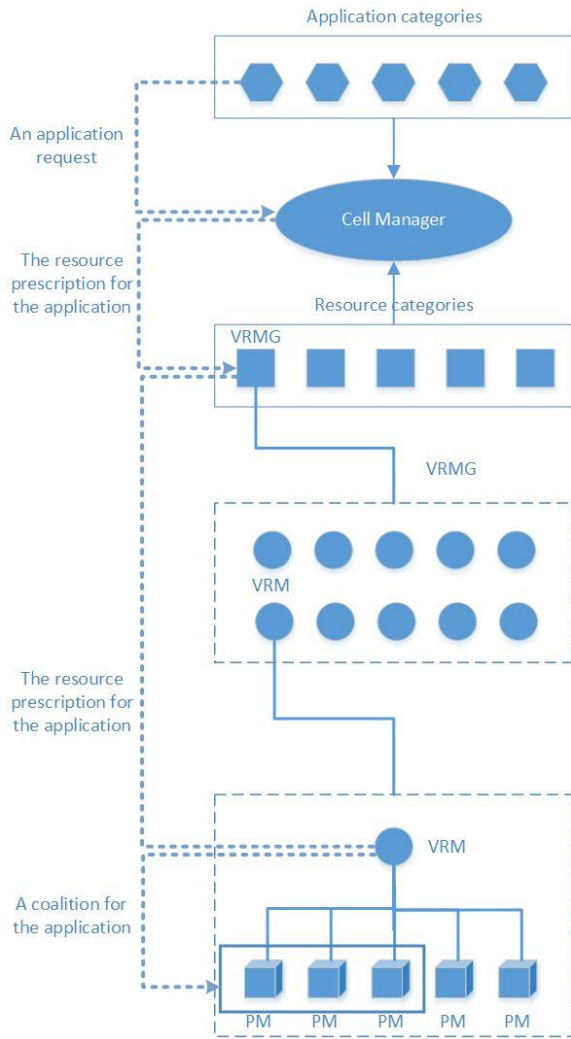

Fig. 1: Hierarchical cloud architecture for heterogeneous resource management and service delivery

by its neighboring layers for the purposes of system adaption and evolution overtime.

1) *Cell Manager:* At the top of the hierarchy, a Cell Manager partitions the space of heterogeneous resources into multiple zones. Each zone is composed of homogeneous hardware types and an associated resource abstraction method. In the CloudLightning architecture, heterogeneous resources are managed using various frameworks and platforms which are widely recognized to be effective and efficient for managing virtualized, containerized and bare metal resources, respectively [38]. For example, CloudLightning may use OpenStack Nova [39] to manage virtual machines on commodity servers, it may use Kubernetes [40], Mesos [41], and/or Docker Swarm [42] to manage containers on GPUs and MICs, and it may use OpenStack Ironi [43] to manage bare metal deployed on FPGAs.

The Cell Manager aims to make an optimal match between service requests and available resources based on multiple

objectives, such as service level agreements (SLA), quality of service (QoS), and specific application constraints (e.g., high performance computing or high throughput computing). Fuzzy pattern recognition [44], heuristic algorithms [45], [46] and evolutionary algorithms [47] are commonly used in multi-objective optimization for high-level (i.e., coarse-grained) resource allocation, which attempt to find an appropriate solution between system performance (e.g., response time) and user-oriented constraints (e.g., SLAs). Similarly, liner programming or dynamic programming can be used to solve VM placement problems [48]–[50] for low-level (fine-grained) resource placement, focusing on optimizing resource utilization and power consumption [51].

2) *vRack Managers within a zone:* Each zone contains a group of vRack Managers (vRMs), each of which is a local resource manager sitting at the bottom of the local resource management hierarchy. Within a zone, vRMs can interact with each other using shared or distributed state information. In the shared state approach, vRMs communicate with each other through a locally centralized mechanism to decide on the best candidate to host the next service. This mechanism may use multi-objective optimization algorithms, and bidding algorithms, for example. In the distributed state approach, vRMs cooperate with neighbors to relocate/reassign the management of physical resources between/among different vRMs to maximize utility for each individual vRM involved. This mechanism may use cooperative game theory and self-organization approaches, for example.

Our previous work suggested using a market-based combinatorial auction [52] mechanism for delivering an appropriate set of resources in response to service requests. In this work, which is an example of the shared state approach, servers of a WSC bid to host services based on the requirements of those services. This approach was shown to out-perform traditional centralized resource management techniques. However, this study did not take account of resource virtualization, nor were critical problems like overbidding and temporal fragmentation addressed in previous studies.

The work presented in Section IV, which is an example of the distributed state approach, examines a self-organizing and self-managing system developed to demonstrate how vRMs compete and cooperate with in order to achieve local goals while managing virtualized resources.

3) *vRack Manager:* The layers of the hierarchy between the Cell manager and the vRMs are designed to guide resource requests associated with specific services to locations within the cloud that would be "most suitable" to host them. This suitability is determined by the availability of resources and the selection of those resources to maximize the nonfunctional behaviors of the cloud. These behaviors include maximizing service delivery, resource utilization and quality of service and minimizing power consumption. The resource request guiding process is implemented using the concept of Perception (see Section IV-B1).

At the bottom level of the hierarchy, vRMs act as local resource managers, each managing a set of physical machines

(PMs). Since the number of these machine is limited and since their associated state information can be monitored frequently and accurately, tight feedback control loops can be established, resulting in efficient resource management. vRMs can make use of the state-of-the-art cloud techniques (e.g., virtualization, and containerization) and can tailor resource allocation to meet the need of specialized application workloads (see Section III-B).

### B. Service-specific coalition formation

In general, a description of the resources needed to execute an associated service is created by the Cell Manager and propagated downward through the hierarchy. This request is called a resource prescription - since it prescribes the resources needed to execute a particular service. Some services are capable of exploiting process parallelism and to facilitate an efficient execution, it is necessary to identify a number of independent, co-located, resources that can be used for their execution. When a prescription associated with such a high-performance service is received by a vRM, an appropriate group of physical/virtual resources, known as coalition, are identified and managed by the associated vRM as a coherent compound resource dedicated to delivering the associated service.

There are several strategies for forming coalitions in terms of the application workload characterization. For example, an HPC workloads may require an isotropic distribution of resources for maintaining a balanced execution, since the efficient execution of an application depends solely on the slowest component, due to the tightly coupled execution path. An isotropy preserving strategy in a vRM can be realized by spreading the required VMs among available servers. An example of this strategy is algorithmically given in Algorithm 1.

However, if the application's internal communication is intensive, using a single physical server to accommodate all of the VMs the associated with the resource prescription may be more appropriate. This strategy can be described by Algorithm 2.

## IV. PROOF-OF-CONCEPT: A SELF-ORGANIZED, SELF-MANAGED, SYSTEM

Fig. 2 depicts the high level architecture for the proposed self-organized, self-managed (SOSM) system.

The Gateway is a front-facing component of the SOSM system, abstracting the inner workings of the back-end components and providing a unified access interface to the SOSM system. The lifecycle of a Blueprint is initiated when a Blueprint is chosen from the Blueprint Catalog, possibly augmented with specific constraints, compiled into a set of Blueprint Requirements and sent via the *Gateway* to a *Cell Manager*. The Cell Manager (CM) identifies one or more solutions meeting those requirements. It then chooses one of these solutions and subsequently sends it to the corresponding vRack Manager Group (vRMG). vRack Managers (vRMs) in the same Group are capable of self-organizing to meet specific objectives, such as reducing power consumption. To

24:    else
25:       $C = \emptyset$ 
26:    return  $C$ 

```

---

do this, they take action based on their local knowledge of underlying resource utilization. vRMs are aware of changes in the environment including new and disappearing resources and adapt, on a negotiated basis, with other vRMs within the same vRMG to meet system objectives.

### A. CL-Resource

In pursuit of a service oriented architecture for the heterogeneous cloud, the SOSM system attempts to eliminate the concept of resource from its interactions with users. Instead, a service interface is created and utilization of all resources is the sole concern of SOSM system. To simplify the process of dealing with multiple physical and virtual resources based on commodity hardware in addition to specialized hardware resource types, the SOSM system uses a single abstract concept of resource, known as a CL-Resource. In response to a service request, the SOSM system identifies a specific CL-Resource that will be used for the delivery of that service. The physical realization of a CL-Resource depends on a number of factors. When dealing with commodity hardware, CL-

```

---

Resources can be bare metal, virtual machines, or containers. In addition, these virtual machines or containers may be created dynamically to suit specific services or they may be persistent and used to host a number of different services at different times. In the latter case, the CL-Resource is considered to be a static virtual resource. Networked commodity hardware may also be treated a single CL-Resource and either offered as a bare metal cluster or as a cluster pre-configured to host distributed applications, for example. Clusters of this type sitting on a dedicated high speed network constitute a specialized CL-Resource that may be employed to host distributed applications having a special requirement for low latency communications.

Servers with attached accelerators such as GPUs, MICs and FPGAs typically can not be virtualized due to the specific nature of the accelerators. As such, the server-accelerator pair are only offered currently as bare metal by cloud service providers. In the SOSM system, these server-accelerator pairs also constitute CL-Resources. In some cases, it may be possible to virtualize the server and to associate a partition of its accelerator with that virtualized component. In that case, the virtual component and the accelerator partition may be seen as a single CL-Resource. The granularity of a CL-Resource is thus dependent on what aspect of the underlying physical

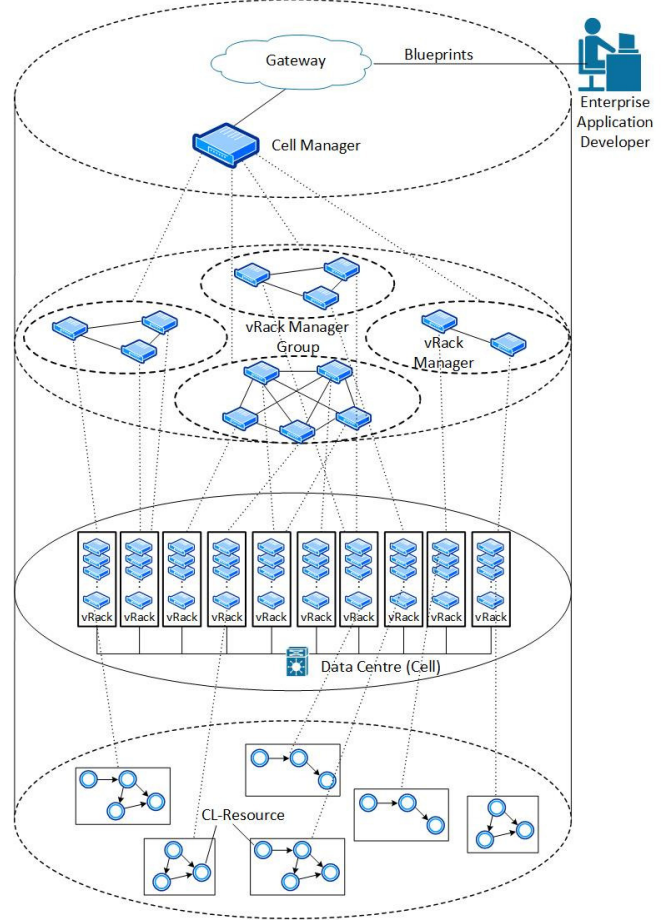

Fig. 2: Proof-of-concept: a self-organizing self-managing (SOSM) system overview

hardware is being exposed to the SOSM system.

An example of this can be seen in Fig. 3 which shows a MIC-world composed of four server-MIC pairs connected on a dedicated local network. The complete MIC-world may be exposed via its local resource manager to the SOSM system where it is seen as a single CL-Resource capable of running MIC-world services. In other configurations, the cluster of servers may be exposed as a networked cluster as described above. Yet, another option is to present collection of virtualized containers to the SOSM system, each representing a different CL-Resource. This concept of attaching resources to the SOSM system can be taken to the extreme by connecting specialized high performance machines, which may be composed of their own dedicated resource fabric. The characteristics of the resulting CL-Resources depend on how these machines are attached to the SOSM system. E.g., if they are attached in bare metal mode, they can be discovered and used to host services written explicitly to run on that bare metal hardware. If they are attached differently, the resulting CL-Resources may constitute entry points into the queuing systems of the local resource managers running on those machines.

Thus, CL-Resources can be categorized as follows:

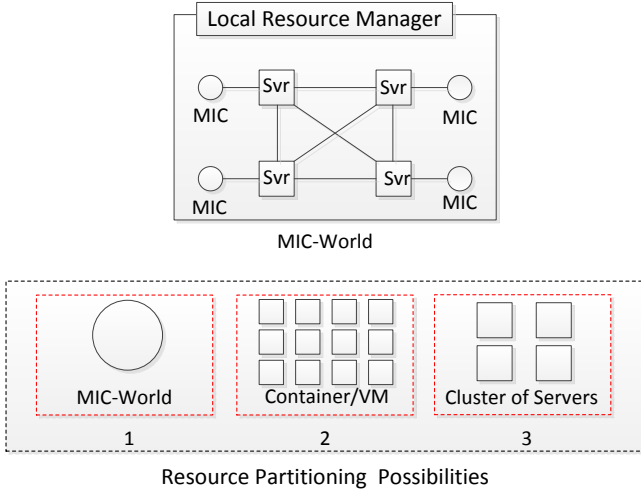

Fig. 3: CL-Resource Concept

- 1) Physical hardware as a single CL-Resource. This assumes that an appropriate management software exists for each hardware type within the SOSM system. The SOSM system can then use the corresponding APIs to manage this hardware resource.
- 2) Resource Manager (RM) as a single CL-Resource. A CL-Resource can be a resource manager, exposing the capacity and availability of its subsystem or cluster to the SOSM system. However, in this case, the SOSM system does not manage the subsystem or the cluster behind the resource manager directly. Instead, the SOSM system simply passes the appropriate resource prescriptions to the resource manager according to its real-time available capacities, and the resource manager takes care of the subsequent execution independently of the SOSM system.
- 3) A networked group of physical hardware as a single CL-Resource. There is benefit in representing hardware resources, of the same type, i.e.  $T$ , situated on a low-latency network, as a single CL-Resource under the control of the same vRM in the SOSM system. CL-Resources of this type can be placed under the same vRMG hosting CL-Resources representing individual physical hardware of type  $T$ . However, the CL-Resources representing the networked group and those representing the individual physical hardware, will usually be placed under different vRMs.

#### B. Self-organized, self-managed framework

A framework for a self-organized, self-managed, hierarchical architecture was proposed in [53].

1) *Self-management mechanism*: The CloudLightning SOSM system is composed of a number of components in each level in the hierarchy. Each of these components manages its own activity and communicates with neighboring components higher-up and further-down the hierarchy. Thus, a perception reflecting the ability of a component to accept new work is passed upwards and an impetus biasing the evolution

of the system is passed downwards, where it becomes part of a weighted calculation affecting the future behavior of the system. The activities associated with self-management include the local calculation of perception and impetus based on the information received from components higher-up and lower-down in the hierarchy. These two concepts are integrated into a single value, known as a Suitability Index. The goal of each component is to maximize its Suitability Index such that perception and impetus achieve dynamic status. In practice, this status can never be achieved since the arrival of resource requests continually perturb the system. At lowest-level in the hierarchy, vRMs manage collections of physical machines under their control. At this level, perceptions are derived from monitoring information and impetuses become associated with weighted assessment functions [53], determining the relative important of these functions in achieving the global system objectives.

Metrics, Weights, Perception, Impetus and Suitability Index can be expressed more formally as:

- A **metric** ( $m$ ) is a measure of a particular aspect of a components state.
- A **weight** ( $w$ ) is an influencing factor, usually towards a local goal.
- **Suitability Index** is a measure of how close a component is to the desired state, and hence how suitable its operating characteristics are for contributing to the global goal.

$$\arg \max_{\vec{w}, \vec{m} \in \mathbb{R}^N} \eta(\vec{I}(\vec{w}), \vec{P}(\vec{m})) \quad (1)$$

where  $\vec{w}$  is an N-dimensional vector of weights corresponding to the Impetus and  $\vec{m}$  is an N-dimensional vector of metrics obtained from the lower levels.

- **Perception** is a function of the metrics from the immediate lower level in the hierarchy.

$$\vec{m}^\ell = \frac{1}{N_{\ell-1}} \sum_{i=1}^{N_{\ell-1}} \vec{m}_i^{\ell-1}, \ell > 1 \quad (2)$$

where  $N_\ell$  is the number of components in the  $\ell$ -th level. For simplicity we choose the Perception of a component to be a function that averages metrics of its underlying components. The mean of the metrics of the underlying level is an approximation of the state of the underlying resources.

- **Impetus** is a function of the weights obtained from the immediate upper level in the hierarchy.

$$\vec{w}^\ell = \frac{1}{2}(\vec{w}^{\ell+1} + \vec{w}'^\ell), 0 \leq \ell < 3, \quad (3)$$

where  $\vec{w}'^\ell$  are the weights in the previous state and  $\vec{w}^{\ell+1}$  are the weights propagated from the upper level. For simplicity, we choose the Impetus to be the average of the weights obtained from the upper level with the current weights of the component. The averaging function is used to attenuate the influence of upper levels to lower levels in order for the system to undergo a smoother transition towards the global goal.

The  $\ell + 1$ ,  $\ell$  and  $\ell - 1$  represents the Cell Manager, the vRMGs and vRMs separately. The Cell Manager specifies a global goal state (e.g., to meet a specific business case), which can be expressed as weights and applied to the underlying vRMGs to steer their behavior in a particular direction, represented as  $\vec{w}^{\ell+1}$  in Eq.3. An analogous process takes place in each level in the hierarchy.

2) *Self-organization mechanism*: To achieve local goals and to accommodate resource requests, it is sometimes necessary for components in the same level of the hierarchy to cooperate and to exchange the management role of certain resource. This self-organizing process is driven specific, reconfigurable, strategies. Some self-organization strategies include:

- Dominate: the component with the greater suitability index has precedence and can demand another component of the same type, but with a lower suitability index, to transfer some resources.
- Win-Win: components may cooperate to exchange resources to maximize the suitability index of each.
- Least Disruptive: minimize disruption with respect to management and administration
- Balanced: maximize load-balancing among each cooperating component
- Best Fit: minimize server fragmentation and/or minimize network latency (this strategy may come from some vRM specific objectives)
- Any meaningful combination of the above.

An example strategy demonstrating "Win-Win" shows how the self-organization works within the SOSM system. The "Win-Win" strategy is triggered by service request arriving at a certain vRM, which has the largest Suitability Index, but lacks the available resources to fulfill this prescription. However, available resources will be present in the same Cooperative. Thus, the vRM initiates the procedure of sending requests to the other vRMs to transfer their resources. If the available resources, before acquiring the new ones are less than half of the prescribed, then the vRM will not acquire them. Instead it initiates the creation of a new vRM which will manage the available free resources, if any, together with any newly acquired resources. The aforementioned process can be described by the following algorithmic procedure:

However, this self-organization strategy can be improved by acquiring resources, when necessary, by the vRacks with the maximum Suitability Indices. By using this technique the suitability index of the vRacks that are required to provide resources is enhanced, because their management costs are minimized. Thus, increasing performance and reducing fragmentation. This process can be described by the following algorithmic procedure:

## V. CONCLUSION

This paper presented a design for a service oriented architecture of a heterogeneous cloud. The cloud, once a collection of commodity hardware, is becoming more and more heterogeneous with the addition of hardware of different types. The trend for hardware vendors to create more and more

            receive  $p_i$  from  $vRM_i$ 
             $required = required - |p_i|$ 
             $a = a \cup \{i\}$ 
             $t = t \cup p_i$ 
            if  $required \leq 0$  then
                remove exceeding resources from  $t$ 
                 $required = 0$ 
                break
        send request to vRMs in  $a$  to acquire resources in  $t$ 
        receive resource handlers from vRMs in  $a$ 
        if  $|p_j| \geq rp/2$  then
            return resource handles to Gateway Service
        else
            create new  $vRM_k$  with resources  $p_j \cup t$ 
            return resource handles to Gateway Service
    else
        return resource handles to Gateway Service

```

---

specialized offering, capable of providing faster, more accurate and more power efficient solutions, looks set to continue. The increasing demand for this hardware and for access to high-performance computing is driving Cloud Service Providers (CSPs) to make evermore exotic IaaS offering available as bare metal. In this type of transaction, the CSP effectively rents the hardware to the customer. In this transaction, the financial interests of both parties are presumably met. However, from a resource utilization perspective, nothing definitive can be said: the customer has no incentive to use the resource efficiently so long as his needs are being met; the CSP no longer has control over the hardware for the duration of the rental period.

In the CL system, CSPs no longer offer Infrastructure as a Service. Instead the CSP undertakes to provide software services to the customer - effectively executing services on their behalf. From this perspective, the hardware is hidden from the customer. The customer no longer is concerned with *how* solutions are provided, they specify only *what* they want done. Hiding the hardware from the customer gives control back to the CSP to decide on how best to respond to customer needs and to balance these needs with its own, such as maximizing resource utilization. If the cloud is heterogeneous, that is, if it is composed of hardware of different types, and if the same

**Algorithm 4**

Let  $j$  be the index of the vRack with maximum suitability index  
 Let  $rp$  be a resource prescription arriving to  $vRM_j$   
 Let  $p_j$  be the set of *free* resources belonging to  $vRM_j$   
 Let  $s$  be a vector containing the suitability indices of all  $vRM_s$  sorted in descending order  
 Let  $I_s$  be a vector containing the indices of vRMs with respect to vector  $s$   
**function** MAXSUITABILITYINDEX( $rp$ )  
    $a = \emptyset$   
    $t = \emptyset$   
   **if**  $|p_j| < rp$  **then**  
      $required = rp - |p_j|$   
     **for**  $k \leftarrow 2$  to  $N_v$  **do**  
        $i = I_s(k)$   
       send request to acquire free resources from  $vRM_i$   
       receive  $p_i$  from  $vRM_i$   
        $required = required - |p_i|$   
        $a = a \cup \{i\}$   
        $t = t \cup p_i$   
       **if**  $required \leq 0$  **then**  
         remove exceeding resources from  $t$   
          $required = 0$   
         break  
       send request to vRMs in  $a$  to acquire resources in  $t$   
       receive resource handlers from vRMs in  $a$   
       **if**  $|p_j| \geq rp/2$  **then**  
         return resource handles to Gateway Service  
       **else**  
         create new  $vRM_k$  with resources  $p_j \cup t$   
         return resource handles to Gateway Service  
       **else**  
         return resource handles to Gateway Service

---

service solution is available on a multiplicity of these hardware type, solutions with different cost/performance characteristics can potentially be offered to the customer. The complexity of managing resources in this way in an heterogeneous cloud environment should not be underestimated. An heterogeneous cloud at scale embodies many hardware types, each with different cost/performance/power profiles. This, together with attempting to satisfy the disparate needs of a large and varied customer community make the heterogeneous cloud a complex system. Complex systems cannot be managed effectively using a central resource manager. They need to employ tools suited for addressing complex systems. Self-organization and self-management are such tools and this is the approach taken by CloudLightning.

# International Conference on Innovative Network Systems and Applications

**M**ODERN network systems encompass a wide range of solutions and technologies, including wireless and wired networks, network systems, services and applications. This results in numerous active research areas oriented towards various technical, scientific and social aspects of network systems and applications. The primary objective of Innovative Network Systems and Applications (iNetSApp) conference is to group network-related events and promote synergy between different fields of network-related research. To stimulate the cooperation between commercial research community and academia, the conference is co-organised by Research and Development Centre Orange Labs Poland and leading universities from Poland, Slovak Republic and United Arab Emirates.

The conference continues the experience of Frontiers in Network Applications and Network Systems (FINANS), International Conference on Wireless Sensor Networks (WSN), and International Symposium on Web Services (WSS). As in

the previous years, not only research papers, but also papers summarising the development of innovative network systems and applications are welcome.

iNetSApp currently consists of tracks:

- CAP-NGNCS'17—1<sup>st</sup> International Workshop on Communications Architectures and Protocols for the New Generation of Networks and Computing Systems
- INSERT'17 - 1<sup>st</sup> International Conference on Security, Privacy, and Trust
- IoT-ECAW'17—1<sup>st</sup> Workshop on Internet of Things—Enablers, Challenges and Applications
- SoFast-WS'17—6<sup>th</sup> International Symposium on Frontiers in Network Applications, Network Systems and Web Services
- WSN'17 - 6<sup>th</sup> International Conference on Wireless Sensor Networks

# 1<sup>st</sup> International Conference on Security, Privacy, and Trust

**A**DMITTEDLY, information security works as a backbone for protecting both user data and electronic transactions. Protecting communications and data infrastructures of an increasingly inter-connected world have become vital nowadays. Security has emerged as an important scientific discipline whose many multifaceted complexities deserve the attention and synergy of the computer science, engineering, and information systems communities. Information security has some well-founded technical research directions which encompass access level (user authentication and authorization), protocol security, software security, and data cryptography. Moreover, some other emerging topics related to organizational security aspects have appeared beyond the long-standing research directions.

The 1<sup>st</sup> International Conference on Security, Privacy, and Trust (INSERT'17) focuses on the diversity of the information security developments and deployments in order to highlight the most recent challenges and report the most recent researches. The conference is an umbrella for all information security technical aspects, user privacy techniques, and trust. In addition, it goes beyond the technicalities and covers some emerging topics like social and organizational security research directions. INSERT'17 is intended to attract researchers and practitioners from academia and industry, and provides an international discussion forum in order to share their experiences and their ideas concerning emerging aspects in information security met in different application domains. This opens doors for highlighting unknown research directions and tackling modern research challenges. The objectives of the INSERT'17 can be summarized as follows:

- To review and conclude researches in information security and other security domains, focused on the protection of different kinds of assets and processes, and to identify approaches that may be useful in the application domains of information security
- To find synergy between different approaches, allowing elaborating integrated security solutions, e.g. integrate different risk-based management system.
- To exchange security-related knowledge and experience between experts to improve existing methods and tools and adopt them to new application areas

## TOPICS

Topics of interest include but are not limited to:

- Biometric technologies
- Human factor in security
- Cryptography and cryptanalysis

- Critical infrastructure protection
- Hardware-oriented information security
- Social theories in information security
- Organization- related information security
- Pedagogical approaches for information security
- Social engineering and human aspects in security
- Individuals identification and privacy protection methods
- Information security and business continuity management
- Decision support systems for information security
- Digital right management and data protection
- Cyber and physical security infrastructures
- Risk assessment and risk management
- Tools supporting security management and development
- Trust in emerging technologies and applications
- Ethical trends in user privacy and trust
- Digital forensics and crime science
- Security knowledge management
- Privacy Enhancing Technologies
- Misuse and intrusion detection
- Data hide and watermarking
- Cloud and big data security
- Computer network security
- Security and safety
- Assurance methods
- Security statistics

**Abstract**—Since software plays an ever more important role in measuring instruments, risk assessments for such instruments required by European regulations will usually include also a risk assessment of the software. Although previously introduced methods still lack efficient means for the representation of attacker motivation and have no prescribed way of constructing attack scenarios, attack trees have been used for several years in similar application scenarios. These trees are here developed into attack probability trees, specifically tailored to meet the requirements for software risk assessment. A real-world example based on taximeters is given to illustrate the application of attack probability trees approach and their advantages.

## I. INTRODUCTION

IN EUROPE certain kinds of measuring instruments, such as gas meters, electricity meters and taximeters are subject to requirements established in the European Measuring Instruments Directive (MID) [1]. The MID was originally published in 2004 with the aim of providing trust in measurements for both customers and users of measuring instruments by defining essential requirements that each measuring instrument used within the common European single market has to fulfill. These requirements cover everything from climatic operating conditions, electro-magnetic compliance testing to requirements on software and data protection. The entire economic sector of legally regulated measuring instruments is commonly referred to as Legal Metrology. In Germany, roughly 137 million such regulated instruments are currently in use and together are responsible for an annual turnover of around 150 billion Euros. For the entirety of the European Union, this amounts to more than 500 billion Euros per year. Each instrument regulated by European or national legislation first has to pass a conformity assessment before it can legally be put into use [1]. This conformity assessment is done according to certain modules, the most common of which is referred to as Module B and essentially comprises tests of a prototype instrument and of the associated documentation. In Germany, one of the conformity assessment bodies tasked with performing assessment according to Module B is the *Physikalisch-Technische Bundesanstalt* (PTB), Germany's national metrology institute. As software plays an ever more important role in measuring instruments, testing of the software nowadays constitutes an integral part of the conformity assessment process. Since April 2016, the documentation submitted by the manufacturer for Module B also has to include an "adequate

analysis and assessment of the risks" [1] associated with the instrument type. To help manufacturers with this task, PTB has developed and published a risk assessment procedure based on ISO/IEC 27005 [2] and ISO/IEC 18045 [3], which also enables objective comparison between different instruments from different manufacturers [4]. The publication also derives detailed assets to be protected and their individual security properties from the legal text of the MID. In line with the definitions in the ISO/IEC 27005, the method defines the term risk as a combination of the consequences resulting from threats to assets and of the probability of occurrence of a threat. Any way to realize a certain threat to an asset is then usually referred to as an attack vector. Since the original method primarily focused on technical aspects of the instrument, PTB also published an extension to the method [5] that takes attacker motivation into account. Despite these improvements and even though the risk assessment method is now actively being used, it still harbors a number of deficiencies. Among these is the fact that there is no prescribed way of constructing above-mentioned attack vectors in a standardized way. In the past, so-called attack trees have been used to this end in similar fields of application, such as the design of cryptographic protocols and access control [6]. A second challenge is the fact that an efficient way to handle the impact of attacker motivation during risk assessment is also still missing. Both problems will be addressed here and a possible solution, based on modified attack trees, will be described. The remainder of the paper is structured as follows. Section II gives a brief overview on the history of attack trees, covers basic principles and describes other applications. Afterwards, Section III revisits the method originally described in [4], touches upon its extension to include attacker motivation and introduces attack probability trees (AtPT) as a way of constructing and evaluating attacks in a standardized manner. In the subsequent Section IV a real-world example from Legal Metrology concerning possibly manipulated taximeters is used to illustrate the AtPTs and their uses. Finally, Section V summarizes the paper and details the planned future work.

## II. LITERATURE OVERVIEW

The international standard ISO/IEC 27005 [2] defines three sub-processes that together form a complete risk assessment, namely risk identification, risk estimation and risk evaluation.

The first sub-process includes the identification of assets to be protected. Assets specifically tailored to Legal Metrology have been derived in [4] and will briefly be revisited in Section III. The risk identification phase also requires the definition or derivation of threats, which may invalidate certain security properties of an asset. Finding technical realizations of a threat, also referred to as attack vectors, is part of risk identification as well. Afterwards, a threat and its associated attack vector are evaluated with respect to probability of occurrence and resulting impact in the risk estimation phase.

For illustration purposes a brief example will be given here: If the integrity of a text document on a PC is to be protected, the document itself can be thought of the asset while its security property is integrity. Should such a file be write-protected due to measures realized in an operating system, a possible attack vector would be the retrieval of the administrator's credentials. With these, an attacker could delete or modify the file at will, thereby invalidating its integrity. To estimate the likelihood of such an attack, the password strength and the accessibility of the computer would, for instance, need to be taken into account. During risk evaluation, the estimated risk is either classified as tolerable or intolerable. In the latter case, countermeasures are selected and the entire risk assessment process is executed again until the risks are reduced to an acceptable level. An example for the selection of suitable countermeasures will be given in Section IV. Details on different risk assessment methods, which could be applied to software in measuring instruments, may be found in [4].

In this paper, the focus will be on the identification of attack vectors and on their efficient graphical and logical representation. While attack trees originally served the principal purpose of illustrating or identifying system vulnerabilities in a graphical manner easily understood by humans, they also show a number of mathematical properties which make them quite suitable for automatic analysis and processing.

#### A. Foundations of Attack Trees

A very detailed introduction to attack trees and their background is given by Mauw and Oostdijk in [6]. There, the authors state that the root node of an attack tree usually represents an attacker's target or goal while child nodes are refinements of such an attack. The leaves of the tree then represent elementary or atomic attacks that can no longer be refined. As an example, Fig. 1 shows a very small attack tree which illustrates ways to manipulate the fare calculated by a taximeter. If two or more child nodes are connected by an arc, these refinements are to be seen as connected by an AND-statement, meaning that both of them have to be fulfilled before the respective parent node/goal itself can be reached. All other child nodes are OR-related so that only one of them needs to be fulfilled to achieve the parent goal. Mauw and Oostdijk refer to these relations as "conjunctive aggregation" and "disjunctive refinements (choice)", respectively.

In the given example, the fare can either be manipulated by modifying the parameters of the taximeter itself or by manipulating the signal coming from the wheel sensor. This

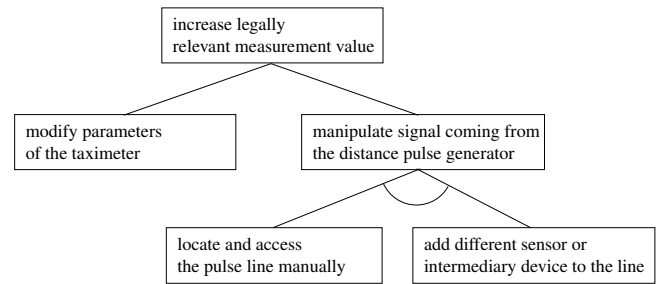

Fig. 1. Simple illustration of an attack tree that shows how the calculated fare/measurement value of a taximeter may be manipulated.

constitutes a simple OR-relationship as both attack vectors will help to achieve the desired goal. To manipulate the signal coming from the wheel sensor one could, for instance, obtain access to the pulse line connecting sensor and taximeter and then buy and install a pulse multiplier that automatically doubles the number of pulses transmitted on the line. Only if both steps have been taken, can the target be reached which corresponds to an AND-statement. In this context, it is not necessary for these actions to happen at the same time. AND-statements can also express a step-wise execution process.

Apart from giving basic definitions relevant to attack trees, Mauw and Oostdijk also state, that leaf nodes are usually given a number of predefined characteristics such as possibility, cost or special tools needed for their execution, also see [7] for further details. In order to estimate the attributes of the parent nodes and finally of the root node, rules for combining information originating from the child nodes are required. Mauw and Oostdijk also stress the point that these rules may usually be directly derived from the characteristics of an attribute. It should be obvious that these rules are generally used in a bottom-up fashion, requiring no additional loops or trace-backs. The results of an analysis are then either the attributes of a root node or a selected sub-tree, where the selected sub-tree may represent a set of likely attacks or may contain information not directly reflected by the values of the attributes but rather by its internal structure. Another important finding in [6] is the fact that individual nodes do not necessarily only have to occur once within an attack as they may have to be used several times. Nodes can subsequently have several copies whose attributes are linked to each other.

Mauw and Oostdijk then introduce the concept of an attack suite to represent a set of attacks which can all be used to achieve a goal without stating their individual branching structure. By means of this concept they are able to prove that attack trees with different structures may represent the same information despite their apparent structural differences. Nodes can also be connected to a multi-set of nodes, which Mauw and Oostdijk refer to as a bundle. Execution of all elements within the bundle will ensure that the goal is achieved. Cycles within an attack tree are not allowed, which restricts attack trees to be "rooted directed acyclic bundle graphs."

In [6] rules are defined for attack tree transformations. The first rule is "associativity of conjunction", meaning that a

sub-bundle can be lifted to the parent node if no other sub-bundles are connected to the parent node and the parent node is thus identical to the sub-bundle itself. An example for such a node will later be given and explained in Section IV, Fig. 6. The second rule is the distributivity of "conjunction over disjunction", meaning that a node with two sub-bundles/sub-trees can be replaced by two copies of the same node with one bundle/subtree each. Proofs for both rules are also detailed in [6]. Some additional remarks are targeted at attributes of attack trees: To calculate the value of an attribute, the semantics of the tree first need to be determined. Afterwards, the value of the attribute belonging to the equivalent attack suite is calculated. One basic assumption, which is going to be reused here, is that attributes of an attack node can always be calculated from the attributes of its attack components/child nodes.

#### B. Software Risk Assessment and Evaluation Process

In [8] Sadiq, Rahmani, Ahmad and Jung use a concept very similar to attack trees within their Software Risk Assessment and Evaluation Process (SREAP). The software fault trees (SFT) are again derived from a thorough examination and very detailed modeling of the target system. It is highlighted that despite attack trees being widely used, there is no standard way to construct such trees yet. However, once a tree has been identified, it can recursively be used to construct larger attacks, which might not have been obvious from the beginning of the investigation.

To rank certain attacks, Sadiq, Rahmani, Ahmad and Jung propose a key node safety metric. The metric is split into two parts, namely the impact of a node in the tree and the collective effect of the node consisting of the size of the underlying subtree, as well as the depth of the node.

#### C. Threat Risk Analysis for Cloud Security based on Attack-Defense Trees

Prior work on attack trees was focused on the description of envisioned attack profiles without taking defensive strategies into account. In [9] Wang, Lin, Kuo, Lin and Wang proposed a new modified version of such trees referred to as Attack-Defense Trees (ADT) which also incorporates defense concepts. The effectiveness of the proposed method has been tested according to a set of predefined metrics. The basic problem to be solved by their method is also referred to as Threat Risk Analysis (TRA), which describes the process of identifying realistic defense strategies based on vulnerability information and attack profiles.

A TRA encompasses both the impact of a realized attack and a precise description of the attack progression. This makes it possible to develop fitting defense strategies. Attack trees generally become very complex when trying to model all possible attacks at the desired level of detail. According to Wang, Lin, Kuo, Lin and Wang, stating both attack and defense strategies at the same time in an ADT is even more complex and usually beyond the scope of an attack tree. Whereas attack trees are used to model system weaknesses, protection

trees offer the opportunity to identify protective strategies by migrating weaknesses. In Section IV it will be shown how good starting point for such a defense tree may be identified.

According to [9], it was historically assumed that attackers strategically plan the attacks based on the easiest available scenario, but this may not always be the case, as an attacker might not have all information necessary to make an informed choice. Equations for calculating the probability of occurrence and other metrics for AND- and OR-connections are also given. These include probability of success, attack cost, impact as well as revised attack cost and revised impact for the countermeasure stage. All metrics in [9] are first calculated for the leaf nodes and are then propagated up the tree.

Afterwards Wang, Lin, Kuo, Lin and Wang introduce the concept of "attack and defense actions". The first of which is to understand the vulnerabilities of the system. Information on vulnerabilities can, for instance, be collected from public databases. This is identical to the procedure described in [4], which is again used here. The next action is the collection of information on recognized attacks, e.g. identifying ways to implement an attack based on known vulnerabilities. Afterwards, an ADT is constructed by finding as many vulnerabilities as possible, which can be used to implement the considered threat. Once the ADT is finished, it is systematically evaluated. Wang, Lin and Kuo observe, that, while the goal is to minimize the probability of occurrence of an attack, the rate of occurrence and the associated impact may not always be available and thus a certain degree of uncertainty remains. It is postulated, that attack cost and defense cost are connected by a transfer function to map one to the other. An example covering Advanced Persistent Threat attacks called Operation Aurora is also included in [9].

#### D. Automated Generation of Attack Trees

As indicated above, currently no method exists that enforces a harmonized generation of attack trees. In [10] Vigo, Nielson and Nielson offer a solution to this problem by inferring attack trees from process algebraic expressions. They explain that attack trees are used by scientists as they are quantifiable and by the public since they are easily understandable. In their implementation, the root again represents a threat to be realized and internal nodes illustrate the manner in which attacks need to be combined to achieve a goal. As indicated above, there may be several attack trees that all describe the same attack logic. Vigo, Nielson and Nielson overcome this problem by resorting to the calculus used to describe the attack process. This is done by translating the attack process into propositional formulae. Since this step can be done automatically, it does not suffer from human interpretation errors.

After the modeling phase, atomic attacks, which constitute the leaves of a tree, need to be labeled with individual costs. Following the process-oriented idea, attacks are seen as interactions between attacker and target in terms of a communication process in [10]. Finally, the cheapest set of atomic attacks needed to achieve a goal is calculated. Section

III will show how a similar process could be realized for attack trees, specifically tailored for measuring instruments that follow harmonized technical requirements established by [11] as an interpretation of the MID.

### III. DESCRIPTION OF THE APPROACH

The risk method assessment method, which will be described in this section, was originally published in [4], although some changes were adopted later on to reflect the experience gathered during the application of the method at PTB over the past two years.

#### A. Basic description of the risk assessment method

The basic procedure and all associated definitions were derived from ISO/IEC 27005 [2], where risk is defined as a combination of impact and probability of occurrence of a threat. Even though the international standard allows both quantitative and qualitative assessment of risks, only numeric representations of probability and impact (and therefore also risk) are used here. In order to be able to assign specific values to probability and impact, assets were defined in [4] by examining and interpreting the essential requirements of the legal text, i.e. of the Annex I of the MID. The interpretation led to the definition of a number of assets to be protected with associated security properties, all of which may be found in [4].

As only one such asset is going to be used for illustration purposes in Section IV, a single example will be given here: Essential requirement 8.4 of the Annex II reads, "Measurement data, software that is critical for measurement characteristics and metrologically important parameters stored or transmitted shall be adequately protected against accidental or intentional corruption." [1]. In this simple requirement three assets are listed, namely measurement data, software critical for measurement characteristics and metrologically important parameters. Each of these can be assigned a number of security properties. Measurement data, for instance, are required to preserve their authenticity and integrity, i.e. measurement data should not be changed and an attacker should not be able to generate false measurement data. An example for a formal description of a threat could thus be given by the following sentence: *An attacker manages to invalidate the integrity of measurement data.*

To assess such a threat, values for impact and probability of occurrence are now required. In [4] five different levels were originally used for impact, but in practice only threats affecting a single measurement (impact of  $\frac{1}{3}$ ) and affecting all future or all past measurements (impact of 1) are actively differentiated. As the threat itself is only a formal statement but gives no explicit instructions on how to realize it, a specific attack vector is needed next. To this end, all possible attack vectors, which could potentially be used to realize a threat, are examined in turn and their individual likelihood is checked. In order to estimate the probability of occurrence of an attack vector, a method called vulnerability analysis from ISO/IEC 18045 [3] is used.

TABLE I  
MAPPING OF THE SO-CALLED TOE RESISTANCE TO THE PROBABILITY SCORE USED HERE, ORIGINALLY PUBLISHED IN [4].

Sum of Points	TOE Resistance	Probability Score
0-9	No rating	5
10-13	Basic	4
14-19	Enhanced Basic	3
20-24	Moderate	2
>24	High	1

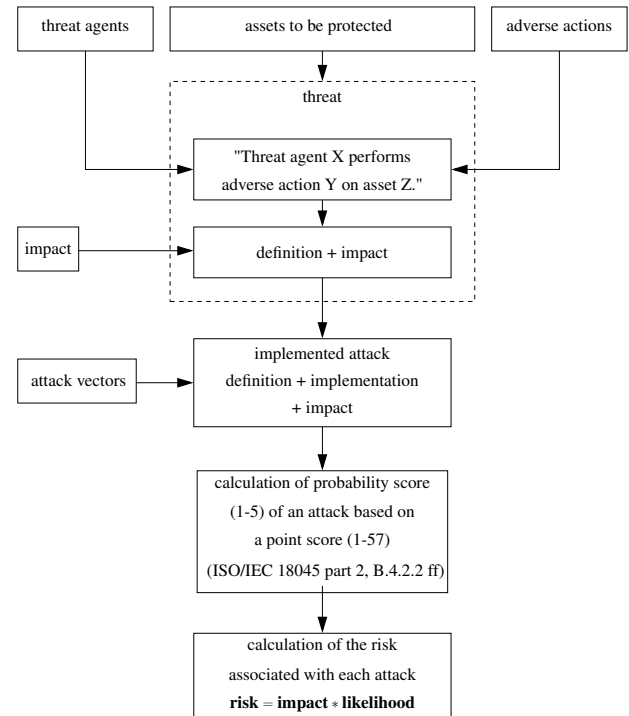

Fig. 2. Flowchart of the basic risk assessment procedure, adopted from [4].

The analysis consists of assigning a point score to the attack vector in five different categories, namely required time, expertise and knowledge of the attacked target of evaluation (TOE) as well as the window of opportunity and special equipment needed. A time score of 1, for instance is given if an attack requires more than a day, but less than a week for its execution. A full example for such a point score in all five categories will be given in Section IV. Explicit instructions on how to assign the scores may be found in [3]. In general, a higher sum score expresses a higher resistance of the TOE to attacks, i.e. an attack is less likely if its sum score is high. In line with this notion, the sum score is mapped to a probability score as given in Table I. Once the probability score has been calculated it is multiplied with the impact score (between 0 and 1) to form the final risk value. A complete flowchart of the entire basic method is given in Fig. 2.

#### B. Description of the extension for attacker motivation

One of the shortcomings of the original method described in [4] was the inability to take attacker motivation into account. As a motivated attacker will certainly be willing to invest

more resources into the execution of an attack, there should definitely be some sort of correlation between motivation of an attacker and likelihood of an attack. In [3], it is specifically stated that attacker motivation will have an influence on the used resources e.g. equipment, expertise, as both may be acquired if sufficient monetary funds are available. Other factors, like the time required for an attack and a possible window of opportunity however, cannot be influenced.

In [5], the original method was extended by a motivation score (0 for high motivation and 9 for no motivation), that acts as a lower limit for the expertise and equipment scores introduced above. Whenever the initially assigned score for one of these categories is smaller than the motivation score, its value is replaced with that of said score. It should be instantly obvious that the scenario with a highly motivated attacker is then identical to the originally calculated score as described in [4] and now it takes on the role of a theoretical upper limit to the probability of occurrence. A lower level of motivation will automatically result in a smaller probability, as the sum score will be increased due to the replacement values for expertise and equipment. A more in-depth discussion and a complete example may be found in [5].

### C. Attack probability trees

In Section I the two main objectives of this paper were stated: to design a method that enables a standardized derivation of attack vectors and also efficiently represents the effect of attacker motivation on the risk assessment results. To this end, attack trees as defined by Mauw and Oostdijk in [6] will be extended here into attack probability trees. These extended attack trees do not only represent the logical relationship between parent and child attacks, but are now also labeled with all the attributes defined in the vulnerability analysis in [3], i.e. each node has its own score for time, expertise, knowledge, window of opportunity and equipment. Based on these values, each node is given a sum score and, subsequently, a probability score. To fully reflect all variables from the method described in [4] each node could also be labeled with an impact score. However, since every node within an AtPT aims at realizing the same threat with a fixed impact, the impact score can safely be omitted. The final attribute of the root node thus only represents the probability of an attack, which can later be turned into a risk if combined with the respective impact score.

Nodes may be linked with each other to either form AND- or OR-statement. As suggested by Mauw and Oostdijk, information will enter the AtPT only via the leaves. The attributes for the parent nodes and finally for the root node can be calculated in a bottom-up fashion by observing the following stated rules. The rationale for each rule is also given.

- Time
  - **AND:** Time scores are logarithmic (1 for more than a day, 2 for a one week to two weeks, 17 for half a year), therefore the maximum of both scores needs to be chosen which is a good approximation for the logarithm of two added time spans.
  - **OR:** The smaller sum-score indicates which time score is to be chosen.
- Expertise
  - **AND:** If expertise in different areas is required (HW/SW), the scores are added with a maximum of 8 in accordance with ISO/IEC 18045. Otherwise, the maximum is chosen.
  - **OR:** The smaller sum-score indicates which expertise score is to be chosen.
- Knowledge of the TOE
  - **AND:** The maximum of both knowledge scores is chosen.
  - **OR:** The smaller sum-score indicates which knowledge score is to be chosen.
- Window of opportunity
  - **AND:** A smaller window of opportunity (higher score) for one node will also affect the other node. Therefore, the maximum is selected.
  - **OR:** The smaller sum-score indicates which window of opportunity score is to be chosen.
- Equipment
  - **AND:** If equipment from different areas is required (HW/SW), the scores are added with a maximum of 9 in accordance with Common Evaluation Methodology [3]. Otherwise, the maximum is chosen.
  - **OR:** The smaller sum-score indicates which equipment score is to be chosen.

When the assumed motivation is changed, the most probable path within the attack tree will also take on a different shape and a simple evaluation of the attributes of the root node does not suffice anymore. Previously, every individual attack then had to be reevaluated individually. With an AtPT in place, the time required for this can be reduced, since many attacks share common nodes whose attributes only have to be recalculated once. This will be illustrated in detail in Section IV. The rules established above should be applicable to methods apart from the one examined here, since the attributes are also used in the vulnerability analysis of the AVA\_VAN class in [3] and in the risk assessment method, which is part of the ETSI standard [12]. As shown by Mauw and Oostdijk, many different attack trees may all be interchangeable representations of each other, therefore, the design of an attack tree is a very subjective procedure. However, in Legal Metrology at least, all devices/measuring instruments share some basic characteristics, due to the fact that most instruments are based on the same acceptable technical solutions described in [11]. It may, therefore, be possible to construct attack probability trees in a reproducible manner by applying the following rules.

- 1) For each user interface of the measuring instrument, collect all known vulnerabilities that may lead to a realization of the threat.
- 2) For each communication interface of the measuring instrument, collect all known vulnerabilities that may lead to a realization of the threat.

Fig. 3. Illustration of the analog signal path connecting a pulse generator at the wheel with a taximeter.

Fig. 4. Illustration of the digital signal path connecting a pulse generator at the wheel with a taximeter.

- 3) For each hardware protection mechanism of the measuring instrument, collect all known vulnerabilities that may lead to a realization of the threat.
- 4) Logical connections between the vulnerabilities gathered in steps 1) to 3) are then expressed by means of boolean expressions, afterwards transformed into the structure of the AtPT. Single attack vectors requiring no other support actions, for instance, will always be represented by direct child nodes of the root node that represents the examined threat/goal.

As these rules still leave plenty of room for subjective interpretation, a full expansion of the steps into formalized instructions to construct an attack probability tree will remain an objective for future work.

#### IV. EXPERIMENTAL EXAMPLE

In the following Section, the combination of the attack probability trees introduced in this paper and the risk assessment method from [4] and [5] will be illustrated with the help of a real-world example from Legal Metrology:

Taximeters are one kind of measuring instrument subject to the requirements of the MID widely used all over Europe. However, the protective measures for such instruments agreed upon on the European level only affect the taximeter unit itself, which consists of display, user interface and open communication interface for a sensor. The signal path between the distance pulse generator at the wheel (i.e. the sensor itself) and the taximeter is only subject to national regulations.

Therefore, some countries do not require any protection for the signal path while others have introduced different protective mechanisms, each being designed with particular attack vectors in mind. Before taking a look at some of these countermeasures, the simple case of an open communication path between signal generator and taximeter will be discussed.

##### A. Formal case analysis for taximeters

The general installation of a taximeter in a car can be described by two very basic configurations, as shown in Fig. 3 and Fig. 4. The first typical installation consists of an analog pulse generator at the wheel of the taxi whose output are distance pulses. Each of these pulses represents a fixed distance traveled. The rate of the pulses is thus proportional to the speed of the car. These pulses may be filtered and amplified several times on their way to the taximeter, with additional electrically decoupling devices being used for safety. Pulse

dividers may be used as well, if the rate expected by the taximeter does not fit the rate of the wheel sensor. This is usually the case when a car is fitted with a taximeter that does not come from the same manufacturer as the car itself. It is important to note, that the signal in this scenario is fully analog all along the signal path.

The second typical installation represents a digital signal path, see Fig. 4. There, too, an analog pulse signal is generated at the wheel. The signal is, however, converted within the safety-relevant controller of the anti-blocking system (ABS) to a digital datagram on the CAN-bus as defined by ISO 11898-1 [13]. The CAN-bus is a well-known bus protocol widely used by car manufacturers around the world to connect different digital systems within a vehicle. Attacks on the analog signal between signal generator and ABS controller are not considered in this paper, as they would very likely result in failures of brakes or acceleration control and could thus not safely be used to influence the calculated taxi fare or the distance traveled. The remainder of the signal path is purely digital, but no protective measure are realized, except for simple checksums, which may be used to test the integrity of received datagrams.

##### B. Attack probability tree for the analog signal path

As mentioned in Section III, the only threat investigated here is an inadmissible increase of the legally relevant measurement value, i.e. the distance traveled or the calculated taxi fare. The root node (A) as given in Fig. 5 reflects this. Since all attacks examined here have an impact on all future measuring values, they are assigned an impact score of 1. Once the sum score of a node has been calculated its respective probability score can be identified using Table I. If this score is then multiplied with the impact score of 1 to calculate the actual risk, it becomes obvious that probability score and risk are identical. For other threats, this will of course be different and the respective tree should be appropriately labeled with the assigned impact score.

For the purely analog signal path, two known attack vectors exist: the manual feeding of additional pulses into the pulse line by means of a needle (node (B) in Fig. 5) and the installation of a different pulse generator or other intermediary device into the signal path (node (C) in Fig. 5). As these two attack vectors are alternatives of one another, they are linked to the parent node (A) by an OR-connection expressed by two simple edges. An arc between two or more edges

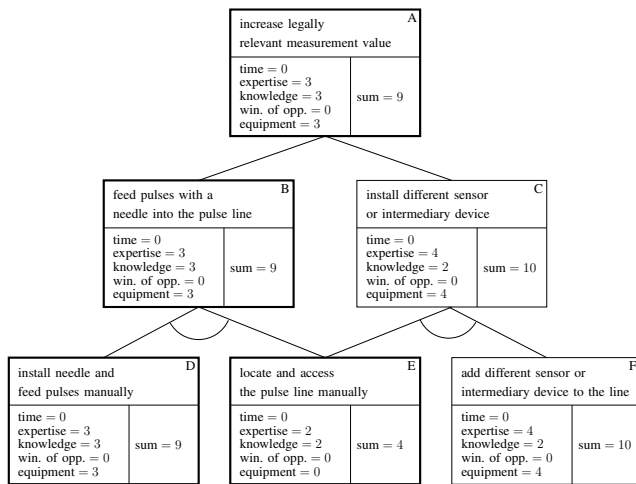

Fig. 5. Exemplary attack probability tree for the analog scenario. This also corresponds to the state of the tree for a highly motivated attacker. Highlighted nodes form the likeliest sub-tree to the root node after successful execution of the algorithm.

would represent an AND-connection. Such AND-statements may be found in the next level of the AtPT. The feeding of pulses by means of a needle (node (B)) requires both access to the pulse line (node (E)) and the manual feeding of pulses itself (node (D)). If a different sensor is to be installed (node (C)), again access to the pulse line is required (node (E)). In addition, the installation itself needs to be realized (node (F)). Again nodes (E) and (F) are linked by an AND-statement. Interestingly, node (E) plays a role in both attacks and thus offers the possibility of functioning as a possible entry point for a countermeasure. To calculate the probability score of the original threat (A), the leaf nodes (D), (E) and (F) are each assigned point scores in the aforementioned five categories. Tables listing all possible scores and an explanation for each may be found in [3].

The actual values given in Fig. 5 can be explained as follows: Finding and accessing the pulse line (node (E)) takes less than a day and is thus given a score of 0 for time. Especially in cars with a greater number of signals lines connecting arbitrary devices, finding the right spot to access the correct cable without the change later being obvious to market surveillance will require only proficient expertise, which corresponds to a score of 2. In addition, only restricted knowledge of the taximeter's installation is necessary to carry out this step, resulting in a score of 2 for knowledge. If the attacker is also the car's owner, he or she will have unlimited access, which is expressed by a value of 0 (unlimited) for the window of opportunity. Also, only standard equipment is necessary for this step (score of 0). The situation is slightly different for the actual installation and usage of the needle to feed additional pulses (node (D)). The expertise and knowledge score are slightly increased as one has to understand the internal algorithm of the taximeter to feed the right amount of pulses while also performing the task without being noticed by

customer/passenger. Finally, the situation is slightly different if some additional sensor or store-bought intermediary device is installed (node (F)). Connecting the device correctly will require a slightly higher level of expertise (score of 4) but no additional information about the actual taximeter (knowledge score of 2). As the additional sensor or intermediary device cannot be considered standard equipment, that score is raised to a value of 4.

Once the attributes of the leaf nodes have all been initialized, these values can now propagate up the tree according to the rules established in Section III. It should be noted that nodes (B) and (C) both have AND-connections to their respective child nodes and thus the maximum value for each score is copied to the next level. At the root node, however, an OR-relationship between both alternative attack vectors exists. Here, scenarios (B) and (C) compete with each other. As (B) has a slightly smaller sum score it is considered more likely and the root node (A) thus becomes a direct copy of (B). The most probable attack scenario resulting from the algorithm is a sub-tree consisting of nodes (A), (B), (D) and (E), which are highlighted in Fig. 5. The sum score of 9 at node (A) corresponds to a very high probability score of 5 and, after multiplication with the impact of 1, to a risk value of 5 which would require changes to the system, before it can pass conformity assessment. Since no limits are imposed here on the expertise and knowledge scores, this scenario corresponds to the case of a highly motivated attacker. For a detailed explanation see Section III and also reference [5].

### C. Attack probability tree for the digital signal path

The AtPT for the digital signal path is given in Fig. 6. In this scenario, there are three alternative attacks ((D), (E) and (F) in Fig. 6) that could all be used to realize an illegal increase of the legally relevant measurement value. Two of them ((D) and (E)) require access to the field bus of the taxi first (node B). Once physical access to the field bus has been established, an attacker could either install an additional signal source that transmits its own datagrams over the bus (node (D)) or the attacker could install a so-called car hacking device (node (E)), which jams the dataflow from other sources before transmitting its own signal and is thus more difficult to detect. Nodes (C) and (F) represent an attack on the control unit which converts accumulated distance pulse counts from the ABS unit into a physical distance in meters. The conversion factor for this operation is usually referred to as  $k$ . Once the configuration interface of the control unit has physically been accessed,  $k$  can be changed using equipment available to most car mechanics.

It should be noted that (F) could also have been split into two separate nodes for accessing the port and changing the configuration, which was avoided here due to space limitations. Again, each leaf node can be assigned point scores for all of its five attributes. The time required for (D) and (E) will still be less than a week, corresponding to a value of 1. In both cases an expert is required to install the new device or signal source (expertise score of 6). However, the

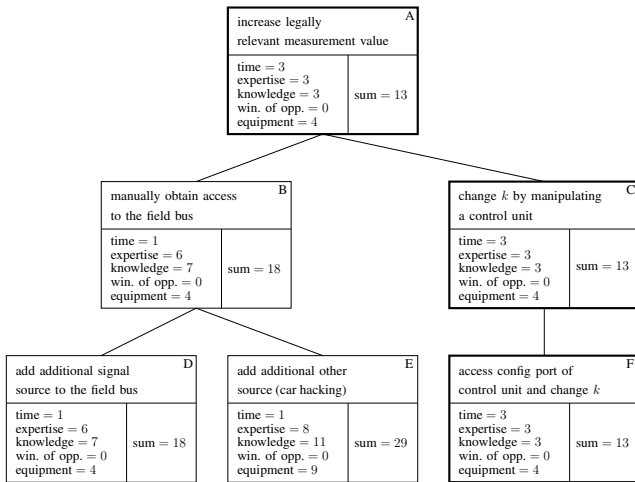

Fig. 6. Exemplary attack probability tree for the digital scenario. This also corresponds to the state of the tree for a highly motivated attacker.

programming of the car hacking device will also require programming skills, which increases the score to 8 (multiple expert). In order to be able to add an additional source to the field bus, sensitive knowledge concerning the addresses used on the bus and possible manufacturer-specific protocol extensions is needed (knowledge score of 7 for node (D)). If a car hacking device is programmed, the exact behavior of all other devices connected to the bus needs to be known first, which increases the knowledge score to 11 (critical knowledge). The window of opportunity is identical to that of the analog scenario. While specialized equipment (score of 4) is needed to install a new signal source (node (D)), multiple bespoke equipment, that cannot be bought legally on the market (score of 9 for node (E)) is required for car hacking. The attack on the configuration port as described by nodes (C) and (F) may take considerably longer (score of 3 for time), since software for breaking the car's security mechanisms (password protection) may be needed. The software, however does not require expert knowledge to be operated (score of 3) and only restricted knowledge, available to most mechanics, is needed to identify the correct port and execute the attack (score of 3). Again, there may be an unlimited window of opportunity and the equipment level is comparable to the one for attack (D).

The algorithm for propagating attributes values is executed in the same manner as before. At node (B) attacks (D) and (E) compete with one another as they are linked by an OR-statement. Since (D) has a smaller sum score and is thus more likely, its values are propagated to (B). (F) is a simple copy of (C) and its values are simply copied to the next level. At the root node the likeliest attack scenario (C) is again selected according to the sum score. The resulting sub-tree with the highest probability of occurrence (nodes (A), (C) and (F)) is highlighted in Fig. The score for probability of occurrence can finally be derived from the sum score of 13 for the root node (A) and takes on a rather high value of 4. The risk associated

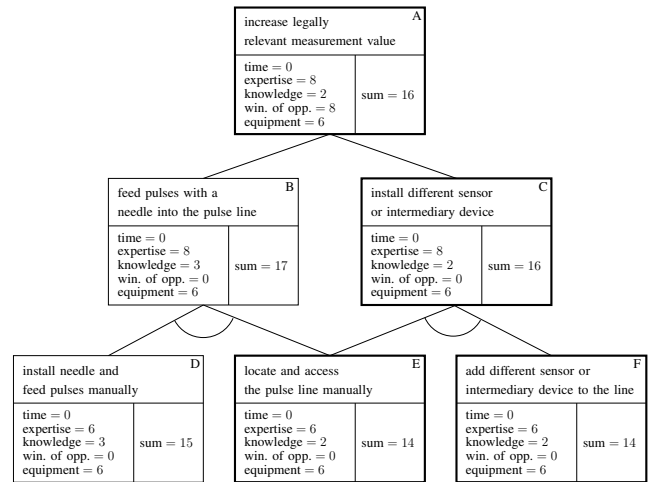

Fig. 7. Exemplary attack probability tree for the analog scenario for an attacker with low motivation.

with the threat is also 4, due to the impact score of 1.

#### D. Effect of attacker motivation

To examine the effect of attacker motivation on an AtPT, the taximeter example with an analog signal path will be used again. As mentioned above, the AtPT given in Fig. 5 corresponds to a scenario with a highly motivated attacker willing to invest virtually limitless amounts of resources. If an attacker with low or medium motivation is considered instead, a lower bound for expertise and equipment is imposed. For medium motivation, this limit takes on a value of 3, see [5] for details. The effect of a low level of motivation (lower limit of 6) can be seen in Fig. 7. Again, the attributes of the leaves constitute the input to the algorithm.

Here, the scores for expertise and equipment are automatically set to a value of 6. Afterwards, the values are propagated up the tree. Node (B) is thus assigned a sum score of 17 while node (C) receives a sum score of 16 due to their expertise value of 8, see expertise rule for AND-statement in Section III. Compared to the original state of the AtPT, node (C) suddenly becomes more probable, which shifts the likeliest sub-tree to the constellation (A), (C), (E), (F). Thus, the properties of (C) are finally copied to the root node (A). It follows, that the most probable attack vector does not only depend upon technical specifications but also on the level of motivation of an attacker. This finding should play an important role when designing and selecting countermeasures to attack vectors.

#### E. Identifying suitable countermeasures

As countermeasures will specifically target one or more attack vectors, they can directly be linked to one or more nodes within an AtPT. With the aim of finding the best node for a countermeasure, inverted sub-trees within an AtPT need to be found. An inverted tree could be any leaf with more than one connected node from the preceding level. The bigger such an inverted tree is, the more parent nodes depend upon the selected leaf. In Figure 5, both (B) and (C) depend upon

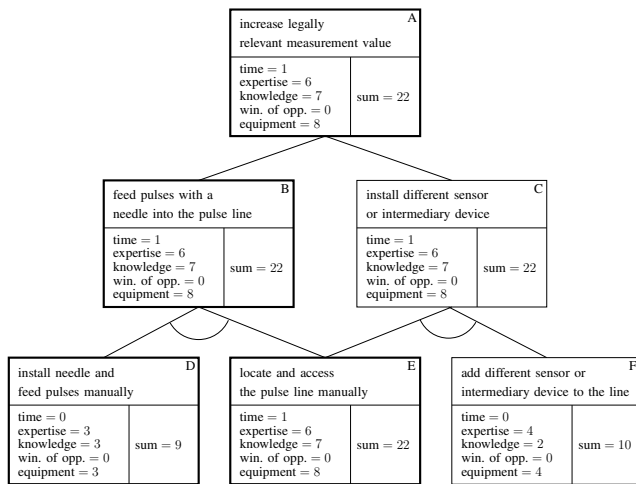

Fig. 8. Exemplary attack probability tree for the analog scenario after the implementation of the armored cable as a countermeasure.

node (E) and the biggest inverted sub-tree is constituted by nodes (E), (B) and (C). A countermeasure specifically targeted at preventing access to the pulse line (node (E)) will thus have the biggest impact in this scenario.

One such countermeasure is the installation of so-called armored cable that will either prevent access to the pulse line with layers of wire mesh or will stop working if one of the meshes is cut from the outside. The effect of the countermeasure on the attack tree is shown in Fig. 8. With the armored cable in place, the time required to access the pulse line is raised to at least a week (score of 1 for node (E)). In addition, expert knowledge (expertise score of 6) and sensitive details about the protective mechanism of the armored cable (knowledge score of 7) are needed. While the window of opportunity remains unchanged, multiple bespoke equipment is needed to successfully obtain access to the pulse line without detection (score of 8). Once these attributes have been propagated up the tree, both nodes (B) and (C) are now only influenced by node (E), with nodes (D) and (F) having no significant effect. Subsequently, the root node (A) also takes on the properties of node (E) and the sum score of 22 expresses the considerably decreased probability of occurrence, which results in acceptable probability and risk scores of 2.

## V. SUMMARY

In this paper, attack probability trees (AtPT) have been introduced specifically tailored to the risk assessment method for software in Legal Metrology described in [4] and extended in [5]. Nevertheless, the rules established here for the propagation of attributes within the AtPT should be applicable for a number of other methods ([3], [12]).

A detailed example was discussed to illustrate the *bottom-up* approach of the algorithm. In addition, the effect of attacker motivation on the assessment results was also examined and it was shown that the most likely attack cannot be identified by examining technical features alone. Instead, the attacker

motivation will have a significant affect on the sub-tree that finally defines the properties of the root node. Finally, it was illustrated how countermeasures may be identified from a complete AtPT by searching for the biggest inverted tree.

Future work will firstly focus on the definition of strict rules to derive attack probability trees from the documentation supplied for conformity assessment, according to Module B and proving their correctness. For this, a general model of measuring instruments derived from [11] may be of some use. Secondly, a formalized method is still needed for identifying optimal countermeasure entry points, standardizing risk and probability measurements. This kind of development will require a sufficient amount of empirical data that could be tested by means of existing Bayesian strategies. Finally, it will be investigated how information originating from the field may be used to validate the risk assessment results.

**Abstract**—This study focuses on multimodal artifact metrics and proposes a technique based on multimodal biometric systems that are a type of biometric identification systems. It is expected that this technique can aid in verifying the authenticity of each artifact in a more accurate manner and in increasing the level of difficulty involved in counterfeiting when compared to those of existing artifact metric techniques. This technique will ensure that artifacts will possess specific characteristics (two or more) that are extracted from different physical characteristics. The study created card-shaped samples with two physical characteristics (electrical and optical characteristics) to prove the feasibility of the proposed technique. The results indicate that two information features, namely sheet resistance and visible light image, which are extracted from the above characteristics, are different in each sample. This indicates that the two information features can correspond to the characteristic information necessary to distinguish each sample.

## I. INTRODUCTION

### A. Background and target

ALTHOUGH the use of artifact metrics is a technique for verifying the authenticity of the artifacts produced daily by manufacturers, its concept is the same as that of biometrics. In artifact metrics, authenticity is verified using characteristic information extracted from an individual artifact. Similarly, biometrics identifies a person using bio-information extracted from an individual.

It can be said that the word “artifact metrics” stems from a word “biometrics.” In biometrics, single modal techniques (methods that use a single type of bio-information to identify individuals) have been prevalent so far; however, multimodal techniques (methods that use multiple types of bio-information to identify individuals) have become common in recent years in order to identify a person with high accuracy and strengthen the robustness of the technique to impersonation attacks. In fact, a technical report on multimodal identification systems was published by ISO [1], and in India, faces, fingerprints, and iris information are

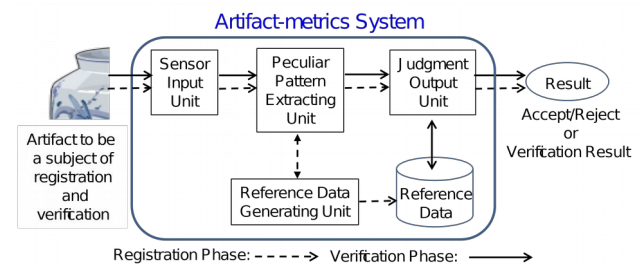

Fig. 1 An overview of the artifact metrics system.

used to identify individuals in the national identification number project [2].

Nowadays, a massive number of copied products that mimic genuine ones have been distributed. Hence, techniques for verifying the authenticity of artifacts with high accuracy and making counterfeiting more difficult are becoming increasingly necessary in manufacturing industries. Therefore, in this paper, we propose a technique that uses “multimodal artifact metrics,” which are based on multimodal biometrics. This technique gives artifacts multiple types of characteristic information with different physical characteristics and can verify the authenticity of each artifact using this information.

This paper describes the following contents: In section 2, we describe our technique’s concept, prerequisites, and the artifacts targeted in this paper. In section 3, we introduce our approach. In section 4, we explain our experiments of verifying the effectiveness of our method and show its results. Authors describe the considerations for practical use in section 5 and conclude this paper in section 6.

### B. Overview of artifact metrics

In this section, we describe how characteristic information extracted from artifacts is used in artifact metrics. In artifact metrics, an artifact’s unique characteristic information is extracted using sensing devices. This information is embedded in the artifact using the simple methods of adding materials (fillers) with one physical characteristic during the manufacturing process. The particles of the added fillers are distributed randomly and non-uniformly and fixed in the artifact. Their degree of

This work was supported by the Kurata Memorial Hitach Science and Technology Foundation and the JSPS KAKENHI Grant Number JP16H07178

distribution reflects the characteristic information. Table 1 shows the physical characteristics of fillers added in the manufacturing process and the characteristic information extracted from them.

Fig. 1 shows an overview of the system (artifact metric system) that uses the artifact metrics. Indicated two phases are almost the same as those of biometrics. In this system, characteristic information is extracted from each artifact before it is shipped and the information is stored in a secure database. To verify the authenticity of an artifact, the system extracts the characteristic information from it and compares this information with the registered feature information from the secure database.

### C. Related studies

In this section, authors introduce related studies in order to clarify our study's position. Characteristic information extracted from artifacts can be changed depending on the environmental circumstances during extraction (such as temperature, humidity, and position of the artifacts relative to the sensing devices). However, even in such situations, the artifact metric system should be able to verify authenticity stably and correctly based on the strong correlation between the characteristic information registered in the database and the information features extracted during verification.

There is an approach to increase the number of characteristic information in order to find strong correlations between both registered and extracted information. A method was proposed to extract two characteristic information from a filler with one physical feature [3]. In this method, a filler with an optical feature (glass phosphor powder) is mixed with paint and glaze and adhered onto the surface of porcelain in order to bond the particles of the filler onto the ceramics during the firing process. There is a difference between the density of light-emitting ions and the particle diameters that depends on the observation points. The method [3] utilizes the difference between the distributions of the light-emitting spectrum and light-emitting intensity that is caused by this difference and uses these two distributions as characteristic information.

## II. MULTIMODAL ARTIFACT METRICS

### A. Concept

The idea for the technique proposed in this paper (multimodal artifact metrics) is based on multimodal identification in biometrics. However, unlike previous study [3], as described in Section 1.3, this technique gives an artifact two or more physical characteristics and extracts two or more types of characteristic information from them. The main difference between our method and that of [3] (i.e., the advantage of our method) is that it is able to increase the number of characteristic information that can be extracted from the artifact. This is because the previous study gives

the artifact only one physical characteristic so that clearly fewer number of characteristic information can be extracted

TABLE I.  
PHYSICAL FEATURES AND EXTRACTED CHARACTERISTIC INFORMATION

Physical characteristics	Extracted feature information
Optical characteristics	Particles' optical characteristics (reflection, transmission, infraction, and fluorescence) and their degree of distribution reflect the characteristic information, which is extracted by sensors that can detect light intensity
Magnetic characteristics	Particles' magnetic characteristics (attraction and repulsive force) and their degree of distribution reflect the characteristic information, which is extracted by sensors that can detect a change in magnetism.
Electrical characteristics	Particles' electric characteristics (electrical charge) and the degree of distribution reflect the characteristic information, which is extracted by sensors that can detect the quantity of electric charge.
Vibration characteristics	Particles' vibration characteristics (sonic waves) and the degree of distribution reflect the characteristic information, which is extracted by sensors that can detect sonic waves.

TABLE II.  
CATEGORIZATION OF SYNTHETIC RESIN PRODUCTS

Type 1	Definition: The majority of the artifact is formed of synthetic resin.
	Usage 1: <u>Credit cards</u> [4] <u>Cash cards</u> [5] SIM cards, etc. Usage 2: <u>Prepaid cards</u> [6] loyalty cards, etc. Usage 3: Exterior finish of home appliances, hardware token (One-time password generator, etc.)
	Material: PVC is used for Usage 1, PET is used for Usage 2, and ABS is used for Usage 3.
Type 2	Definition: The surface of the artifact is coated or painted by synthetic resin.
	Usage 1: Products made of ABS or polycarbonate without a baked finish (e.g., <u>wrist watches</u> [7] and spectacle frames for eyeglasses). This finish requires more than 150°C. Usage 2: Products made of aluminum or brass without a baked finish (e.g., <u>cast aluminum wheels</u> [8]).
	Material: Acrylate resin, urethane resin, fluorine resin, or epoxy resin is used for coating or painting in both usages.

from the artifact, whereas our method gives the artifact two or more physical features.

Our method has two contributions to artifact metrics technology. One is the ability to verify the authenticity stably and correctly (as we mentioned in the previous section), as our method can find a strong correlation between the characteristic information registered in a

database and the feature information extracted from the artifact by increasing the number of characteristic informati-

Fig. 2 A cross section of a valuable card.

on contained in artifact. Another one is to heighten the difficulty of counterfeiting for forgers, as the number of characteristic information contained in genuine products is increased.

#### B. Application to valuable card made from synthetic resin

Although we are still investigating artifacts that are appropriate for multimodal metrics, we focus here on artifacts made from synthetic resin as one application in order to verify the applicability of our method.

We have two reasons for focusing on this type of artifact. One is that such artifacts are common in our daily life. In general, synthetic resin is easy to form and resists acid and alkaline corrosion. Furthermore, it is used to add features and characteristics to products in order to make them fit for use. Although it has the reputation of being non-conductive, flammable, and non-biodegradable, new types of synthetic resin with electro-conductive, flame-retardant, and biodegradable features have been developed. It can also be recycled.

Another reason is the existence of copied synthetic resin products. Table 2 categorizes synthetic resin products. Products for which the existence of copied products have been confirmed are underlined and the reference given. (In Table 2, products are categorized into two groups, and the definition, purpose of use, and specific name of the synthetic resin are indicated.) We predict that security devices (such as SIM cards and hardware tokens which are categorized in Type 1) would be copied in the near future.

Specifically, the present study focuses on valuable cards composed of synthetic resin (such as credit cards) that are widely used worldwide. Additionally, a technical approach is also proposed to provide characteristic information with respect to the products and to verify the applicability of the proposed method through experiments.

#### C. Requirements

This section lists four requirements that must be satisfied by the technical approach in which multimodal artifact metrics are applied to valuable cards.

**Requirement 1:** Characteristic information can be formed on the print surface of valuable cards.

It is desirable for the technical approach to form characteristic information on the print surface of valuable cards such that the printing of card information and the

formation of characteristic information can be performed on the same surface. This includes the advantages of simultaneously reading and extracting the two above-mentioned pieces of information. As a reference, valuable cards are formed by four resin layers (two core layers and two skin layers) [9, 10] as shown in Fig. 2, and the characters and images printed on the surface of core layer are protected by a skin layer.

**Requirement 2:** Characteristic information is not affected by temperature.

Valuable cards are used in a situation characterized by a wide range of temperature. Hence, it is necessary that temperature should not affect the characteristic information formed on the surface of the core layer.

**Requirement 3:** Valuable cards should be tamper-resistant.

Valuable cards should possess a tamper-resistance function to ensure the difficulty involved in copying the characteristic information. With respect to concrete, the characteristic information breaks easily if the skin layer is stripped.

**Requirement 4:** Materials used to form characteristic information are safe.

Materials used to form valuable cards (such as synthetic resin and the paint) are associated with a low risk of affecting human skin. Hence, it is necessary that the material used to form characteristic information on the surface of core layer should possess the same feature.

#### D. Preconditions

We set the prerequisites shown below in order to clarify our discussion.

**Condition 1:** The goal of this study involved verifying the applicability of the proposed approach to apply multimodal artifact metrics to valuable cards. In the case of concrete, three objectives are involved: (1) Creating samples with two characteristic information features (derived from different physical characteristics) on the surface of resin plate that is used in a manner similar to a real core layer; (2) Extracting two types of characteristic information from samples; (3) Confirming the differences in the types of characteristic information extracted from each sample.

**Condition 2:** The goal of this paper is to determine whether we can apply multimodal artifact metrics to samples made of synthetic resin (conductive polymer). Hence, the implementation of multimodal artifact metrics (the construction of an artifact metric system and its evaluation) is not within the scope of this paper.

Fig. 3 Conductive polymer paint (left) and IR up-conversion phosphor (right).

Fig. 4 Thin film and adhesive layers.

Fig. 5 Reflection and scattering.

### III. APPROACH

#### A. Forming characteristic information

To satisfy four requirements described in section 2.3, it is necessary to form a thin film on the surface of the core layer. In this paper, we use a mixture of conductive polymer paint and small amount of infrared up-conversion phosphor (hereinafter referred to as IR phosphor powder). The conductive polymer paint (as shown in Fig. 3) possesses low electrical resistance and is used as a material to create a transparent electrode. It also possesses the three features, namely the conductivity is not affected by temperature [11], there is a low risk of affecting human skin, and it is more flexible and possesses high transparency when compared with that of Indium Tin Oxide used as a material for making transparent electrodes. The transparent electrode formed by the polymer paint is not broken, and its electrical resistance (sheet resistance) is not changed by the bending force. However, it is easily broken by a physical force such as scratching. Conversely, this leads to the realization of tamper-resistance for the characteristic information. For example, as shown in Fig. 4, a tamper-resistance function is realized by sandwiching the thin film with a high-transparent adhesive allocated to the core as well as the skin layer. If the skin layer is peeled off, then the characteristic information included in the thin layer will be broken such that it is not possible for a counterfeiter to easily analyze the film.

The IR phosphor powder (as shown in Fig. 3 with a particle diameter of approximately 2–3  $\mu\text{m}$ ) is a non-conductive substance. The optical characteristics are not affected by temperature and the toxicity is significantly lower than that of other phosphors that emit visible light (e.g., quantum dot semiconductor phosphor). The IR phosphor powder emits visible light with a peak wavelength of X by optical excitation with a peak wavelength of Y. Both peak wavelengths can be changed by adjusting the composition of the IR phosphor powders. Additionally, due to ease of handling, IR phosphor is widely used for bio-imaging, tracking, and simple authentication of products.

#### B. Reasons for selecting a thin film to form characteristic information

This section describes the reasons for adopting the thin film instead of the core layer as the location to form characteristic information. The core layer of valuable cards is composed of PVC or polyvinyl chloride. Specifically, PVC is a non-conductive substance and does not possess distinguishing optical and electrical characteristics, and thus it is necessary to add a filler with two physical characteristics in PVC. Incidentally, the preliminary experiment indicates that it is possible to induce electrical characteristic in a non-conductive synthetic resin (epoxy). However, it is not appropriate to consider the extracted resistance as a type of characteristic information because the resistance is very high and not stable (with a value between  $4.0\Omega$  and  $6.0 \times 10^{12}\Omega$ ) [12]. This indicates that the same situation could occur in PVC.

The optical characteristic is also considered. A large part of light irradiated to the core layer reflects on its surface such that it is hard for scattering to occur due to the high glossiness of the PVC (as shown in Fig. 5). Hence, the amount of optical characteristic information is low since the luminescence is observed in a 2-dimensional surface and not in a 3-dimensional manner even if the IR phosphor powder is added to PVC.

Conversely, in the proposed approach, observed electrical resistance is likely to be low and stable since a major part of the thin film is dominated by a conductive substance. Additionally, reproducibility (this implies that the same resistance is observed throughout at the same point) can be observed if the resistance is stable. Hence, it is possible that the resistance extracted from the thin film can correspond to the electrical feature information.

This is followed by examining the optical characteristic. The glossiness of the thin film formed by the conductive polymer is significantly lower than that of the PVC, and thus the light irradiated to the thin film scatters on its surface (as shown in Fig. 5). Hence, the IR phosphor that exists both at the surface and inside the thin film is excited, and the luminescence of IR phosphor can be captured 3-dimensionally by a camera (this means that the amount of optical feature information increases). Thus, the thin film is

Fig. 6 An illustration depicting densities of the bonded molecules.

Fig. 7 An overview of the eddy current measuring method and its electrical circuit.

Fig. 8 Photo shooting method.

adopted as the location for the formation of characteristic information because of the fore-mentioned reasons.

### C. Forming information features

This section describes the manner in which the two types of information features are formed by using a mixture of a conductive polymer and IR phosphor powder as described in section 3.1. The thin film is formed when the moisture evaporates after a thin coat of the liquid mixture is painted on the surface of core layer. Thus, the connections between the particles of the polymer are variable because they spread randomly and non-uniformly due to the existence of IR phosphor particles when the thin film is formed (as shown in Fig. 6). Hence, it is possible to extract electrical resistance as an information feature because it is reflected by the above connection. Furthermore, the size of each IR phosphor particle (it is reflected as light emission intensity), the degree of reflection, transmission, and inflection of the light, and the degree of dispersion of the phosphor particles are also simultaneously determined in the thin film. Hence, they are reflected as the characteristic information and extracted as an information feature by capturing images using a camera with optical excitation. The proposed approach that extracts two types of characteristic information without

contact is applied. Hence, this can avoid the risk of scratching the surface of valuable cards while extracting characteristic information.

### D. Extraction of characteristic information

First, the extraction method of electrical resistance (sheet resistance) is described. In general, probes are used to measure electrical resistance of samples and there are two types of methods of using probes (two-terminals and four-terminals measuring method). On the other hand, in order to measure the resistance of thin film (or the sheet resistance), there is a method not to touch any probes to the samples (it is called eddy current measuring method). In this method, as shown in Fig. 7, sample is set between the gap of the probe. Measuring procedure of the surface resistivity is shown below:

- (1) Generate magnetic flux by adding high frequency between the probe.
- (2) Eddy current occurs in the sample when sample is inserted between the gap of the probe. At this time, electrical power loss occurs as the current is consumed in the sample. The current in the circuit is also decreased in proportion to the above loss.
- (3) As decreased current value is inversely proportional to the sample's resistance, surface resistivity is calculated by using these values and the thickness of the sample.

The fore-mentioned measurement method appears as appropriate since it is easy to break the thin film composed of a conductive polymer when it is subject to a physical force (e.g., scratching). In the experiment (refer section 4), the difference between the sheet resistances extracted from samples is then confirmed.

This is followed by describing the shooting method of the luminescence of the IR phosphor caused by an optical excitation by using a camera. As shown in Fig. 8, the photographing devices and the sample are set in the dark box. This is because the aim includes capturing the visible light components only from the luminescence by using an image sensor of the camera. The camera faces the sample, and IR light is irradiated on the sample surface. The particles of the IR phosphor emit visible light with a specific peak wavelength by optical excitation, and the scene is captured by using the camera. This is followed by confirming the differences between each image obtained from the samples (refer section 4.)

### E. Verification of authenticity

Similar to other techniques proposed for artifact metrics so far, authenticity verification is done by calculating the degree of similarity between the information features registered in a secure database beforehand and those extracted during verification. As described in section 2.4, the implementation of multimodal artifact metrics is beyond the scope of this study because the main aim of this study involves creating samples with two types of characteristic

information derived from different physical characteristics on the surface of the resin plate, extracting two different types of information features from the samples, and confirming the differences between the extracted information. Hence, in this paper, we refrain from describing how to set the threshold level for calculating the degree of similarity. However, if we implement our technique, we should carefully calculate the degree of similarity in order to avoid incorrectly determining genuine products as copied products and vice versa [3].

#### IV. EXPERIMENTS

##### A. Appropriate amount of IR phosphor powder

Generally, the decrease in moldability and the decline in strength can be observed if there is an increase in the amount of fillers added to the synthetic resin [13, 14]. Conversely, it is not possible to extract sufficient characteristic information if a low amount of fillers is used. Hence, to determine the appropriate amount of IR phosphor powder to be added to the conductive polymer, four types of mixtures with different weight ratios of phosphor powder (5%, 10%, 20%, and 40%) are created. The liquid mixture is then used to confirm whether or not the thin film is formed on the surface of the resin plate that is used to resemble the real core layer.

A polypropylene plate with hydrophilic characteristics is used. The mixture of liquid spreads in a circle on the surface of the plate and corresponds to a thin film state due to hydrophilic features of the plate and the gravity following the infusion of 5 ml of liquid by using a syringe. The mixture is kept undisturbed for 60 min to evaporate moisture from the liquid, and a transparent blue thin film is formed from 5% and 10% mixture liquid. The film does not form from 20% and 40% mixture liquid (as shown in Fig. 9). However, the existence of the IR phosphor powder is clearly observed. This phenomenon corresponds to that observed in previous studies [13, 14].

It is desirable for the synthetic resin to possess a smaller amount of fillers. Hence, it is determined hereinafter that a 5% weight ratio of IR phosphor powder is necessary to form the mixture with a conductive polymer. There are several methods to create a thinner film including the spin-coating method and the dip-coating method. However, these methods are not used as the aim of this study involves verifying the applicability of the proposed approach.

##### B. Sample making

It is necessary for the sample thickness to range between 0.5 mm to 1.5 mm and for the film diameter to exceed the probe diameter when the sheet resistance of the thin film is measured. In the experiment, the sheet resistance meter that includes a probe with a diameter of 14 mm is used, and thus a transparent polypropylene plate with a thickness of 0.5 mm is used to resemble the real core and skin layer. The thin film with a diameter exceeding 14 mm is used on the surface of the core layer, and the film is sandwiched by the core and

the skin layer. A total of 20 samples are created, and each sample has a thin film and two polypropylene layers.

##### C. Extraction of feature information (sheet resistance)

As shown in Fig. 7, an experiment is performed to confirm the differences in the sheet resistance between samples. Fig. 10 shows the sheet resistance extracted from the central part of the samples. The vertical axis shows the sheet resistance (ohm/square) and the horizontal axis shows the sample number. The results indicate that there are differences in the sheet resistance between the samples and that the same resistance can be extracted from same point even when there are differences between the insertion angles of the sample and the probe (this implies that the result is replicable).

Fig. 9 Formed thin film (Left: 5%, Right: 20%).

Fig. 10 Sheet resistance (Weight percentage 5%).

Fig. 11 Sheet resistance (without IR phosphor powder).

Fig. 12 Measurement of sheet resistance.

Fig. 13 Sheet resistance (Weight percentage 5%).

Fig. 14 Experimental system.

Fig. 15 Sample images (Weight percentage 5%).

As a reference, Fig. 11 shows the sheet resistance extracted from the central part of the samples without IR phosphor powder. The degree of variation in the samples is less than that shown in Fig. 10 (where Sample number 1 exhibits high sheet resistance. It is assumed that the tiny solid pieces contained in the conductive polymer paint probably behaved as the resistance and affected the eddy current).

As shown in Fig. 12, the sheet resistance is measured at each point when the sample is moved by 2 mm from the reference point. Fig. 13 shows the line graph. The vertical axis denotes the sheet resistance (ohm/square), the horizontal axis denotes the distance from the reference point, and each line denotes the samples. The results indicate the difference in the sheet resistance from different samples, and the same resistance could be extracted from same point on the sample even if there are differences in the insertion angle between the sample and the probe (this implies that the result was replicable). The findings also reveal that there are differences in sheet resistances within the same sample albeit extracted from different observation points. Therefore, it is assumed that the sheet resistance is potentially a type of characteristic information that can be used to authenticate valuable cards.

#### D. Extraction of feature information (visible light images)

As shown in Fig. 8, another experiment is conducted to verify two characteristics. The first characteristic involves observing the visible light emission from IR phosphor contained in samples with peak wavelengths of 548 nm and 554 nm by optical excitation with a peak wavelength of 980 nm. The second characteristic involves observing the differences in the luminescence states in each sample. We made experimental system shown in Fig. 14 and irradiated IR light (width: approx. 1mm, length: approx. 5mm) at the center of the surface of samples. Fig. 15 shows six images obtained from 20 samples (the bottom right corner shows the sample number). The luminescence of the IR phosphor particles is expressed as whitish spots and the differences in the emission intensities and the degree of the dispersion of phosphors can be observed from the images. Hence, it is assumed that the visible light images can potentially correspond to a type of characteristic information that is used to distinguish valuable cards.

### V. CONSIDERATIONS

This section considers the requirements that satisfy the proposed approach and the difficulty of counterfeiting feature information. The section also discusses the feasibility of the proposed method.

#### A. Satisfaction of the requirements

This section describes the manner in which the proposed approach satisfies the requirements listed in section 2.3. First, with respect to Requirement 1, the proposed approach forms a thin film on the surface of the core layer and provides two types of characteristic information with respect

to the film. In the experiment, the thin film is formed on the surface of the polypropylene plate used to resemble the real core layer and to extract two types of characteristic information from it. It is possible to perform printing on the surface of the polypropylene in a manner similar to other types of synthetic resins such as polyethylene, polyvinyl chloride, and polystyrene. Hence, it is assumed that the approach satisfies Requirement 1.

This is followed by considering Requirement 2. It is possible to use both materials (the conductive polymer paint and the IR phosphor powder) adopted in the proposed approach across a wide range of temperatures since the materials are not affected by temperature. Additionally, mixing the above materials does not produce any substances that are susceptible to temperature. Hence, it is assumed that the approach satisfies Requirement 2.

With respect to Requirement 3, although the thin film composed of the conductive polymer is flexible, it breaks easily when subject to physical force (such as light scrubbing on the surface of the thin film by using a finger). Therefore, it is assumed that a tamper-resistant feature can be realized by sandwiching the thin film between the core and the skin layer with adhesive (see Fig. 4). Hence, it is assumed that the proposed approach satisfies Requirement 3.

With respect to Requirement 4, a conductive polymer does not contain any toxic elements and uses safe solvents such as water and ethanol. Similarly, the IR phosphor is not harmful since it is a stable oxide. An example of a stable oxide is lead glass in which lead glass is not poisonous although lead is toxic, and thus it is used as a material to create fine glass tableware. Hence, the synthetic resin and filler used in the proposed method do not pose any risks to human skin, and it is assumed that the approach satisfies Requirement 4.

#### B. Difficulty of counterfeiting information features

This section describes the difficulty of counterfeiting two types of feature information. First, the sheet resistance is considered. As shown in Fig. 10 and Fig. 13, there are differences in the sheet resistances extracted from samples. Additionally, differences in sheet resistances are observed at each observation point located in the same sample. A reason for these differences could be attributed to the dispersion of the non-conductive IR phosphor particles that are spontaneously and randomly scattered in the conductive polymer paint.

This implies that the density of IR phosphor particle does not form evenly. To counterfeit a genuine sample to create a fake sample that has the same sheet resistance as the genuine sample, the following tasks are necessary:

- (1) Obtaining materials (polypropylene plate, IR phosphor powder, and conductive polymer paint) used to create a genuine sample A.
- (2) To create a thin film with same area, thickness, and density of sample A, it is necessary to compose a

Fig. 16 Light paths (left) and counterfeiting method (right).

Fig. 17 Inflection, transmission, and reflection at the surface of particle.

mixture of conductive polymer and IR phosphor powder and to drop the mixture on the surface of the polypropylene plate. Next, prior to drying the mixture of liquid and converting it into a thin film, it is necessary to move and fix each IR phosphor particle (with an approximate particle diameter of several micrometers) at the same three-dimensional location wherein the particle from sample A exists in its thin film.

It is relatively simple to perform Step (1) in manufacturing of a genuine sample. However, to perform Step (2), a counterfeiter would need to use “a high resolution microscope” and “a technique to move and fix each particle at the designated three-dimensional location. Each particle exists in the liquid that is gradually cured.” Hence, a high level of difficulty is associated with counterfeiting. Additionally, as the size and the shape of each particle are spontaneously and randomly determined, it is extremely difficult to create a fake sample with the same particles as those contained in genuine sample A.

Next, we consider the visible light images. Each sample and camera was faced each other and the samples are set on the optical surface plate, so that the images were shot along the z-axis. The intensity of the visible light emission has a relationship with the density of the IR phosphor particles, and a higher density leads to stronger infrared light emission. In addition, there are three possible light paths for the visible light emitted from the IR phosphor particle (see Fig. 16, left). One is the path directly from the center of particle, the second one is the path after inflection at the particle’s boundary, and the last one is the path that does not come out of the particle because of repeated reflection at the particle’s boundary. It seems that the sample might be counterfeited if counterfeiters could gather particles with direct light paths, as shown in Fig. 16, left (1) and

accumulate them on the z-axis as in Fig. 16, right. However, as shown in Fig. 17, visible light emitted out of IR phosphor particle A might have reflection, inflection, and transmission at particle B's boundary, so it is hence quite difficult to emit visible light only along the z-axis as intended by counterfeiters (in fact, counterfeiting is quite difficult as the shape of the particles is not spherical). Hence, we conclude that it is difficult to counterfeit samples with the same visible light images because of the above considerations.

As previously mentioned, the proposed approach can increase the level of difficulty involved in counterfeiting.

#### C. Application of the Phase-Only Correlation method

In a biometric system, it is difficult to observe reproducibility in images involving scans of fingerprints, iris, and retina, and differences (such as slight parallel translation, rotation movement, and brightness) are observed between the fore-mentioned images. Hence, an image matching technique termed as Phase-Only Correlation (POC) is adopted [15] to stably evaluate the similarity in images despite the existence of the fore-mentioned differences. This system corrects the angle and the position displacement and extracts common areas between the registered image and the image obtained in the verification phase. This is followed by calculating the degree of correlation degree and deriving the similarity. The results indicate that the proposed algorithm is more robust than algorithms proposed by previous studies with respect to differences in a photo shooting environment.

We will conduct an experiment in order to confirm the applicability of this method with visible images used in our approach. In concrete, we change the intensity of excitation light and the location of samples and shoot visible images while having optical excitation. We then confirm the degree of similarity in each sample by using obtained images.

#### D. Consideration of forming thin film

In the experiment, a liquid mixture consisting of the conductive polymer and the IR phosphor powder is dropped by using a syringe to create a thin film by employing gravity in conjunction with the hydrophilic features of the resin plate. Although the thickness is low, the film is opaque (as shown in Fig. 9 (left)) as it is much thicker than the transparent electrodes composed of conductive polymer paint.

To avoid affecting the visibility of characters and images printed on the surface of the real core layer, it is necessary to form a thin layer with a thickness equal to that of the transparent electrodes on the entire surface of the real core layer. This is because the visibility of printed characters and images could be affected by angularities generated at the boundary between the thin film and the core layer if the thin film is formed on the part of the surface of the core layer.

In contrast to the dip-coating method, the spin-coating method described in section 4.1 has an advantage as it forms a thin film with a small amount of coating liquid [16]. Additionally, other spin-coating methods, such as using

conductive polymer paint as a coating liquid and its application to the surface of the synthetic resin plate, were proposed by extant studies. Therefore, it is assumed that the proposed approach (forming a thin layer on the surface of the core layer) is associated with high feasibility. A future study will confirm two objectives, namely forming a thin film on the surface of the core layer by using a liquid mixture and the spin-coating method and extracting two information features from a thin film without contact.

## VI. CONCLUSION

In this paper, we proposed multimodal artifact metrics in order to authenticate an artifact with high accuracy and heighten the difficulty of counterfeiting. This technique is based on multimodal identification in biometrics. This method can give two or more information features generated from two or more physical characteristics into an artifact and verify the authenticity of each artifact using the extracted information.

The study focused on valuable cards composed of synthetic resin as artifacts for the application of multimodal artifact metrics because the existence of copied cards was reported by extant studies. Additionally, an experiment was conducted to confirm the applicability of the proposed approach (forming characteristic information on the surface of the core layer). In the experiment, a thin film was formed on the surface of polypropylene plate by using conductive polymer paint and an IR phosphor powder. Samples consisting of a thin film and two polypropylene plates were composed in which the thin film was sandwiched by the plates. Two types of information features, namely sheet resistance and visible images, were extracted from samples without contact. The result of the experiments indicated that there were differences in the information extracted from each sample, and thus there is a high possibility that this can be used as feature information. Furthermore, the proposed approach satisfied four requirements and demonstrated that it increased the difficulty of counterfeiting.

To implement the approach stated in this study, a future study will involve developing a visible image matching algorithm by using a POC method and confirming the feasibility of forming a thin film on the surface of the core layer. Thus, future studies will explore developing the proposed multimodal artifact metrics and related techniques.

**Abstract**—There are several reports and white papers which attempt to precise 5G architectural requirements presenting them from different points of view, including techno-socio-economic impacts and technological constraints. Most of them deal with network slicing aspects as a central point, often strengthening slices with slice isolation. The goal of this paper is to present and examine the isolation capabilities and selected approaches for its realization in network slicing context. As the 5G architecture is still evolving, the specification of isolated slices operation and management brings new requirements that need to be addressed, especially in a context of End-to-End (E2E) security. Thus, an outline of recent trends in slice isolation and a set of challenges are proposed, which (if properly addressed) could be a step to E2E user's security based on slices isolation.

## I. INTRODUCTION

PROGRESS of work on the 5G network architecture can be characterized as the moment of movement from storming phase to forming phase. There is still a wide range of projects related to different areas of the 5G network [1] hence there are several main approaches to the architecture and implementation. Many 5G projects deal with network slicing aspects taking into consideration both technology and business perspectives. It is assumed that the ideas will continue to evolve for some time to give the final result in the foreseeable future.

Idea of isolation in the network is not new however currently considered technologies give new capabilities that can bring value in this field. For example isolation considered as security enabler depends on the quality of isolation mechanisms used in the various components of the network. In 5G networks there will be rather a portfolio of isolation technologies available than single one like virtual private network (VPN). This means that it will be necessary to integrate and manage a variety of isolation mechanisms on different levels. Basing on the assumption that isolation techniques are among important enablers for security in 5G, an analysis of the isolation capabilities and selected approaches for its realization in network slicing context are presented. On one hand it is important to identify native isolation capabilities but on the other hand it is also necessary to propose improvement of existing concepts and identifying the missing parts. Considering agile but secure solutions one can notice existence of opposite

poles. At one end there are demanding business requirements, especially in relation to 5G network, at the other end there are technical conditions that have to meet the expectations without breaching security standards. Business perspective has determined expected network parameters and introduced more open approach for network management. It forced changes that have positive impact from the client perspective. Multi-vendor and multi-tenant network concept based on automation and elasticity are real way to meet the needs but brings new challenges at the same time, introducing new potential vectors of attack. One of the hardest challenges concerns isolation in relation to Quality of Service (QoS) and Quality of Experience (QoE). At the same time expected QoS/QoE should be preserved with proper Quality of Security. If it fails, users of the network can request a return to the rigid mechanisms which can cause the collapse of the concept of programmable, open networks as such. Therefore, realization of elasticity and agility is strongly connected with isolation technologies supporting security. Isolation level should be considered as an important parameter determining service realization in future networks.

The goal of this paper is to examine the isolation capabilities and selected approaches for its realization in network slicing context. As the 5G architecture is still evolving specification of isolated slices operation and management bring new requirements that need to be addressed. The rest of the paper is structured as follows. Section 2 provides brief overview of challenges for 5G networks. In Section 3 we present known network slicing concepts, while Section 4 presents more details about isolation techniques and network slicing management. Section 5 summarizes known research problems related to 5G software-defined ecosystem and slicing. Section 6 presents new perspective of designing sliced environment and providing E2E slices isolation in 5G networks. Finally, in section 7 conclusions and future research plans are presented.

## II. SLICING: THE 5G CHALLENGE

The new network concept (5G) will be more focused on business point of view than previous generations of mobile networks. Sets of requirements described in [2], [3], [4], [5]

are very difficult or expensive to be satisfied in the whole network at the same time. However, it is feasible to provide some subsets of such requirements and a Network Operator can configure multiple logical networks with different network efficiencies and properties. This is the reason for splitting one physical network into multiple logical networks. Such a 5G-based virtual environment will provide a platform for a services with some sets of specific properties (Key Performance Indicators, QoS/QoE parameters, etc.), which can be used to define new logical networks [6]. Each of these networks has its own application (voice communication, video streaming, Internet of Things, e-health, etc.) and its own properties based on business requirements for each service, which will be provided over this network [2], [7], [8]. In the whole set of requirements with high probability exist many subsets of properties, which cannot be satisfied at the same time. However, reducing the set of requirements for a logical network could improve some selected properties critical for the service provided over this network.

#### A. The isolated slices

The logical networks described above are a core of the network slicing concept. In this concept the network and available resources can be partitioned in many slices, which are associated with services and sets of requirements. Each slice can be considered as (at least) one logical network. Network slicing is usually considered together with orchestration concept, which supports slice management (creating slices, changing slices' properties, reconfiguration of slice's network, etc.) and provides interfaces (northbound interface, API) for service providers, other network operators and other allowed (authorized) users. The purpose for this feature is to make services and network more agile and adjustable to business and user's requirements or current network situation.

#### B. Security in a sliced network

This new concept with new elements brings new security questions and problems as these new elements also could bring new security issues. It is important to define who and how can use orchestrator and other modules to avoid security threats like exhaustion of resources or Denial of Service attack (DoS). The slicing concept itself is a source of security issues. Systems which support slicing may be exploited by attackers. Slicing could also use heterogeneous platforms and solutions: slicing components can be implemented in firmware, OS kernel level, in the virtualization software systems or even in regular software. In this wide spectrum of environments, the slicing components may be provided by different vendors. Ensuring common level of security for all applications which build slicing concept in this case can also be difficult.

Adding special properties to slices (isolation, protection, etc.) might create new attack methods, i.e. by exploiting weak isolation providing system to reach resources in other slice with better parameters, lower costs or sensitive data stream. An attack on these properties could also be a part of more

complex attack scenario (it could be subject to attack in the Attack Jungle concept [9]).

In slicing for 5G there are some common network services or functions like Mobility Management or AAA (Authentication, Authorization, Accounting) service [10], which are shared between more than one slice instance. This concept is in contrary with isolation property and should be considered how to solve this problem, especially in 5G, where we have more shared functions than in wired networks.

#### C. The major challenge in sliced 5G network

The key problem in 5G networks is implementation of the 5G RAN (Radio Access Network). The solution for some of problems could be using small cells in the mmWave [11]. Attenuation in this frequencies is bigger than in regular wireless networks (2G- 4G), but in some windows the propagation parameters are good enough to provide small cell with 200 m range [11]. This property naturally isolates traffic between different cells. Using two types of cells enables architecture, where part of data is transmitted by macro cells (i.e. data from C-Plane, what was described in [11]) and rest of them is transmitted by small cells (i.e. data from U-Plane). In slicing terms one can look at this as a special meta-slice, which allows User Equipments (UE) to communicate with RAN and CN (Core Network).

However, not all new solutions have this positive effect on isolation level or naturally enable slicing in a network. For instance, NOMA (Non-Orthogonal Multiple Access) assumes that more than one UE receives a message on the same frequency channel, code and time slot [11] and it recognizes messages depending on the signal power level. In this case the Base Stations (BS) must consider UEs membership in slices while frequencies, codes and time slots are assigned to avoid the isolation violation. Another technology which could be useful in 5G networks, but which provides new isolation problems is Cognitive Radio [11].

### III. CONCEPTS OF NETWORK SLICING

#### A. Network Slicing definition

Network slicing is one of the crucial technologies that enables flexibility, scalability and that improves security as it allows creation of multiple separated logical networks spanned over a shared hardware infrastructure. First idea of network virtualization and slicing was introduced in the paper [12], where the authors described an overlay network, the PlanetLab, which was able to produce slices of the network to provide environment for simultaneous design and utilization of different services. Since then this concept has grown considerably and has become the subject of extensive investigations. In recent studies and designs the network slicing idea is based on the three-layers model [13]:

- Service Instance Layer,
- Network Slice Instance Layer,
- Resource Layer.

The Service Instance Layer describes the services (e.g. business services or end-user services) which should be supported.

Each service is created as a Service Instance. Usually a service can be provided by a network operator or 3rd parties, so the Service Instance can be created by both operator services and 3rd parties services.

A Network Slice Instance is a set of (virtualized) network functions implemented at resources which enable running these network functions. It forms a complete instantiated logical networks to meet certain network characteristics (e.g. ultra-low-latency, ultra-reliability, etc.) required by the Service Instance. A network slice instance could be isolated from another network slice instance in several ways, e.g., full or partial isolation and logical or physical isolation. To create a Network Slice Instance, a network operator uses a Network Slice Blueprint (description of the structure, configuration and the flows and how to control the network slice instance during its life cycle). A Network Slice Instance ensures the network characteristics which are needed by a Service Instance. Therefore, a Network Slice Instance can be shared with multiple Service Instances provided by the network operator. The Network Slice Instance Layer contains many instance of network slices.

The Resources Layer contains both physical and logical resources. The Network Slice Instance can consist of Sub-network Instances, which can be shared with multiple network slice instances. The Network Slice Instance is defined by a Network Slice Blueprint. For creating every Network Slice Instance are required dedicated policies and configurations.

#### B. Vertical and horizontal slicing

Another slicing concept is described in [14], where the authors describe two approaches to network slicing: vertical and horizontal. On the vertical network slicing one network is sliced into multiple network slices, each designed and optimized for particular services or applications. The horizontal network slicing enables sharing of resources between nodes and network devices. Both approaches can be implemented in parallel and they can work together.

#### C. E2E Network Slicing

The concept of Network Slicing in 5G refers to three areas [15], [16]: at the air interface, in the RAN and in the CN.

1) *Network slicing at the air interface*: The idea of Network Slicing of Air Interface refers to proper partitioning of physical radio resources (PHY layer), mapping them into logical resources and creating the operations of MAC (Media Access Control) and higher layers based on the logical PHY resources.

2) *Network slicing in the RAN*: The Network Slicing in the RAN describes an optimal configuration of Control Plane and User Plane considering the specificity of slice. Besides two aspects should be investigated:

- The Radio Access Type (RAT) which supports services provided by a particular slice,
- The proper configuration of RAN capabilities with interfaces. It applies also to a correct cell deployment in every slice based on requirements. Based on factors such as

QoS requirements, traffic load or type of traffic, the RAN architecture should be properly tailored to each slices.

This is a huge challenge because some goals associated with 5G usage cannot be met at the same time (e.g. low latency and high reliability usually have an impact on the spectral efficiency).

3) *Network slicing in the CN*: Network Slicing in CN is possible due to two technologies: Network Function Virtualization (NFV) and Software Defined Networking (SDN). The goal of SDN is to separate the control plane from the data plane. Moreover, the control plane should be programmable through APIs in order to bring flexibility in management. Supporting the SDN-like separation of planes is one of the main principles of 5G core network architecture, because it allows, see [17]:

- Data and control resources to be scaled independently,
- Data plane closer to the users' devices,
- Appropriate choice of the data plane function required for different slices,
- Decomposition of data plane into smaller functions,
- Possibility of migration to cloud deployments.

The goal of NFV is to virtualize network functions into software applications that can be run on standard servers or as virtual machines running on those servers.

### IV. NETWORK SLICING: ISOLATION, MANAGEMENT, SECURITY

#### A. Isolation and security

One of key expectations of network slicing is resources isolation. Each slice may be perceived as isolated set of resources configured through the network environment and providing defined set of functions. Level and strength of isolation may vary depending on requirements and usage scenarios for slicing. At one scenario there may be requirement for strict slices isolation, but in another there may be required some communication between slices. Thus isolation may be perceived in many different ways and constitute a set of properties chosen according to implementation needs. After analysis of 5G network slicing security issues [18] the following isolation properties may be defined:

- Ring-fencing of each slice operational resources (e.g. storage, processor, operational memory), so that one slice cannot exhaust other slice's resources in any situation,
- Ring-fencing of resources for security protocols inside slice,
- Not supporting communication between slices (while ring-fencing resources concerns guarantee of minimal set of resources, this point concerns lack of information flow between two separate slices),
- Supporting communication between slices on strictly defined rules (like the previous point, it can be applied with complementary technique of ring-fencing of proper resources: operational and security),
- Cybersecurity assurance in the sense of protection against hacking one slice to influence another one,

- Signaling and management isolation to provide secure communication between slice and orchestrator as well as secure communication between elements inside slice,
- Reliability assurance of different pieces of physical equipment which used to span a slice,
- Secure communication between multiple network slice managers,
- Isolation concerning level of emission of information to slices environment (e.g. side-channel attacks resistance),
- Isolation in hybrid environment including regular network functions (NF) and virtualized NFs,
- Isolation of slices with one user equipment connected to multiple slices at a time.

Not all of the properties should be implemented in each solution. There can be subsets of those properties chosen in order to meet specific requirements. Isolation may be achieved by different means, including [19]:

- Language based isolation (type systems, certifying compilers),
- Sandbox based isolation (Instruction Set Architecture, Application Binary Interface, Access Control List),
- Virtual Machine (VM) based isolation (Process VM, Hypervisor VM, Hosted VM, Hardware VM),
- Operating System (OS) kernel based isolation,
- Hardware based isolation,
- Physical isolation.

Referring the above techniques of isolation to the slicing layers and to the network media interfaces it can be noticed that language-based and sandbox-based techniques are especially suitable for providing isolation in Service Instance Layer and Network Slice Instance Layer. The VM-based and OS kernel-based techniques are applicable at the Network Slice Instance Layer and the Resource Layer while hardware-based isolation and physical isolation can help in infrastructure/virtual infrastructure sharing among slices, especially at the interface RAN-CN, which is the hardest one for providing slices isolation.

Isolation enabling means can be grouped using general categorization presented in the above list. Aside from this categorization, isolation assurance problem may be considered on network protocols level. There are several technologies enabling isolation of network resources, each one with its own characteristics and limitations. Below there are listed example slices isolation enabling technologies:

- Tag-based network slices isolation such as MPLS (Multi-Protocol Label Switching) uses special tags within packets to determine which slice they belong to,
- VLAN-based network slices isolation uses switch ports to partition the network on the second layer of OSI model,
- VPN-based network slices isolation uses special protocols such as IPsec, SSL/TLS (Secure Socket Layer/Transport Layer Security, DTLS (Datagram Transport Layer Security), MPPE (Microsoft Point-to-Point Encryption), SSTP (Secure Socket Tunneling Protocol), SSH (Secure Shell) to provide authentication and confidentiality for transmission within each slice,

- SDN-based network slices isolation provides additional abstract layer to provide flexibility of slices management and is considered one of key enablers of 5G slicing [20].

To evaluate each of above technologies as well as other not listed there is a need to define sets of common desired isolation properties and measures for those properties. Each set would represent specific business needs and description how to satisfy and measure them. A review of known communication protocols providing isolation on different security level can be found in [21].

### B. SDN for Network Slicing

One of technologies mentioned above is SDN, which is considered as slicing enabler for Core Networks in 5G. It is a powerful tool that provides flexible services tailored to fit business needs. However, as a technology itself it carries also new attack vectors.

SDN security project [22] defines several areas of potential vulnerabilities including firmware abuse, eavesdropping, man-in-the-middle, APIs abuse, resource exhaustion, packet flooding and more. Research [23] presents other attack vectors for SDN: misconfiguration of access to remotely accessible interfaces, malware infection at build time and runtime, and tenant attacks. As a response to these new threats security assessment tools are being developed [24], [25]. Such tools and new attack vectors may be used to define desired isolation properties and measures. To satisfy properties selected for given slice configuration there should be chosen suitable technologies working under certain configuration and assumptions. One property can be satisfied by different technologies. Choice for suitable technology should be made according to optimization criteria for each case.

### C. Isolation in wireless domain

In wireless domain there are some techniques for slices isolation which are dedicated especially for this domain. This is because of special properties of air interfaces and medium. According to [8] there are the following strategies for resource isolation in 3GPP LTE and WiMAX:

- Physical Resource Block (PRB) scheduling,
- Slice scheduling,
- Traffic shaping.

For IEEE 802.11 (WiFi) network there are similar strategies:

- EDCA (Enhanced Distributed Channel Access) control,
- Slice scheduling,
- Traffic shaping.

The following solutions can constitute an example of isolation techniques usage in wireless domain [8]:

- Virtual Basestation [26] in WiMAX implements slices' isolation with traffic shaping techniques in downlink,
- CellSlice [27] in WiMAX implements slices' isolation with slice scheduling and traffic shaping in uplink and sustained rate control in downlink,
- The papers [28], [29] describe assigning resources in LTE with PRB scheduling in downlink,

- Virtual WiFi [30] describes client virtualization in 802.11 networks using slice scheduling.

#### D. Management and orchestration

Network management is a fundamental function for establishment and functioning of the sliced network and for its security. The management starts with setting up slices and initiating communication in the sliced environment. Next, it manages slices and controls data transmission in a stable network state. Finally, it closes slices, makes accounting for transmission and cleans after-effects to prevent remainder attacks. Requirements and future expectations concerning management in sliced network are the subject of reference papers, public discussions and research projects, see e.g. [31], [32], [33]. The papers presenting 5G management and orchestration, which is this part of management that can be automated, usually consider the ETSI NFV-MANO [34] as a reference model. ETSI NFV-MANO pretends to satisfy all expectations of future virtualized networks, including 5G. However, since it is very general, it needs additional specifications and clarifications. Some attempt of doing this is made by introducing additional standards specifying information flow at reference points (see [35]) but some of them are still draft standards, some other are under reconstruction, so the system is not complete. Since the ETSI NFV-MANO system is very general, it does not explicitly consider such real network problems like: multi-tenancy, multi-vendor/multi-domain network's infrastructure and, what is the most important for security, it considers slicing isolation only on a basic level of performance isolation. Therefore, modifications and extensions of the management and orchestration system for 5G and virtualized networks are the subject of extensive studies.

One of possible improvements of ETSI NFV-MANO is joining it with SDN-like management, see, e.g., [36], [37]. The systems are compatible because they have plane-based/layered structure and both of them assume centralized management. Another extension tries to simplify management in multi-domain, multi-vendor and multi-tenant systems by introducing hierarchical management and orchestration structures (see e.g., [6], [38], [39], [40]). Such an approach enables application of the ETSI NFV-MANO system directly for a single domain or instance and provide a supervision over a number of management systems. It also enables Virtual Functions and slice chaining in heterogeneous environment or when a slice is built over several domains, see e.g., [41], [42], [43].

Another aspect of MANO in a multi-domain networks was considered in paper [44]. In such networks each domain can work under different constraints (legal, technological, security, etc.). To establish a joint service (slice) over all domains one must negotiate common conditions for all domains. This paper proposes using Service-Level Agreement (SLA) criteria of orchestration. They are considered in frames of orchestration model which represents a centralized approach assigned to a network's owner. However, in some specific networks (in our case: specific slices), e.g., Internet of Things systems, it is more suitable to apply a decentralized approach

called a choreography (see e.g., [45]), where decision rules are negotiated among network elements according to their own particular interests.

Enhancing slicing property of the expected 5G networks led to extended ETSI NFV-MANO systems. Some approaches try to make an order in information flow in MANO (which is a critical and still unsolved problem) introducing it as a specific ETSI NFV-MANO service, see [46]. The other paper adds new orchestration functions dedicated specially for slicing, slicing in multi-tenant and multi-domain environments (see [47]).

All MANO schemes presented above, both the ETSI NFV-MANO and extended models, consider the network as a sliced medium with slices isolation on a level of a performance isolation, which is natural in 5G slices concept. For a stronger, secure (cryptographic) isolation, a new orchestration aspect should be taken into account, which is secure isolated slice establishment at the slices establishment stage, and isolation checking at the second, network exploiting stage. Finally, when the slice is being closed, secure critical data destruction must be performed to prevent post-dated loose of isolation. Thus, a new MANO scheme must be proposed, where isolation establishment at each stage of a slice lifetime is considered. The scheme must take into account also such elements as: slice chaining, isolation establishment, and isolation checking and monitoring.

The analysis of requirements and constraints appearing in such a complicated environment proves that every MANO system trying to reflect all aspects of reality would be completely nonfunctional and too heavy to be implemented and controlled. Thus, should be considered a single management and orchestration system or it is better to divide it into several cooperating and interdependent/hierarchic MANO subsystems? This proposal should be further analyzed to outline frames of each MANO subsystem and to integrate them. Such an approach restricts the number of required information flow specifications on MANO interfaces (where not all are defined yet) and introduces a few information flows between MANO subsystems to specify.

#### V. CONCERNED ISSUES IN 5G NETWORKS

5G, as a future generation of telecommunications standards, faces new issues every day when already posed or identified tasks are solved. In this section a number of problems which have been recently identified by prominent research groups and which stand for actual 5G issues are briefly presented.

On the web page of the IEEE SDN Technical Community there is a White Paper [48] presenting actual issues inspired by conditions resulting from techno-economic conditions and policy constraints and proposing a change of paradigms in the design and operation of future telecommunications infrastructures dedicated to 5G networks. The main issues identified in the paper [48] are:

- Softwarization of the RAN, which is implemented as a C-RAN concept: the centralized, collaborative, clean and Cloud Radio Access Network, resulting in new network's

architecture, resources allocation, virtualization, SDN-like solutions, etc.;

- An end-to-end vision for 5G, which should result in new service capabilities, interfaces, management and control schemes, access and non-access protocols with suitable procedures, functions, advanced algorithms and new classes of virtual or physical resources;
- Application the Open Mobile Edge Cloud (OMEC), a functional node which will be deployed to provide seamless coverage and execute various control plane functions as well as some of the "core functions" currently placed in various nodes of the Evolved Packet Core (EPC);
- New solutions for planning, policy and regulation resulting from different trust domains of virtualized functions and virtualized and non-virtualized infrastructure, which include:
  - The creation of a resilient policy,
  - The mapping and application of the policy to real hardware and software,
  - The visualization and enforcement of the policy, typically through visualization and enforcement tools;
- Provisioning of appropriately secure infrastructure (both, virtual and non-virtual);
- Management and maintenance of a deployment with multiple trust domains (which has been described in more detail in Section 4),
- Application of open source software as strategic for interoperability, innovations and research impacts, robustness and, as a consequence, network reliability and security.

The recent technical report [49] of the 3rd Generation Partnership Project (3GPP) concentrates on slicing as a crucial problem for development of 5G networks. It identifies several detailed key issues to be studied to provide and manage an isolated sliced environment for future networks. The basic questions in this area are:

- How to achieve isolation/separation between network slice instances and which levels and types of isolation/separation will be required?
- How and what type of resource and network function sharing can be used between network slice instances?
- How to enable a User Equipment (UE) to simultaneously obtain services from one or more specific network slice instances of one operator?
- Which operations are crucial with regards to Network Slicing: network slice creation/composition, modification, deletion, etc.?
- Which network functions may be included in a specific network slice instance?
- Which network functions are independent of network slices?
- The procedure(s) for selection of a particular Network Slice for a UE;
- How to support Network Slicing Roaming scenarios ?
- How to enable operators to use the network slicing concept to efficiently support multiple 3rd parties (e.g.

enterprises, service providers, content providers, etc.) that require similar network characteristics ?

Future networks expectations undergo different trends, visions and requirements which must be taken into account to obtain effective, flexible and reliable systems. Among them, the crucial are: heterogeneity in use cases, need to support different requirements from vertical markets, multi-vendor and multi-tenant network models, etc. The method which could solve essential problems of 5G networks is slicing, in particular, end-to-end slicing approach. Paper [50] addresses the key issues of how 5G devices may be enabled to discover, select and access the most appropriate E2E network slices. Except of general requirements concerning E2E network slicing, the authors propose specific solution called Device Triggered Network Control mechanism. They define steps of the E2E slice selection and present results of simulations verifying usability of the mechanism proposed.

Fig. 1. The slice chaining concept, based on [51]

The overview studies related to providing E2E slices and slice isolation in future 5G networks presented in previous sections lead to some additional issues that extend the 3GPP considerations and focus them on E2E isolation approach. The E2E network slicing refers to a logical decomposition of the network instance layer including a specific character of network domain functions such as RAN or CN. In the E2E approach slicing is associated with a term "slice chaining", which is an equivalent of the service chaining [10]. The service chaining is a technique for selecting and steering data flows using different kind service functions. Thus, the main idea is to choose proper resources of the network to establish connection with the required SLA level. In 5G approach, the slice chaining (see Fig.1) is defined as a way to establish one E2E connection through RAN and CN networks to a particular service provider. Among many problems associated with the network slicing from the security point of view, the isolation of slice chaining is one of the most challenging. A flexible nature of the network slice should be characterized by a minimal influence on the services of this slice or other slices. Moreover, operators should assure the maximum amount of resources for every slices and their independence. Thus, the isolation of resources/slices should be provided. In the following Section 6 we present a number of tasks and issues which should be addressed to provide E2E secure isolation in sliced network without unreasonable restricting the requirements of a network business model and network's technological constraints like: accountability, sovereignty, performance, interoperability, etc.

## VI. TOWARDS 5G ISOLATED SLICING: NEW CHALLENGES

As a result of the investigations and analyses the following key challenges are proposed. Considering them should result in providing an effective sliced network with E2E secure isolation.

### A. *Providing standardized methods of design of isolated network slicing: patterns, parameters, technologies*

According to high diversity of each operator's network, the mechanisms, technologies or configuration used for isolation of slices are going to be different in each case. In order to assure the proper quality of design for network slices isolation there should be developed a framework covering requirements gathering and analysis. Such normalized approach would help network operators to take into account the most important security issues and assure that common goals for network slicing are properly reached. One of the assumption of 5G is that slices must provide inter-slice isolation of sensitive data, approaching that of physically separated networks. To enable that research in isolation domain should be performed.

5G must enable seamless inter-working of different network technologies, mobile, fixed as well as satellite, potentially with different security levels (access control to 5G network) without exposing the security level of each slices. In context of slicing, an isolation on a different level is required. One of the crucial issues is a definition of the isolation parameters. The isolation of the slices can be considered in at least four areas [52]:

- Isolation of a traffic: All slices using the same network resources, so the network slices should ensure that data flow of one slice does not move to another
- Isolation of a bandwidth: All slices allocate some bandwidth and should not utilize any bandwidth assigned to other slices. Thus, it is required to ensure the isolation of bandwidth on the links and nodes CPU/storage/network capacity.
- Isolation of a processing: While all virtual slices use the same physical resources, a proper processing of packet is required, which will be independent of all other slices.
- Isolation of a storage: Data related to a particular slice should be stored separately from data used by another slice.

Each area is marked by specific parameters which describe it. Even with knowledge about areas which should be isolated, there is nearly no information about parameters that need to be used to ensure the isolation. Some works associated with the isolation were done in the SDN idea but still they are far from being mature. In context of 5G network slicing it is insufficient, as the isolation in 5G refers not only to SDN, but also to RAN.

A definition of parameters used in the isolation allows to create a methodology of their measurement. Based on that it will be possible to determine their proper values. Finally, it will be helpful to check the isolation on the different levels. An unquestioned advantage of this methodology will be possibility to evaluate if isolation exists or not. The parameters of isolation have relations with other, so a set of their values and relations will be a literal proof of isolation existence.

Once a set of properties for slice is determined, proper technologies should be selected. There is a need to perform analysis of available slicing enabling technologies and then to determine potential security risks connected with each of the technology. On the basis of this risk analysis there should be proposed countermeasures to minimize the risk. Technology can be connected with protocols (e.g. OpenFlow as SDN protocol, routing protocols, cryptographic protocols), architecture paradigm (e.g. Software Defined Networking), implementations (e.g. SDN controller implementations, devices' firmware, operating systems) and hardware (e.g. used processors, Trusted Platform Modules, smart cards, USIM chips).

Further step in network slicing isolation design process is delivering proof of isolation on different levels of assurance. Once adequate isolation properties and technology are selected with respect to performed risk analysis, there is a need to define what kind of assurance a network operator would provide to his customers. There can be different levels of assurance from best effort to very strict security requirements, which would be defined during SLA agreement negotiations.

### B. *Secure E2E slice and inter-slice access and management*

The 5G E2E approach to slicing brings additional complexity for slice and inter-slice access management. Two types of access procedures can be identified:

- Device selecting and attaching to the appropriate slice, cf.[50],
- Paring between RAN and CN.

Every entity of 5G network can have different access possibilities to different resources, due to specific requirements of every slice. For example, entities in the IoT network can have access to proper slices of IoT services, but access to e-health slices should be forbidden or restricted. A management of this access is very important in the context of proper slice creation. Lack of it causes security problems such as unauthorized access, which finally can be a reason of frauds.

Another aspect of this problem is mutual access between RAN and CN resources. A proper definition of paring functions is crucial when a slice is created: some RAN areas can establish connection with CN slices and some of them cannot. A proper management of the access to a particular slice is an important requirement to achieve a secure E2E path. Perhaps properly applied C-RAN concept could be a remedy here.

In a sliced network we also should consider services, which are connecting to ME (Mobile Equipment) via the slice that is specific for a given service. In such a case ME must be able to receive traffic from RAN (considering 5G case), even if a slice instance used by this traffic has not been used before by this ME. Thus, one expects to have a protocol (governed by RAN or CN) that allows to attach securely a ME to the slice instance.

### C. *Support for method of providing access to common network functions shared between isolated slices*

In network with slice isolation there exists an unsolved problem of common network services and functions, like Mobility

Management and AAA. It can be resolved for some services by adding a proxy server between an origin service and a user of services; each proxy should be assigned per slice. Proxies created for a single service could be connected with each other (if number of them is relatively small) or managed by part of management layer (orchestration or choreography). This solution is suitable for cases without very strict constraints in the time domain, because in generic form it requires to solve the readers-writers problem between slices in reference to the shared service or network function. Some of the operations can be handled in parallel (the read operations) but it depends on the context and internal implementation of the specific service. In other scenarios, the exclusive access to network function is necessary, it leads to situation where service client must wait in a queue for free time slot or client's request must be rejected by service, when the queue is full.

*D. Providing a method of creation new slices without violating current level of isolation between existing slices (especially in the 5G RAN)*

Adding a new slice to currently established set of slice instances could cause some problems with satisfying QoS/QoE and isolation level in all slices. Even if resources are available, slices can affect each other. In the RAN, one can see this problem by interleaving communication channels in the frequency domain, which degenerates SNR (signal-to-noise ratio) and consequently BER (Bit Error Rate), throughput as well as causes packet loss, jitter, etc. Spread spectrum systems also have this problem, but in another way: the noise level increases with number of simultaneous transmissions which leads to similar problems. In the fibers, we have the FWM (Four-Wave Mixing) problem: two different wavelengths produce unwanted new two wavelengths, which degenerates output signal from fiber. This effect can be minimized by properly chosen wavelength, but it limits the number of dynamically created isolated slices (and there are some other technical problems, like maximal number of waves handled by an optical terminal and non-zero distance between wavelength in grid).

Another practical problem is that each medium has some maximum available ratings like available throughput for all users, so always exists the maximum number of parallel users which use specific medium or resource. In the 5G network this problem is generally more related to RAN than with the CN and this part should be optimized in order to avoid degradation of isolation by exhaustion of resources important for slices.

The isolation problem exists in RAN and CN simultaneously and should be considered in both part of network. However, in some scenarios the CN part can be unused (i.e., a teleconference inside a single RAN cell), where all UEs are connected to one specific RAN part and end-to-end scenario does not need the CN to transport data.

The isolation problem can be considered over E2E approach (whole slice chain) or only over a single slice from slice chaining. Isolation in slice chaining should satisfy the rule: the isolation level of whole slice chain is not greater than the isolation level of any of slices inside the chain. The

consequence of this rule is that network should first guarantee properly creation slices inside each slice domain (RAN, CN and other) and in next step try to look after E2E slices' isolation. The slices in each domain can be created independently, but simultaneously creation could create additional problems with Isolation. The E2E slice could use slices created earlier if the slices' parameters are compatible (i.e. provided isolation level, throughput, availability).

The following solutions also can be considered: monitoring resources' utilization level and prevention of creating new slice instances if new instance harms QoS/QoE or isolation level; arranging slice instance reconciliation protocol which allows to change instances' requirements (maybe for a limited period of time).

*E. Accounting and non-repudiation for slices' users and operators*

While managing slices there is always risk of unexpected events occurrence. Sometimes they are caused by hardware or software malfunction but also intended attacks may be performed involving one or more adversaries. In complex network environment with multi-vendor, multi-operator and roaming support it is hard to determine strict areas of responsibility for given incidents. It is important to deploy mechanisms able to point out in whose area of responsibility it is to deal with certain incidents and who is by law responsible for not holding proper isolation properties according to SLA (Service Level Agreement).

Accounting is connected with non-repudiation in such a way that non-repudiation provides evidence which prevents entity from denying of having performed given actions and thus enables accounting in accordance with those actions. Accounting and non-repudiation may be performed on different levels, beginning from single operator level in operator-operator and operator-customer relationships and finishing on single device in operator's network environment.

There are different means to reach non-repudiation using symmetric and asymmetric cryptography and proper trust relationships. The most commonly used techniques are based on Public Key Infrastructure (PKI) with digital certificates, but they are not always applicable, so there is a need to determine what kind of techniques can be used to provide accounting and non-repudiation in network slicing environment in general and specifically in 5G. Apart from strict hard security means like cryptography and security protocols, soft security methods, like trust relationships, have to be implemented in comprehensive solution. In PKI as an example, hard security is realized by asymmetric algorithms like RSA (Rivest-Shamir-Adleman algorithm) or ECDSA (Elliptic Curve Digital Signature Algorithm), used for certificate signing, while trust in certain Certificate Authority is a soft security.

In slicing environment there is a need for gathering and utilizing evidence for certain actions and situations connected with users and operators. Further research should be done to develop architecture and mechanisms providing proper accounting and non-repudiation.

#### *F. Design of MANO system suitable for a heterogeneous, dynamic, multi-vendor and multi-tenant network*

Concerning management and orchestration in the architectural framework for a multi-domain, multi-tenant isolated sliced environment it has been reached the question if it should not be divided into several interconnected and hierarchic MANO subsystems concentrated on specific areas and periods of network functioning. They could be, e.g., for isolated slices establishment and for their usage. It must also cover security management, including strong isolation establishment and checking.

The network management system for isolated slices establishment should cover, as a novel element, slices chaining (also: services chaining within slices), as well as deciding which virtual service is exclusively assigned to a specific slice instance and which is shared. Network management system for isolated slices usage must concentrate, except for usual network management, on users assignment to specific slices and sharing competences among all actors involved: network providers, service providers and end users. The security management system is crucial for strong slices isolation and it must provide mechanisms for strong isolation establishment and permanent checking if isolation is not weakened or lost.

Another isolation problem which should be addressed in a context of network management is fulfillment of legal conditions related to telecommunication networks and network security. Such conditions can be different for different network domains (e.g., due to specific national regulations). Requirements on a Lawful Interception (LI) are a good example of such a problem. A solution could be including the legal conditions into Service Level Agreement requirements specific for each domain (or a network vendor) and then negotiating a common SLA for the whole slice. As a result, an operator can have some access control delivered at slice level with end to end isolation (ciphering) in a way appropriate for all domains.

#### *G. Unified interface (API) and protocol for access the Orchestrator*

Services (service providers) and other networks should be treated in the same way from the Orchestrator's perspective; also common interface could be used here. Requests from other networks should have identified service source so it is rational to handle this cases in the common way. There should exist a negotiation protocol between orchestrators from different Network Operators which uses some slicing maintenance policy. The protocol should satisfy following requirements:

- It should be fast enough, to be used during connection establishment between two or more endpoints,
- It should support energy saving devices in simplified version of protocol (which could be a part of the entire protocol),
- The protocol should use authentication mechanisms to avoid abuse and attacks,
- It should allow to renegotiate currently established slices' parameters when it is required to satisfy new slice's set of requirements (i.e., KPIs, QoS, QoE). The order in which

slices should be included in renegotiation part should be defined in slicing maintenance policy.

- The protocol should allow to drop incoming API requests which are not authorized (if the authorization is required). It also should be resistant to DoS attacks.
- The API should share information about network's client only if the client accepted this earlier. Client could be able to specify which services and networks can have access to information about him or her.

Sometimes new demands cannot be satisfied, even if the renegotiation has been used. This kind of situation also should be handled by maintenance policy. Demands could be queued in a priority queue; priority should depend on the type of demand source.

### VII. CONCLUSIONS AND NEXT STEPS

In this paper an attempt to reconsider the concept of secure slicing in a realistic ecosystem of heterogeneous multi-vendor multi-tenant 5G network has been made. In such a network, in order to assure E2E isolation on a certain strength level and to introduce adequate security policy it is necessary to identify isolation attributes and to create a kind of abstraction layer. Properly defined attributes are the basis to determine the E2E level of isolation. It is the way which allows the user to define, deploy and adapt (if necessary) concrete security policies accordingly to the expectations and service protection needs. Consideration of resource description in 5G networks leads to conclusion that currently there is no common description of isolation capabilities that could be used for automatic deployment. In order to define an abstraction for different resources it is necessary to specify attributes allowing unambiguous definition and rigorous verification of isolation level in a given slice. It is important to define expected initial isolation level (e.g. performance isolation) as well as to design mechanisms for dynamic isolation improvement for a given service. Dynamic isolation mechanism should be also able to create isolated resources with proper capabilities or to address inter-slicing communication to use virtual resources from a different slice in the way that will not breach global security policy rules.

To make the general idea presented above applicable in practice, it has been decided to formulate detailed issues which cover partial tasks leading to the complete solution. The tasks set out in this paper as well as the analysis which precedes it are the result of extensive state-of-the-art studies on network slicing and network sovereignty and long discussions held between research groups of Orange Labs and Warsaw University of Technology last year. Proposed tasks, although they cover a wide range of issues related to isolated network slicing, do not cover all important areas for slice isolation. We deliberately skipped the areas related to communication hardware-based technologies, concentrating on those solutions which are management-related and which are expected to be software-based.

The next steps of the research are: filling the draft frameworks presented above with hard principles and structural elements along with their interdependencies, estimating expected

parameters and verifying experimentally functionality of the resultant isolated slices model.

**Abstract**—Key exchange algorithm based on homomorphic encryption idea is reviewed in this article. This algorithm might be used for safe messaging using one-time pads. Since algorithm requires a low amount of computing resources, this method might be used in IoT to provide authentication.

**Keywords**— *homomorphic encryption; key exchange; one time pad*

## I. INTRODUCTION

THE EXPECTED evolution of quantum computers is causing the intensive development of cryptographic primitives called postquantum cryptography. February 6, 2016 was the day that the *National Institute of Standards and Technology* (NIST) offered to start the development of new postquantum cryptography standards which might be used in governmental needs. According to documents submitted by NIST, algorithms based on a discrete logarithmic problem are vulnerable to quantum attacks. Moreover, elliptical cryptography methods are considered to be vulnerable. Therefore, we need to replace the Diffie-Hellman key exchange algorithm in TLS protocol. Nowadays, offered postquantum key exchange algorithms are based on lattice theory [4] (LWE, RLWE [2]), which is used in key exchange algorithms named New hope [1] and Frodo [3]. These algorithms are being supported by Google as TLS postquantum update.

We represent the key exchange algorithm based on basic homomorphic encryption properties and linear algebraic methods. The main purpose of this algorithm is to ensure secure messaging. It's assumed that the one-time pad method will be used. To use the algorithm in TLS one should change it in accordance with specification.

## II. NOTATION

In this section we will describe the notation that will be used.

Let  $\mathbb{Z}$  be a ring of integer numbers. For  $n \in \mathbb{N}$  let's call  $\mathbf{a} = (a_1, \dots, a_n)$  *n-dimensional integer vector* if  $\forall i \in \{1, \dots, n\} a_i \in \mathbb{Z}$ . For  $n \in \mathbb{N}$  let  $\mathbb{Z}^n$  denote the set of all possible *n-dimensional integer vectors*. Moreover, it's assumed that *n-dimensional vectors* have the following properties:

- 1) For each pair  $\mathbf{x}, \mathbf{y} \in \mathbb{Z}^n$  the following is true  $\mathbf{x} + \mathbf{y} = (x_1 + y_1, \dots, x_n + y_n)$ .
- 2) For each  $\mathbf{x} \in \mathbb{Z}^n, \alpha \in \mathbb{Z}$  the following is true  $\alpha \mathbf{x} = (\alpha x_1, \dots, \alpha x_n)$ .

Moreover, for  $\mathbf{x}, \mathbf{y} \in \mathbb{Z}^n$  let's call  $\mathbf{x} \cdot \mathbf{y} = \sum_{i=1}^n x_i y_i$  a *dot product*. Let  $\chi$  be a probability distribution over  $\mathbb{Z}$ . Accordingly,  $x \leftarrow \chi$  denotes sampling  $x \in \mathbb{Z}$  according to  $\chi$ . Moreover, for  $a, b \in \mathbb{Z}, a < b$  let  $x \leftarrow U_{a,b}$  denote sampling  $x$  uniformly from  $\{a, a+1, \dots, b\}$ . Moreover, let  $\mathbf{x} \leftarrow U_{a,b}^n$  denote sampling  $\mathbf{x}$  in the following way:  $\mathbf{x} = (x_1 \leftarrow U_{a,b}, \dots, x_n \leftarrow U_{a,b})$ .

**Definition II.1.** Homomorphic encryption Let  $\mathbf{x} \in \mathbb{Z}^n$  be a fixed *n-dimensional integer vector* for some  $n \in \mathbb{N}$ . Moreover, let's consider that  $\mathbf{x}$  has *at least 2 coprime components*. For number  $d \in \mathbb{Z}$  and vector  $\mathbf{x}$  we will call a vector  $\mathbf{a} \in \mathbb{Z}^n$  an *interpretation* if  $\mathbf{x} \cdot \mathbf{a} = d$ .

Therefore we have a mapping  $\Phi_{\mathbf{x}} : \mathbb{Z} \rightarrow \mathbb{Z}^n$ . Easy to notice that this mapping has the following properties:

- 1)  $\Phi_{\mathbf{x}}(\mathbf{a}_1 + \mathbf{a}_2) = \Phi_{\mathbf{x}}(\mathbf{a}_1) + \Phi_{\mathbf{x}}(\mathbf{a}_2)$
- 2)  $\Phi_{\mathbf{x}}(\alpha \mathbf{a}) = \alpha \Phi_{\mathbf{x}}(\mathbf{a})$

This mapping is called *homomorphic encryption*.

## III. KEY EXCHANGE BASED ON HOMOMORPHIC ENCRYPTION

In this section we represent the key exchange algorithm. We suppose that 2 users – Alice (server) and Bob (client) decides to get a common key. Moreover, we suppose that both users trust each other (Authentication is completed) and both users know the value of  $k \in \mathbb{N}$ .

- 0) Alice and Bob, together, choose  $z, z' \in \mathbb{Z}$  such that  $z < z'$  and number  $n \in \mathbb{N}$ .
- 1) Alice chooses the number  $n \in \mathbb{N}$  and the secret vector  $\mathbf{x} \leftarrow U_{z,z'}^n$ , the set of vectors  $\mathbf{a}_1 \leftarrow U_{z,z'}^n, \dots, \mathbf{a}_k \leftarrow U_{z,z'}^n$ . Then Alice calculates  $d_1 = \mathbf{a}_1 \cdot \mathbf{x}, \dots, d_k = \mathbf{a}_k \cdot \mathbf{x}$ . In addition, Alice chooses the number  $p \in \mathbb{N}$  and finds the set of vectors  $\mathbf{s}_1, \dots, \mathbf{s}_p \in \mathbb{Z}^n : \forall i \in \{1, \dots, p\} \mathbf{s}_i \cdot \mathbf{x} = 0$ . Alice sends  $\mathbf{a}_1, \dots, \mathbf{a}_k, \mathbf{s}_1, \dots, \mathbf{s}_p$  to Bob.
- 2) Bob chooses the number  $m \in \mathbb{N}$  and the secret vector  $\mathbf{y} \leftarrow U_{z,z'}^m$ , the set of vectors  $\mathbf{b}_1 \leftarrow U_{z,z'}^m, \dots, \mathbf{b}_k \leftarrow U_{z,z'}^m$ . Then Bob calculates  $h_1 = \mathbf{b}_1 \cdot \mathbf{y}, \dots, h_k = \mathbf{b}_k \cdot \mathbf{y}$ . In addition, Bob chooses the number  $q \in \mathbb{N}$  and finds the set of vectors  $\mathbf{r}_1, \dots, \mathbf{r}_q \in \mathbb{Z}^m : \forall i \in \{1, \dots, q\} \mathbf{r}_i \cdot \mathbf{y} = 0$ . Bob sends  $\mathbf{b}_1, \dots, \mathbf{b}_k, \mathbf{r}_1, \dots, \mathbf{r}_q$  to Alice.
- 3) Alice calculates  $\mathbf{v} = d_1 \mathbf{b}_1 + \dots + d_k \mathbf{b}_k + \mu_1 \mathbf{r}_1 + \dots + \mu_q \mathbf{r}_q$ , where  $\mu_1 \leftarrow U_{z,z'}, \dots, \mu_q \leftarrow U_{z,z'}$ . Alice sends vector  $\mathbf{v}$  to Bob.

- 4) Bob calculates  $\mathbf{w} = h_1\mathbf{a}_1 + \dots + h_k\mathbf{a}_k + \lambda_1\mathbf{s}_1 + \dots + \lambda_p\mathbf{s}_p$ , where  $\lambda_1 \leftarrow U_{z,z'}, \dots, \lambda_p \leftarrow U_{z,z'}$ . Bob sends vector  $\mathbf{w}$  to Alice.
- 5) Alice calculates  $l = \mathbf{w} \cdot \mathbf{x}$ .
- 6) Bob calculates  $t = \mathbf{v} \cdot \mathbf{y}$ .

Let's prove that  $l = t$ .

$$l = \mathbf{w} \cdot \mathbf{x} = (h_1\mathbf{a}_1 + \dots + h_k\mathbf{a}_k + \lambda_1\mathbf{s}_1 + \dots + \lambda_p\mathbf{s}_p) \cdot \mathbf{x} = (h_1\mathbf{a}_1 \cdot \mathbf{x} + \dots + h_k\mathbf{a}_k \cdot \mathbf{x}) + (\lambda_1\mathbf{s}_1 \cdot \mathbf{x} + \dots + \lambda_p\mathbf{s}_p \cdot \mathbf{x}) = h_1\mathbf{a}_1 \cdot \mathbf{x} + \dots + h_k\mathbf{a}_k \cdot \mathbf{x} = h_1d_1 + \dots + h_kd_k$$

$$t = \mathbf{v} \cdot \mathbf{y} = (d_1\mathbf{b}_1 + \dots + d_k\mathbf{b}_k + \mu_1\mathbf{r}_1 + \dots + \mu_q\mathbf{r}_q) \cdot \mathbf{y} = (d_1\mathbf{b}_1 \cdot \mathbf{y} + \dots + d_k\mathbf{b}_k \cdot \mathbf{y}) + (\mu_1\mathbf{r}_1 \cdot \mathbf{y} + \dots + \mu_q\mathbf{r}_q \cdot \mathbf{y}) = d_1\mathbf{b}_1 \cdot \mathbf{y} + \dots + d_k\mathbf{b}_k \cdot \mathbf{y} = d_1h_1 + \dots + d_kh_k$$

$l = t$ . Therefore key exchange is accomplished.

#### IV. MITM PASSIVE ATTACK

In this section we estimate how successful a *Man In The Middle* (MITM) passive attack can be. Passive means that an adversary can't edit the data transmitted by Alice and Bob. An adversary has vectors  $\mathbf{a}_1, \dots, \mathbf{a}_k, \mathbf{b}_1, \dots, \mathbf{b}_k, \mathbf{s}_1, \dots, \mathbf{s}_p, \mathbf{r}_1, \dots, \mathbf{r}_q$ . Also, the following system of equations is known by adversary:

$$\begin{aligned} \mathbf{w} &= (\mathbf{b}_1 \cdot \mathbf{y})\mathbf{a}_1 + \dots + (\mathbf{b}_k \cdot \mathbf{y})\mathbf{a}_k + \lambda_1\mathbf{s}_1 + \dots + \lambda_p\mathbf{s}_p \\ \mathbf{v} &= (\mathbf{a}_1 \cdot \mathbf{x})\mathbf{b}_1 + \dots + (\mathbf{a}_k \cdot \mathbf{x})\mathbf{b}_k + \mu_1\mathbf{r}_1 + \dots + \mu_q\mathbf{r}_q \\ \mathbf{s}_1 \cdot \mathbf{x} &= 0, \dots, \mathbf{s}_p \cdot \mathbf{x} = 0 \\ \mathbf{r}_1 \cdot \mathbf{y} &= 0, \dots, \mathbf{r}_q \cdot \mathbf{y} = 0 \end{aligned}$$

Choosing proper values for  $p, q, k, m, n$ , users can make the system underdetermined. Hence the needed solution can't be found by adversary. To improve the algorithm users can substantially increase dimension using sparse vectors.

#### V. TOY EXAMPLE

In this section we reduce the number of dimensions to show the way algorithm works.

Let  $k = 4, n = 3, m = 2, p = 2, q = 2, z = 0, z' = 7$ .

- 0) Alice and Bob chooses  $z = 0, z' = 7, k = 4$ .
- 1) Alice chooses  $n = 3, \mathbf{x} = \begin{pmatrix} 2 & 3 & 4 \end{pmatrix}$ ,  
 $\mathbf{a}_1 = \begin{pmatrix} 4 & 3 & 7 \end{pmatrix}$ ,  
 $\mathbf{a}_2 = \begin{pmatrix} 3 & 0 & 1 \end{pmatrix}$ ,  
 $\mathbf{a}_3 = \begin{pmatrix} 3 & 5 & 3 \end{pmatrix}$ ,  
 $\mathbf{a}_4 = \begin{pmatrix} 1 & 3 & 7 \end{pmatrix}$ .  
 $d_1 = 45, d_2 = 10, d_3 = 33, d_4 = 39$ .  
 $\mathbf{s}_1 = \begin{pmatrix} -3 & 2 & 0 \end{pmatrix}$ ,  
 $\mathbf{s}_2 = \begin{pmatrix} 0 & -4 & 3 \end{pmatrix}$ .
- 2) Bob chooses  $m = 2, \mathbf{y} = \begin{pmatrix} 1 & 5 \end{pmatrix}$ ,  
 $\mathbf{b}_1 = \begin{pmatrix} 6 & 5 \end{pmatrix}$ ,  
 $\mathbf{b}_2 = \begin{pmatrix} 6 & 6 \end{pmatrix}$ ,  
 $\mathbf{b}_3 = \begin{pmatrix} 5 & 7 \end{pmatrix}$ ,  
 $\mathbf{b}_4 = \begin{pmatrix} 5 & 4 \end{pmatrix}$ .  
 $h_1 = 31, h_2 = 36, h_3 = 40, h_4 = 25$ .  
 $\mathbf{r}_1 = \begin{pmatrix} -5 & 1 \end{pmatrix}$ ,  
 $\mathbf{r}_2 = \begin{pmatrix} 10 & -2 \end{pmatrix}$ .

TABLE I  
PERFORMANCE

	Alice	Bob
Key size	2290 bits	
Time spent on initialization	130 ms	108.5 ms
Time spent on calculation	5.2 ms	5.6 ms
Time spent on data transmission	2.9 ms	2.9 ms
Time spent on key exchange with preparation	8.1 ms	8.5 ms
Time spent on key exchange without preparation	138.2 ms	117.1 ms
Amount of transmitted data	19208 bytes	19016 bytes

- 3) Alice chooses  $\mu_1 = 6, \mu_2 = 5$ , then calculates  $\mathbf{v} = 45\mathbf{b}_1 + 10\mathbf{b}_2 + 33\mathbf{b}_3 + 39\mathbf{b}_4 + 6\mathbf{r}_1 + 5\mathbf{r}_2 = \begin{pmatrix} 710 & 668 \end{pmatrix}$ .
- 4) Bob chooses  $\lambda_1 = 7, \lambda_2 = 3$ , then calculates  $\mathbf{w} = 31\mathbf{a}_1 + 36\mathbf{a}_2 + 40\mathbf{a}_3 + 25\mathbf{a}_4 + 7\mathbf{s}_1 + 3\mathbf{s}_2 = \begin{pmatrix} 356 & 370 & 557 \end{pmatrix}$ .
- 5) Alice calculates  $\mathbf{x} \cdot \mathbf{w} = 4050$
- 6) Bob calculates  $\mathbf{y} \cdot \mathbf{v} = 4050$

#### VI. IMPLEMENTATION AND PERFORMANCE

We implemented this algorithm using the C++ programming language. Implementation uses open source long arithmetics library GNU MP (GMP). The values for  $k, n, m, p, q$  are fixed:  $k = 60, n = 45, m = 40, p = 30, q = 35$ . Table 1 represents the average results of 400 tests being executed on the single PC with CPU Intel Core i7-640M Processor with 4M Cache, 2.80 GHz. Here what represents each row:

- 1) Key size – amount of bits required to contain the key in memory.
- 2) Time spent on initialization – time taken by Alice to perform part 1 of algorithm (part 2 for Bob respectively).
- 3) Time spent on calculation – time taken by Alice to perform calculations from part 3 and 5 (4 and 6 for Bob respectively).
- 4) Time spent on data transmission – this time is a theoretical value. We calculated it assuming that both users have stable Internet connection of 50 Mbps.
- 5) Time spent on key exchange with preparation – time taken by user to perform the key exchange assuming that user already generated the data from part 1-2.
- 6) Time spent on key exchange without preparation – the opposite, time taken by user to perform key exchange with data generation.
- 7) Amount of transmitted data – size of messages sent by users.

#### VII. CONCLUSION

The reviewed algorithm is a promising cryptographic primitive that is believed to be resistant to quantum attacks. The implementation results are presented in Table 1. The benchmarking results are measured on Intel Core i7-640M

with 2 cores running at 2.8 GHz. The implementation details are shown in GitHub repository<sup>1</sup>

**Abstract**—A mobile ad hoc network (MANET) is a collection of mobile nodes that do not need to rely on a pre-existing network infrastructure or centralized administration. Securing MANETs is a serious concern as current research on MANETs continues to progress. Each node in a MANET acts as a router, forwarding data packets for other nodes and exchanging routing information between nodes. It is this intrinsic nature that introduces the serious security issues to routing protocols. A black hole attack is one of the well-known security threats for MANETs. A black hole is a security attack in which a malicious node absorbs all data packets by sending fake routing information and drops them without forwarding them. In order to defend against a black hole attack, in this paper we propose a new threshold-based black hole attack prevention method. To investigate the performance of the proposed method, we compared it with existing methods. Our simulation results show that the proposed method outperforms existing methods from the standpoints of black hole node detection rate, throughput, and packet delivery rate.

## I. INTRODUCTION

WITH the popularity of mobile devices and the development of wireless communication technology, mobile ad hoc networks (MANETs) have recently attracted attention. MANETs can be constructed by mobile nodes without a pre-existing network infrastructure or centralized administration and can be set up at any time and place. MANETs are useful in a variety of applications, such as emergency communications at disaster sites and vehicle-to-vehicle communications for driver assistance and safety. These types of applications require highly secure communications between mobile nodes because they handle vital information concerning human life and safety. However, MANETs are more vulnerable than conventional networks using fixed infrastructure to attacks such as data modification, identity spoofing, intentional packet dropping, and unauthorized packet reception because the third party nodes act as routers and forward unrelated packets between source and destination nodes.

A *black hole attack* is one of the well-known serious security threats in MANETs [1], [2]. A black hole attack is a security attack in which a malicious node, called a *black hole node*, can absorb all data packets by sending fake routing information, untruthfully claiming a new or fresher route to the destination, and then drops them without forwarding them to the destination. This type of attack significantly degrades network performance, such as packet delivery rate

and throughput, because of their repeated packet drops and the routing load due to frequent route reconstructions. AODV [3], one of the principal routing protocols used in MANETs, is significantly threatened by a black hole attack because a black hole node can easily make the source node believe that the path through the black hole node is the best (shortest) path by sending a Route REPLY (RREP) packet with a highest sequence number and a small number of hops to the source node.

In this paper, we propose a method of defense against a black hole attack in AODV. The proposed method classifies nodes into two different classes, either normal node or black hole node, by using a dynamically updated sequence number threshold. This threshold is calculated from the total number of active nodes and the time elapsed from the reception of the last routing control packet. In the proposed method, each node checks whether the received RREP sequence number is higher than a dynamically updated threshold value. If it is higher than the threshold value, then the source node of the RREP is considered to be a black hole node and is blacklisted. The proposed method establishes a secure route by excluding the blacklisted nodes. Blacklists maintained by nodes are checked and updated by flooding a dummy Route REQuest (RREQ) packet periodically to avoid misjudgment of black hole nodes. To investigate the performance of the proposed method, it was compared with an existing secure AODV protocol. Our simulation results show that the proposed method outperforms the existing protocol from the standpoints of black hole node detection rate, packet delivery rate, and throughput.

The rest of this paper is structured as follows.

We provide a short introduction to the AODV protocol in Section II and describe the characteristics of a black hole attack in Section III. In Section IV, we provide a detailed description of the proposed method. We study the performance of the proposed method and compare it with the existing protocol through detailed simulation in Section V. Finally, Section VI concludes the paper.

## II. AODV

The Ad Hoc On-Demand Distance Vector (AODV) routing [3] is a protocol widely used in MANETs. AODV establishes a route between the source and destination nodes only when it is desired by the source node, using RREQ and

Pkt Type	Reserved	Hop Count
RREQ ID		
Destination IP Address		
Destination Sequence Number		
Source IP Address		
Source Sequence Number		

(a) RREQ

Pkt Type	Reserved	Hop Count

Destination Sequence Number		
Source IP Address		
Lifetime		

(b) RREP

Fig. 1. AODV packet formats.

RREP packets. AODV uses a destination sequence number (*DSN*) to determine an up-to-date path to the destination. A node updates its path information only if the *DSN* of the current packet received is greater than the last *DSN* stored at the node. The route discovery process in AODV is as follows:

- 1) The source node broadcasts a RREQ to its neighbors.
- 2) The node receiving the RREQ checks whether there is an entry for the destination node in its routing table. It rebroadcasts the RREQ only if there is an old entry or no entry for the destination in its routing table.
- 3) If the node that received the RREQ is the destination node or an intermediate node that has a fresh enough entry for the destination in its routing table, the destination/intermediate node responds by unicasting a RREP packet back to the source node.
- 4) The RREP packet is routed back to the source node along the reverse path that is set up when the RREQ is forwarded.
- 5) A bidirectional path between the source and destination nodes is established through steps 1–4. If the source node receives multiple RREP packets via different paths, it selects a fresher (having a higher *DSN*) and shorter (having a smaller hop count) path from among them as an optimal route.

Figure 1 shows the packet formats for RREQ and RREP. Pkt Type indicates the packet type (“1” for RREQ or “2” for RREP). Hop Count is the number of hops from the source node to the node currently processing the packet. RREQ ID is a sequence number uniquely identifying the particular RREQ originated by a given node. Destination IP Address and Destination Sequence Number are the IP address of the destination node and the last known sequence number of the destination node, respectively. Source IP Address and Source Sequence Number are the IP address of the node that originated the RREQ and the current sequence number associated with the source node, respectively. Lifetime is the

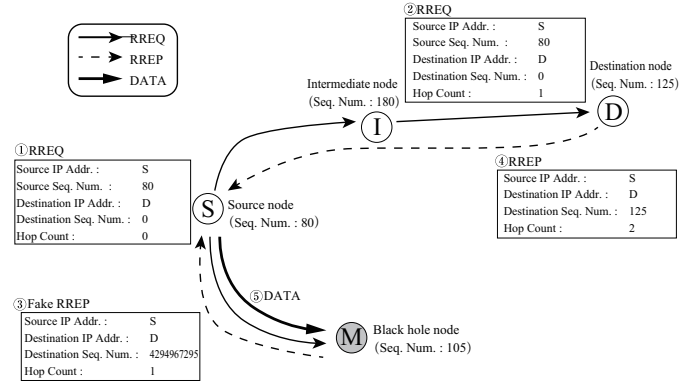

Fig. 2. Black hole attack in AODV.

time for which nodes receiving the RREP consider the route to be valid.

### III. BLACK HOLE ATTACK

A black hole attack is a kind of denial of service where a black hole node can absorb all data packets by sending a fake RREP, untruthfully claiming a new or fresher route to the destination, and then drops them without forwarding them to the destination. Upon receiving a RREQ packet, a black hole node creates a fake RREP packet with a smaller hop count and a spoofed destination sequence number, which is a relatively high destination sequence number in order to pretend that it has a short and fresh route. Once the source node receives the fake RREP packet from the black hole node, it incorrectly recognizes the path through the black hole node as a best path and routes its data packets along that path. Figure 2 shows an example of a black hole attack in AODV. As shown in this figure, the destination node D and the black hole node M receive the RREQ sent from the source node S (1, 2). D sends a RREP packet that contains its sequence number back to S (4). On the other hand, M sends a fake RREP packet that contains a spoofed (large) destination sequence number back to S (3). Although S receives both the legitimate RREP and the fake RREP, it selects the path through D because of the spoofed sequence number and sends data packets to M (5). A black hole node absorbs all the data packets and does not forward them to the destination node; therefore, packet delivery rate and throughput are significantly degraded. Additionally, a large amount of control traffic generated by a retransmission control mechanism of the destination node may have a negative impact on the entire network.

### IV. BLACK HOLE ATTACK PREVENTION METHOD USING DYNAMIC THRESHOLD

A black hole node advertises a spoofed destination sequence number to the source node. To prevent a black hole attack, various methods have been proposed [4], [5], [6], [7], [8], [9]. Threshold-based methods [7], [8], [9] detect a black hole node by checking whether the destination sequence number of the RREP is higher than a threshold value. An important

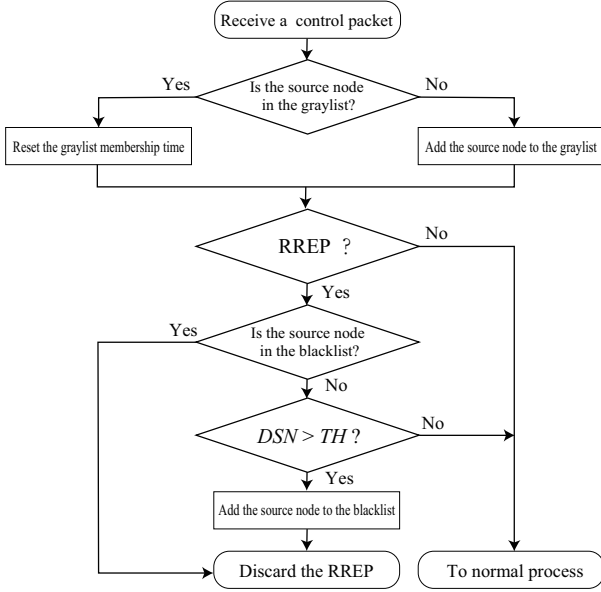

Fig. 3. Black hole node detection flow chart.

technical issue in threshold-based methods is to calculate an appropriate threshold to achieve a lower false detection rate and a higher true detection rate. In this paper, we propose a new threshold-based method in which the threshold value is dynamically updated by each intermediate node based on the total number of active nodes in the network and the time elapsed after it knows the last sequence number of the destination node. Additionally, the proposed method rejudges black hole (blacklisted) nodes periodically by using a dummy RREQ packet. The proposed method aims to improve the true detection rate while reducing the false detection rate by using both a threshold-based detection mechanism and a dummy RREP-based mechanism.

#### A. Blacklist construction

Upon receipt of a RREQ or RREP packet from its neighbors, each node adds the source node of the received packet to its graylist. A graylist entry has four information fields: 1) node address, 2) RREQ flag, 3) RREP flag, and 4) membership time. The node address is the address of the source node of the RREQ/RREP packet. When a node receives a RREQ/RREP packet and then adds an entry to its graylist, it sets the RREQ/RREP flag to 1. The membership time is the lifetime of the graylist membership; the entry is deleted from the graylist after the membership time has elapsed.

When a node I receives a RREP packet, it also checks whether the source node of the RREP packet is in its blacklist. A blacklist entry has two information fields: 1) node address and 2) membership time. If the source node of the RREP packet is blacklisted, I drops the received RREP packet. Otherwise, I checks whether the destination sequence number  $DSN$  is higher than the threshold  $TH$ . If  $DSN > TH$ , then the source node is blacklisted; otherwise, I processes the RREP

packet in the normal way. Figure 3 shows the flow chart of the black hole node detection process.

#### B. Threshold calculation

In the proposed method, each node calculates  $TH$  dynamically based on the total number of active nodes in the network and the time elapsed after it knows the last sequence number of the destination node. We performed preliminary experiments to find appropriate calculation methods for  $TH$ . Because of space constraints, we omit the details of the preliminary experiments. It was found that a destination sequence number is approximately proportional to both the total number of active nodes and time. Based on this observation, we define the following equation for  $TH$ :

$$TH = (\alpha N + \beta)t + DSN_{\text{known}} \quad (1)$$

Here,  $\alpha$  and  $\beta$  are positive constants to reflect the growth trend of sequence numbers of active nodes.  $N$  is the estimated number of active nodes in the network. We use the number of graylist entries as the value for  $N$ .  $DSN_{\text{known}}$  is the last destination sequence number known to the calculating node. If the calculating node does not know the destination sequence number, then  $DSN_{\text{known}}$  is set to 0.  $t$  is the time elapsed after the calculating node obtains  $DSN_{\text{known}}$ . If  $DSN_{\text{known}} = 0$ , the time elapsed since the AODV protocol was started at the node is used as the value for  $t$ .

#### C. Black hole node rejudgment

The proposed method uses a blacklist membership time for each blacklisted node in order so that nodes blacklisted falsely, i.e., nodes that are not true black hole nodes but have been mistakenly added to a blacklist, are not blacklisted permanently. At every expiration of blacklist membership, each node rejudges its blacklisted nodes and determines whether to delete from its blacklist the blacklisted node whose blacklist membership has expired, or to reset the time. The remaining time of the blacklist membership is stored as the membership time filed with the blacklist entry. Each node creates a dummy RREQ packet destined for a randomly generated address and broadcasts it whenever a blacklist membership in its blacklist expires. Only a black hole node will respond to the dummy RREQ by sending a RREP packet back to the RREQ source node without checking the destination address of the dummy RREQ. If the node receives a RREP, it adds the source node of the RREP to its blacklist. If the source node of the RREP is already in its blacklist, it resets the blacklist membership time of the source node. Figure 4 shows the flow chart of the black hole node rejudgment process.

## V. PERFORMANCE EVALUATION

In this section, we describe our investigation of the performance of the proposed method by comparing it with that of an existing method. For our simulations, we used the network simulator ns-2 [10].

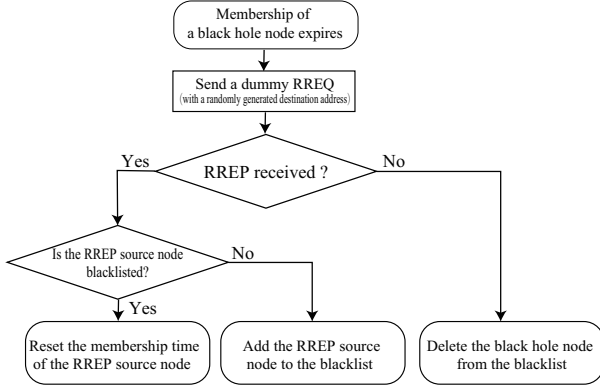

Fig. 4. Black hole node rejuvenation flow chart.

TABLE I  
SIMULATION PARAMETERS.

Parameter	Value
Simulation time	200 [s]
Number of nodes	10, 20, 30, 40, 50, 60, 70, 80, 90, 100
Network area	800 Å 800 [m]
Mobility model	Random Waypoint
Transport layer protocol	UDP
Application type	CBR
Number of black hole nodes	5
Parameters $\alpha, \beta$	$\alpha = 0.002, \beta = 0.1$
Blacklist/Graylist membership time	30 [s]

#### A. Simulation model

In our simulations, 50% of non-black hole nodes try to send their data packets to destination nodes randomly selected from among non-black hole nodes. We assume that black hole nodes always respond to all received RREQs by sending fake RREPs with spoofed destination sequence numbers. The spoofed destination sequence number in a fake RREP is one and a half times as large as the true destination sequence number. AODV with/without a black hole attack and SRD-AODV [9], one of the threshold-based secure AODV protocols, were used as the targets for comparison. Each simulation was run 20 times independently, and the results are an average of the 20 observations. Other simulation assumptions are listed in Table I.

#### B. Performance metrics

We evaluated the performance using the following metrics:

1) *True detection rate  $R_t$* : We evaluate the accuracy of detection of a black hole node by the true detection rate  $R_t$ .  $R_t$  is defined by the following equation:

$$R_t = \frac{N_{\text{black}}}{N_{\text{fakeRREP}}} * 100 \quad (2)$$

Here,  $N_{\text{fakeRREP}}$  is the total number of fake RREPs received by non-black hole nodes during the simulation.  $N_{\text{black}}$  is the total number of blacklist entries (excluding the entries for the nodes blacklisted falsely) of all non-black hole nodes.

Fig. 5. True detection rate vs. number of nodes.

2) *False detection rate  $R_f$* : The inaccuracy of black hole node detection is evaluated by the false detection rate  $R_f$ .  $R_f$  is defined by the following equation:

$$R_f = \frac{N_{\text{discard}}}{N_{\text{RREP}}} * 100 \quad (3)$$

Here,  $N_{\text{RREP}}$  is the total number of legitimate RREPs (not including dummy RREPs and fake RREPs) received by non-black hole nodes during the simulation.  $N_{\text{discard}}$  is the total number of legitimate RREPs discarded by non-black hole nodes because of their misidentification.

3) *Throughput*: Throughput is defined by the following equation.

$$\text{Throughput} = \frac{\text{PktSize} * 8 * N_{\text{recv}}}{T} \quad (4)$$

Here,  $\text{PktSize}$  is the data packet size,  $N_{\text{recv}}$  is the total number of data packets received by the destination node, and  $T$  is the time elapsed from the time the source node receives the first RREP to the end of the simulation.

4) *Packet delivery rate PDR*: PDR is the proportion of data packets successfully received by the destination out of all data packets sent by the source node. PDR is defined by the following equation:

$$\text{PDR} = \frac{N_{\text{recv}}}{N_{\text{sent}}} * 100 \quad (5)$$

Here,  $N_{\text{sent}}$  is the total number of data packets sent by the source node.

#### C. Simulation results

Figure 5 shows the true detection rate characteristics for the proposed method and SRD-AODV. As shown in this figure, the proposed method achieves complete black hole node detection. In the proposed method, the black hole node detection mechanism using both a dynamic threshold and

Fig. 6. False detection rate vs. number of nodes.

dummy RREPs contributes to the completeness of the detection. On the other hand, the  $R_t$  for SRD-AODV decreases with an increase in the number of nodes. When destination sequence numbers are small, i.e., for a certain period of time after the simulation starts, spoofed destination numbers are also small, and so SRD-AODV cannot detect black hole nodes by using a pre-defined static threshold. SRD-AODV achieves a higher  $R_t$  with a larger number of nodes. The reason is that the destination sequence numbers increase quickly with the increase in the number of nodes.

Figure 6 shows the false detection rate characteristics for the proposed method and SRD-AODV. As shown in this figure, SRD-AODV achieves a much lower  $R_f$  (less than 5%) than the proposed method.  $R_f$  for the proposed method increases with an increase in the number of nodes. The threshold value calculated dynamically using equation (1) is likely to be smaller than the destination sequence numbers when the number of nodes is large, i.e., when the destination sequence numbers are likely to be large. As a result, the false detection rate increases. However, the proposed method was able to delete all the non-black hole nodes from the blacklists by the black hole node rejudgment mechanism with dummy RREPs in our simulations.

Figure 7 shows the throughput performance for the proposed method, AODV with/without black hole (BH) attack, and SRD-AODV. In this figure, AODV without BH attack (i.e., with no black hole nodes) represents the target performance. The proposed method achieves better throughput performance than SRD-AODV and AODV with BH attack. In AODV with BH attack, only very few packets are received by destination nodes because of the black hole attacks. Both the proposed method and SRD-AODV achieve a certain level of throughput performance because both methods can establish a secure route by excluding the black hole nodes. The throughput

Fig. 7. Throughput vs. number of nodes.

Fig. 8. Packet delivery rate vs. number of nodes.

performance of the proposed method is less than that of AODV without BH attack because the dummy RREP traffic generated by the proposed method causes collision with data packets. SRD-AODV cannot detect black hole nodes for a certain period of time after the simulation starts. This results in the degradation of the overall throughput of SRD-AODV. The throughput performances of the proposed method, SRD-AODV, and AODV without BH attack all become worse with a smaller number of nodes. The reason is that frequent path breaks due to node mobility occur between the source and destination nodes when the number of nodes is small.

Figure 8 shows the packet delivery performance for the proposed method, AODV with/without BH attack, and SRD-

AODV. Similar to the results shown in Fig. 7, the proposed method achieves a higher packet delivery rate than SRD-AODV and AODV with BH attack. The packet delivery rates of the proposed method, SRD-AODV, and AODV without BH attack all increase with an increase in the number of nodes. The reason is that path break probability decreases with the increase in the number of nodes.

## VI. CONCLUSION

In MANETs, all nodes act as routers. This feature is what leads to the security issues in the routing protocols. The black hole attack is one of the well-known security threats in MANETs. In order to defend against a black hole attack in AODV, we have proposed a prevention method, which detects a black hole node by using a dynamically updated sequence number threshold and dummy RREPs. With simulation experiments, we investigated the effectiveness of our proposed method by comparing its performance with that of existing methods. The simulation results show that our proposed method achieves complete black hole detection and improves throughput and packet delivery performance.

Issues for further research are to validate the proposed method on different scenarios with various network sizes and node mobilities, and to decrease the false detection rate of the proposed method. The false detection rate can be improved by optimizing the values of the  $\alpha$  and  $\beta$  parameters. Therefore, we plan to propose a method for optimizing the parameter values according to network conditions.

**Abstract**—Health care systems have started using advanced technologies, such as Sensor Networks and Internet of Things (IoT), to make health care solutions affordable and easier to access. However, elderly patients who are unconvinced about its dependability hesitate to use the immense facilities provided by the advanced technology. A remedy to this problem is to make the health care system dependable and patient-centric so that patients can be convinced to trust the system. Towards achieving this goal, this paper defines a multi-faceted design, explains how the dependability properties can be integrated in it, and briefly illustrate it in a design pattern for sensors that can be used for an elderly home monitoring system.

## I. INTRODUCTION

WITHIN the health care sector, elderly health care is regarded as an emerging sector of concern [1], [2]. Although old age that defines “elderly” does not necessarily imply “ill health or disability”, the risk associated with both ill health and disability increase as people grow older. A significant conclusion by recent reports is that the proportion of care givers (including income earners) to the elderly with risky profile will be decreasing, while the cost of giving care to the elderly will be increasing. Thus, modern advances in technology should be combined with human wisdom and ethics in order to create “smart systems” that provide *trustworthy* health care for the elderly. In computing literature, *trustworthiness* is defined as the *system property* that denotes the degree of user confidence that the system will behave as expected [3], and *dependability* is defined as “the ability to deliver services that can justifiably be trusted” [3], [4]. A comparison between the two terms presented in [3] has concluded that the two properties are equivalent in their goals and address similar concerns, and suggests that the terms *trustworthiness* and *dependability* can be used interchangeably.

*Electronic Patient Records* (EPR) and Sensor Networks may be regarded as the two significant moves to use advanced technology in health care. Sensor networked systems, currently developed by several industries and universities [5], [6], have immense potential to provide remote patient monitoring and home care of the elderly whenever and wherever necessary. Because the elderly will become dependent on these technologies, it is necessary to convince them that their expectations are met, in the sense that the services provided to them satisfy the privacy concerns prescribed by them, their personal data is secure and safe, and service providers follow ethical principles. In this paper we explore these issues with particular emphasis in the design of elderly home care.

## II. TRUSTWORTHINESS AND DEPENDABILITY

The most common issues regarding health care needs of elderly are *receiving timely remote care*, *getting daily personal care*, *getting support for loneliness and abuse prevention*, and *acquiring basic health care knowledge*. These requirements must be met without compromising their safety, privacy, and dignity. So health care actors must provide these services in different contexts in a trustworthy manner and respect medical ethics. In addition, every patient should be given a mechanism to state, as part of her EPR, what health information can be shared or disclosed, with whom and when. Using this information, the health care actors should act faithfully in serving the elderly and earn their trust. The system, that consists of health care actors and other technology enabled artifacts should be dependable (trustworthy) in the sense it ensures *safety*, *security*, *survivability*, *privacy*, *availability*, *reliability*, and *accountability* for its clients. Following are some examples of safety policies: (1) Elderly homes should be well-equipped with smart devices; (2) Only certified medical devices that are interoperable should be part of Integrated Clinical Network (ICE); and (3) Care givers should monitor elders in order to protect them from physical and psychological abuses. RFID and Sensor network technology may be used to monitor and prevent unsafe situations in patient care. Security is a system level property that ensures the implementation of appropriate methods to protect confidentiality, authenticity, and integrity of health data of patients, vital research and administrative data of the institution. Survivability refers to the capacity of a health care system to fulfill its mission, in a timely manner, in the presence of attacks and emergency situations including failures to its infrastructure. Privacy is a user-centric issue. Every human actor in the system has the right to define the information that they (do not) want to share, how they want to share and in what contexts, and how the information may be used and by whom. Availability and reliability are factors arising from system robustness and resilience to external attacks and internal failures. Accountability is the ability of the system to trace the history of every action in the system’s life cycle.

## III. EXTENDING ROLE BASED ACCESS CONTROLS WITH CONTEXT FOR PROTECTING ELDERLY HOME

We conceptualize an elderly health care in three layers. The lowermost layer is the “Elderly Home” (EH), the middle layer is the “Cloud” (CC), and the top layer is for “Health Care

Service Provision” (HCSP). In EH layer, patients and their caregivers are coordinated and monitored by “trustworthy” sensory network. The layer CC represents the server where all medical information from EH layer is received, persisted, and made available to HCSP layer. The actors in HCSP layer are Health Care Providers (HP) which includes Physicians (PH), Emergency Care (EC), Pharmacists (PA), Clinical Staff (CL), and a variety of actors with administrative roles. The EH encloses two collections of entities - a collection of elderly patients (EPs) and a collection of care givers (CGs). In our system, a care giver needs to have a unique identification. Each EP also has a unique identity. Both EP and CG have their own profiles. The profile may include personal information as well as system-related information. There is a many-to-many relationship between EP and CG within EH. This means that a care giver in EH may monitor several patients and a patient may be monitored by several care givers. Each EP has a unique *Electronic Patient Record* (EPR). In addition, each EP may be monitored by a set of sensors. Dependability of EH involves protecting its EPR and its associated sensors in EH layer. To achieve this goal, we use “Contextual Role Based Access Control” (CRBAC).

Standard bodies in the US have chosen the Role Based Access Control (RBAC) model [7], [8] to enforce access control policies in traditional health care IT systems. In RBAC, roles of subjects and their access rights are predefined. Exceptions are emergency (unanticipated) situations that threaten patient safety. In such situations, the need arises to override the predefined set of access rights so as to assure patient safety. In [9] a *Break The Glass* (BTG) approach is used to override predefined access controls in emergency situations and argued that it has the *non-repudiation* property. Yet, RBAC is not a “privacy-aware” method. As an example, it is possible for a healthcare actor (playing a role) to comply with access control policies and retrieve personal health information of patients at instances “when they may not be required” for treating the patient and then misuse the information. Recognizing this flaw, *context* that includes “purpose” attribute was introduced [10] into the RBAC model. This extended model is called “Contextual Role Based Access Control” (CRBAC). Informally, a context includes information on “what” (request), “where” (location/spatial), “when” (time, day, and duration), “why” (purpose), and “who” (role). A “contextual constraint” is a conjunction of “constraints” where each constraint is expressed as a  $\langle \text{key}, \text{value} \rangle$  pair. The “key” is one of the five parameters: “what”, “who”, “when”, “where” and “why”. The “value” is a boolean expression. As an example, consider a care giver  $c$  who works in the same department where a patient with id  $pid$  is admitted/registered. Assume that the care giver requests read and write access to a sensor with id  $sid$ . Somewhere in the records, it should have been mentioned that this care giver is attending the patient. If the patient is a physician, the care giver must have a minimum service record of 5 years. If the care giver is a nurse, she must be the head nurse of the department. The contextual constraints for this problem can be stated as fol-

lows: (1) what:  $\text{readAccess}(pid, sid) \wedge \text{writeAccess}(pid, sid)$ ; (2) who:  $\exists c : \text{CareGiver} \bullet \text{department}(c) = \text{department}(pid) \wedge \text{attending}(c, pid) \wedge (c.\text{role} = \text{'physician'} \Rightarrow \text{service}(c) \geq 5) \wedge (c.\text{role} = \text{'nurse'} \Rightarrow \text{headNurse}(c, \text{department}(c)) = \text{'yes'})$ ; (3) when:  $\text{time} = \text{'alltime'}$ ; (4) where:  $\text{location} = \text{room}(pid)$ ; (5) why:  $\text{purpose} = \text{'monitor'}$ .

#### IV. SECURE ELDERLY HOME

The three aspects to be protected in EH are (1) EPRs, (2) Sensor Network, and (3) Care giver actor (CG).

**Protecting EPRs:** The EPR of a patient is either created by the patient or by care givers in charge of the patient. The EPR includes the health status, personal information, a list of friends and family members authorized to share patient information, and names of medical staff and care givers attending the patient. If EPR is prepared by care givers, then it is legally certified that persons who prepared the EPR will use it ethically for patient care. The EPR of a patient can be encrypted and saved in a mobile device associated with the patient, and care givers of the patient are given access to this device. It is uploaded to CC, from where physicians and other health care providers may access it, and may add details on the services provided to the patient. Here we briefly discuss the safety, security, and privacy issues of the EPR stored at patient’s computing platform.

Every patient has a unique mobile unit. The pair  $(PID, MID)$  constitutes the key for encryption in EPR, where  $PID$  refers to the patient identity and  $MID$  refers to the mobile unit identity. This key is also used for authenticating others to access EPR. The authentication rules are set by the patient, in consultation with the care giver, so that any desired part of EPR information may be disclosed in a privacy-preserving manner when CRBAC is used to enforce access to the information. The mobile unit used by the patient uses RAS to encrypt EPR information while transmitting to CC. It may use its own internal (hard-wired) method for encrypting EPR and store it locally. As a consequence, neither the patient nor any of her authorized users need to worry about data integrity. All users, except the patient, will have “read only” access to disclosed information. Only the patient or her authorized agent has the right to add, delete or modify the information in the EPR. It is expected that the agent (relative or care giver) will be bound by ethical principles while following the instructions of the patient. To safeguard against threats, the profile of the agent may be collected in each context of agent’s access to the mobile unit of the patient, and the history of access may be audited periodically. Emergency situations for each patient may be enumerated. For each emergency context an appropriate access rule should be provided. For this discussion, an emergency situation is one in which the authenticated person has the right to access the EPR but may not have the right to perform a task related to the patient’s care (e.g., an operation on the patient). The following steps are followed in emergency situations: When an authorized person signs in, the system at first *denies* access because the current

context is an “emergency” context (not anticipated earlier). It checks the “history of access” of the person to verify whether or not any violation of ethics was recorded; if the answer is “yes”, the system sends a “SOS” message to the supervisory control through the Cloud and “freezes”. If the answer is “No”, and the user agrees to “non-repudiation” (recording her access and reporting to supervisory system), she is given access right to perform the requested task. In the “Yes” case, the system remains “frozen” until either a response is received from the supervisory system or receives biometric data of the current user; in the former case, the system follows the supervisory protocol; in the latter case, the system uses the biometric data for non-repudiation procedure.

**Protecting Sensor Network:** A variety of sensor types are used in an EH. Broadly classified, these are (1) bodyware sensors, and (2) external sensors. Each EP has a unique ID, a data collection inspector (DCP) and has one or more sensory devices. The design details of DCP and sensor, described below, contribute towards dependable EH design.

**Sensor:** In [11] we have introduced “Health Care Design Pattern” paradigm, and illustrated the design of *Sensor Design Pattern* (SDP). SDP has been designed using three well-known software design patterns - Abstract Factory pattern, Observer pattern and Strategy pattern. It contains a sensor hardware that actually gathers the data, a RF chip to transmit the data out of the sensor, and a micro controller that coordinates the activities of the sensor hardware and the RF chip. In addition, the micro controller also enables a user to store, retrieve and modify authentication data to protect data access from the sensor. Using appropriate protocols such IEEE standard 802.15.2.6 - Level 3 which requires both authentication and encryption, data access from a SDP can be tightened. Though any amount of details can be stored and processed in the micro controller, it is preferable to store only minimal necessary information and to keep processing within the micro controller to the minimum in order to save battery life of the sensor and to protect the sensor from adversaries [12]. Typically, for a sensor used in an elderly home, the following information is sufficient: patient ID, sensor ID, authentication data to access the sensor (includes the authorized entities such as devices, software entities and humans, who can access the data from the sensor), and a log of transactions where each log includes the date and time of access as well as the ID of the entity which accessed the data from the sensor. While authentication data provides security to the sensor, the list of authorized entities enables the sensor to protect the privacy of data collected by the sensor. The authentication details within the micro controller can be described in the form of contextual descriptions in which case the SDP will act as an independent entity by itself. Instead, we suggest that the authentication details should be kept to the minimum in the micro controller (to prolong the life of the hardware in SDP) and more contextual details should be loaded in DCP (discussed next). System-related information such as encryption keys and code implementing secure communication

protocol between the sensor and authorized entities will also be stored in the micro controller.

**Data Collection Inspector:** The Data Collection Inspector (DCP) acts as a front end that manages data collection from various sensors associated with the patient and also enables data manipulation stored in SDPs. Generally, a mobile device such as a smart phone or a laptop acts as DCP. It includes the profile of the patient, the set of all sensors associated with the patient, the list of other authorized entities who will use these sensors, and a contextual description for data access from each sensor. The DCP is responsible to gather data from each SDP and provide authenticated access to it to the entities in EH layer and through CC to entities in other layers. It has built-in mechanisms for data authentication, data integrity, and data privacy. Another important functionality is that it periodically transfers log transactions from each SDP to both local and CC units. Requests for data access from the sensors associated with an EP should be made through the DCP of the corresponding EP. Each request must specify the sensor ID from which data is requested and parameters required for constructing the contextual description. After validating the request based on the context, the DCP executes a command to gather the data or provides a summary of already gathered data from the particular sensor. The DCP acts as the console for EP so that the patient may change privacy and security parameters at any time. Since most patients are not computer savvy, it is important to design the DCP user interface that is easy to use and easy to operate. Thus, the DCP user interface will provide simple dialogs for the five parameters by which the patient can recognize the meaning of each parameter and provide the required information for each parameter. A patient who is unable to use the DCP interface can be substituted by one of those authorized by her in her EPR. This is achieved in our design through role delegation.

**Care Giver Authentication:** An entity with *Care Giver* (CG) can monitor a patient’s status through the sensors associated with the patient, only after an authentication of her credentials. Each entity in CG role must have been registered in the patient’s DCP. Every care giver attending a patient must be a member of the list of care givers included by the patient in her EPR, which being part of the DCP is controlled by the patient. Each care giver is given an Access Control Point (ACP) through which the care giver communicates with the corresponding DCP of the patient. Like DCP, each ACP also has a unique ID. When a care giver wants to access a patient’s status, the care giver makes a request (including purpose/why) through her corresponding ACP. This request will be checked against the access control list of the corresponding DCP. If matches, the request will be converted internally into a contextual description and the corresponding DCP will execute the request. Like the DCP for a patient, the ACP thus acts as the front end for a care giver. It is generally installed on a mobile device or a laptop. Therefore, a care giver has complete control over his/her ACP and can set up an initial profile. This profile can include the set of

patients to monitor and hence the corresponding DCPs to access.

## V. CONCLUSION

Elderly health care is a critical sub-sector of health care infrastructure. From the review of many existing health care systems and mobile apps that support them [13], [14], [15], [16] we are convinced that they are focused on providing information to and aiding medical staff, but not in improving quality of care. More importantly, these systems do not guarantee the trustworthiness perspectives. From a user-centric view of system usability, these systems are not fully embraced by elderly patients either because their interfaces are complex to learn or because the patients do not have sufficient knowledge and technical skills to use them. The root of this problem can be traced to the early stages of designing these systems, wherein patient-centric modeling decisions have not been made. In our short exposition in this paper, we have explained how quality of care can be improved by instituting a dependable elderly home infrastructure and integrate it with CC for remote health care service provision. A summary of results are as follows:

**Safety:** In an elderly home environment, there are two groups of people - patients and care givers. A patient's safety is ensured by using only certified medical devices which are operated by only authorized people. While selection and certification of medical devices is beyond the scope of this paper, the DCP of the patient protects her from unauthorized people accessing the sensors. Further, the sensor logs are stored inside and possibly in the DCP as well. This, to some extent, can be used to trace attacks by adversaries. Since care givers monitor the patients remotely using their ACPs, it is guaranteed that they are free from contamination and infections.

**Security:** The use of contextual information in authenticating sensor data access is the biggest advantage of our approach. Every access to the sensor is protected by the patient's DCP. The "who" parameter of the contextual description ensures that only registered people can access the data, and the "when" parameter ensures that these people are allowed to access the data at the time specified in the contextual description. Thus, the role-based access model along with the contextual description ensures high security.

**Privacy:** All sensors are protected by the DCP of the patient. The patient (or the representative of the patient who is legally authorized) has ultimate authority of issuing access rights to the care givers and others. In addition, the patient also has the ability to change the settings on access rights at any time by changing the corresponding contextual description. Therefore, we claim that our model ensures privacy of patient information.

**Availability:** The system is considered to be "unavailable" when any sensor data is not accessible by a role who is authorized to access. We claim that the sensors and the DCP can be configured to log sensor data gathering as well as to log transactions at appropriate time intervals. These can be transferred to the cloud via EH and can be automatically monitored

to be continuous. If there is a break or gap in the log, the system must generate an alarm and then the corresponding role can interfere the sensor network to find out the cause. Thus, our design is capable of ensuring "availability".

**Accountability:** This property is important to identify the cause and the role when something goes wrong. As stated earlier, the log transactions will help trace the identity of the role who accessed and the duration of the access, from which it should be possible to determine who is accountable and for what. As we stated earlier, ethical behavior of all roles including patients are covered by this property.

**Abstract**—The Internet of Things (IoT) revolution promises to make our lives easier by providing cheap and always connected smart embedded devices, which can interact on the Internet and create added values for human needs. But all that glitters is not gold. Indeed, the other side of the coin is that, from a security perspective, this IoT revolution represents a potential disaster. This plethora of IoT devices that flooded the market were very badly protected, thus an easy prey for several families of malwares that can enslave and incorporate them in very large botnets. This, eventually, brought back to the top Distributed Denial of Service (DDoS) attacks, making them more powerful and easier to achieve than ever. This paper aims at provide an up-to-date picture of DDoS attacks in the specific subject of the IoT, studying how these attacks work and considering the most common families in the IoT context, in terms of their nature and evolution through the years. It also explores the additional offensive capabilities that this arsenal of IoT malwares has available, to mine the security of Internet users and systems. We think that this up-to-date picture will be a valuable reference to the scientific community in order to take a first crucial step to tackle this urgent security issue.

## I. INTRODUCTION

THE Internet of Things (IoT) is rapidly and unavoidably changing our society, affecting the way we live and work. The IoT mission is to enable everyday objects to communicate with each other through the Internet, resulting in a figurative tsunami of connectivity. From a business perspective, IoT is all about excitement. Firms are rushing the development of their IoT products in order to commercialise them as soon as possible, and stay on the crest of the wave. IoT predictions by several consultancy firms (like Bain, McKinsey, General Electric, to mention only a few) clearly show that the IoT market will become massive in the coming 10 years. For instance, IHS forecasts that the IoT market will grow from a base of 15.4 billion devices in 2015 to 30.7 billion devices in 2020 and 75.4 billion in 2025<sup>1</sup>.

From a security perspective, all this excitement goes to the detriment of the IoT devices security, causing a potential disaster. Indeed, security still represents the most overlooked characteristic when quickness is considered of paramount importance for business. Moreover, the massive distribution of such connected devices to the “average security-unsavvy user”, evokes IoT acronyms like the not-so-funny “*Internet of Troubles*”<sup>2</sup>. More connected and non-secure (or unsecured)

devices entails more attack vectors and more possibilities for hackers to target us, access our sensible data and control our devices. Talking about security and IoT devices, the 2016 is still remembered as the year of *Mirai*, namely a powerful malware that managed to infect hundreds of thousands of connected devices all over the world through a dictionary attack (composed of just 50 entries), relying upon the fact that these devices use default login credentials and that most of the users never change those credentials. On October 21st 2016, this massive botnet (network of infected devices) was used to struck what is currently considered the largest Distributed Denial of Service (DDoS) attack ever seen, reaching a magnitude of about 1.2 Terabits per second.

*Contribution of the Paper.* The security disaster in this IoT tsunami of connectivity has made DDoS attacks more and more popular among the cyber-criminal community. DDoS attacks have rapidly evolved in the last few years, becoming more complex and especially more powerful and effective, as *Mirai* showed. Besides, to the best of our knowledge, the last research work discussing a taxonomy of DDoS attacks has been conducted in the early 2008 [1], long before the IoT outburst. Therefore, this paper aims at studying DDoS attacks with focus on the IoT context. In particular, the contribution of our analysis is twofold:

- 1) We start from an up-to-date comprehensive taxonomy of DDoS attacks based on previous scientific literature and the latest performed attacks, and we place the emphasis on IoT devices. The taxonomy is obtained by combining several surveys in the literature [1]–[13] and by refining the taxonomy previously proposed in [14].
- 2) Using the new DDoS taxonomy as foundation of our study, we provide a detailed analysis of all the DDoS capable IoT malwares since 2008. The analysis clearly shows the evolution of these malwares through the years, as well as the increasing number of new malware families per year.

The overall aim of the paper is to provide a first comprehensive reference to the security community, in order to understand the latest DDoS attacks targeting the IoT domain.

*Outline of the Paper.* Section II introduces DDoS attacks, focusing on the key characteristics that make them possible and so powerful. Sections III and IV present the proposed taxonomy of DDoS attacks and the analysis of DDoS-capable

<sup>1</sup><https://www.ihs.com/Info/0416/internet-of-things.html> [May 10th, 2017].

<sup>2</sup><https://security-online.net/iot-like-internet-troubles> [May 10th, 2017].

IoT malwares, respectively. Section V analyses the collected data and draws some remarkable observations. Finally, Section VI sums up the contribution of the paper.

## II. HOW DDoS ATTACKS ARE POSSIBLE?

What makes DDoS attacks possible and extremely powerful is the intrinsic nature of Internet itself, designed with the aim of functionality, rather than security. While being utterly effective, the Internet is inherently vulnerable to several security issues that can be used to perpetrate a DDoS attack [3], [5]:

- *Internet security is extremely interdependent* – It does not matter how well secured the victim system may be, its vulnerability to DDoS attacks depends on the security of the rest of the global Internet;
- *Internet entities have limited resources* – Each Internet entity (such as hosts, networks, services, etc.) has limited resources that can be saturated by a given number of users;
- *Many is better than a few* – Coordinated and concurrent distributed attacks will always be effective, if the resources of the attacker are greater than the resources of the victim;
- *Intelligence and resources are not collocated* – Most of the intelligence, needed to guarantee services, is located in end hosts. Nevertheless, the requirement of large throughput brought to design high bandwidth pathways in the intermediate network. As a result, attackers can exploit the abundant resources of the intermediate network in order to deliver a great number of malicious messages to the victim;
- *Accountability is not enforced* – In IP packets, the source address field is assumed to carry the IP address of the host that creates the packet. However, this is an assumption which is not validated or enforced at all, therefore there is the opportunity to perpetrate an *IP source address spoofing*<sup>3</sup> attack. This attack provides attackers a powerful mechanisms to avoid responsibility for their actions;
- *Control is distributed* – Internet management is distributed and each network can work with local policies defined by its administrators. Consequently, there is no way to deploy a global security mechanism or policy and it is often impossible to investigate cross-network traffic behaviour due to privacy issues.

Notably, a DDoS attack needs to go through the following phases in order to be struck [3], [5]:

- 1) *Recruitment*. The attacker scans for vulnerable machines (called *agents*), aiming to use them later in the DDoS attack against the real victim. In the past this process was performed manually but nowadays several scanning tools can be used to do this automatically;
- 2) *Exploitation & Infection*. The agent machines are exploited using the discovered vulnerabilities and the

malicious code is injected. This phase has also been automated and nowadays several self-propagating tools can be used for further recruiting new agents;

- 3) *Communication*. The attacker uses the handlers or the IRC channel (depending on the botnet architecture, refer to subsection III-A for further details) to identify which agents are up and running, when to schedule the attacks or when to upgrade the agents;
- 4) *Attack*. The attacker commands the onset of the attack and the agent machines start to send malicious packets. Attack parameters (such as victim, duration, malicious packets properties, etc.) are tuned in this phase. Although IP spoofing is not always required for a successful DDoS attack, attackers usually opt for an additional anonymity layer, hiding the identity of agent machines during the attack.

## III. DDoS ATTACKS CLASSIFICATION

DDoS attacks can be classified in many ways (Fig. 1). In this section, we succinctly report a complete taxonomy, obtained by combining several surveys in the literature [1]–[13].

### A. Architecture Model

The architecture of a DDoS attack considers how the involved actors interact. There are basically four types of network architectures that can be used to perpetrate a DDoS attack [1], [9]: *Agent-Handler Model*, *Reflector Model*, *IRC-Based Model*, *Web-Based Model*.

1) *Agent-Handler Model*: This model (Fig. 2a) is composed by *clients*, *handlers* (or *masters*) and *agents* (or *daemons* or *secondary victims*) [2]. Clients are used by the attacker to communicate with the handlers, which are software packages located somewhere in the Internet, that infect network resources and rely information from the clients to the agents. The agent is a block of code that runs on a compromised system and performs the attack against the final victim. The term agent is used to refer both to the compromised machine and to the running code. According to the configuration of the network architecture, the set of agents (referred as a *botnet*) can equally interact with a single handler or multiple handlers.

2) *Reflector Model*: This model (Fig. 2b) is similar to the Agent-Handler one, but exhibits an additional set of uninfected machines, called *reflectors*. The reflectors are induced by the handlers to send a stream of packets against the victim. Often, the handlers spoof the victim IP address, in order to solicit the reflectors to send the replies to the victim. This leads to the production of a large amount of network traffic addressed to the target host [1]. The reflectors are often used as amplifiers by sending the stream of packets to the broadcast address<sup>4</sup> of the reflector network and triggering reply packets from each host within their LAN. A Reflector can be any host in the Internet able to respond to IP requests (e.g., a web server that responds to TCP SYN requests) because the attacker does not

<sup>3</sup>*IP source address spoofing* is a cyber-attack which consists in creating an IP packet with a false source IP address, hiding the identity of the real sender or even impersonating another Internet entity.

<sup>4</sup>*Broadcast IP address feature*: when a sending system specifies a broadcast IP address as the destination address, the routers replicate the packet and send it to all the IP addresses within the broadcast address range [2].

Fig. 1. DDoS Attacks Taxonomy

need to infect it. DDoS attacks that use this model are also known as *Distributed Reflection Denial of Service* (DRDoS) attacks and they are harder to trace back than the ones based on the Agent-Handler Model [4], [5], [15], [16].

3) *Internet Relay Chat-Based Model*: This model (Fig. 2c) is similar to the Agent-Handler one, with the only difference that the client connects to the agents relying on an IRC-based communication channel, instead of the handlers. *Internet Relay Chat (IRC)* is a client/server textual protocol, used to implement a multi-user and multi-channel chat system.

4) *Web-Based Model*: This model is similar to the IRC-Based one, but here the communication is HTTP/HTTPS based. Moreover, the majority of the agents are fully configured and controlled through complex PHP scripts and encrypted communications, while a number of agents is used only to report statistics to a controlling Web site [9].

### B. Exploited Vulnerability

DDoS attacks can exploit different vulnerabilities to jeopardize their victims. Based on the strategy that is used to deny services, it is possible to classify them in two different categories [1]–[4], [7], [10], [13]: *Bandwidth Depletion* (or *Brute-Force*) and *Resource Depletion*.

1) *Bandwidth Depletion (or Brute-Force)*: In this type of attacks, a great amount of apparently legitimate packets are sent to the victim, in order to clog up its communication resources (e.g., network bandwidth) and also its computational ones (e.g., CPU time, memory, etc.) preventing them to be reached by legitimate traffic. These attacks can be further divided into *Flood* and *Amplification* attacks [1], [2], [5], [6], [10], [13]. In Flood attacks, the botnet directly sends a large volume of IP traffic to the victim machine to congest its network resources and prevent access by legitimate users, while in Amplification attacks the agents use intermediaries reflectors (Section III-A), exploiting the *broadcast IP address feature* with the spoofed address of the victim.

Flood attacks are the most used ones because they are easy to achieve, yet very effective; well-known examples are SYN Flood and UDP Flood attacks. On the other hand, DNS Amplification is a highly popular type of Amplification attack: based on the principle that tiny DNS requests generate much bigger reply packets, a whole botnet can impersonate the target, spoofing its IP address, and send a high number of requests in its stead. As expected, the target will be hit by a massive quantity of replies and experience a DoS event.

Another emerging DDoS attack, exhibited recently by Mirai,

Fig. 2. Architecture Models examples

is the so-called Valve Source Engine (VSE) Flood, which is a particular type of UDP Amplification attack that targets gaming servers by sending them specific requests (TSource Engine Query) from many different devices.

2) *Resource Depletion*: These attacks aim to preventing the victim to process legitimate requests, by exhausting its resources, and can be further characterized in *Protocol Exploit* and *Malformed Packet* attacks [1], [2], [5], [6], [10], [13]. In Protocol Exploit attacks, an implementation bug of a protocol or a specific feature installed on the victim are exploited in order to consume its resources, whereas in Malformed Packet attacks incorrectly formed IP packets are sent from the agents to the target (e.g., putting the same IP address into both source and destination fields).

An interesting example of Malformed Packet attack is the so-called TCP XMAS. This type of attack consists into manipulating some packets by turning on all the flags (especially URG, PUSH and FIN flags). It is very unusual and totally unexpected that this combination of flags appears into a standard packet, and a lot of time and effort is required, in order to process it, which can eventually crash the target system.

### C. Protocol Level

DDoS attacks can be distinguished according to the TCP/IP layer of the protocol used during the attack [9], [17]: *Network Level* and *Application Level*. In Network Level DDoS attacks, either Network or Transport layer protocols are used to carry out the attack, while in Application Level DDoS attacks the victim resources (e.g., CPU, memory, disk/database, etc.) are exhausted targeting Application layer protocols. Clear examples of Network Level attacks are SYN Flood, UDP Flood and TCP Flood attacks, whereas HTTP Flood, DNS Query Flood and DNS Amplification attacks belong to Application Level group of attacks.

An interesting example of an Application Level attack is the DNS Water Torture, which is a DDoS attack that targets specifically Authoritative DNS servers, which are indirectly disrupted by sending a huge quantity of random queries to

Open Resolvers, queries that are forwarded to Cache DNS servers and, finally, to the Authoritative DNS servers. Even though the intended target is the latter, as a side-effect also Cache DNS servers face huge slow-downs in their operations.

### D. Degree of Automation

Based on the Degree of Automation, DDoS attacks can be classified into three different categories [1], [3], [5]: *Manual*, *Semi-automatic* and *Automatic*.

1) *Manual*: In Manual DDoS attacks, the attacker individually scans remote devices looking for any vulnerability. Once a vulnerability is found, the attacker manually breaks into the machine, installs attack code and then commands the onset of the attack. Only the early DDoS attacks belong to this category because today all the attack phases are automated.

2) *Semi-automatic*: In Semi-automatic DDoS attacks the recruitment and exploitation & infection of the agents are automated. The only phases which are still manually performed by the attacker are the communication phase (when the attacker instructs the botnet with type, start time, duration and victim of the attack) and the attack phase [18]. Based on the *Communication Mechanism* used between attackers and handlers (see Section III-A), Semi-automatic DDoS attacks can be done by *Direct Communication* (if based on the Agent-Handler Model) or by *Indirect Communication* (if based on the IRC-Based Model).

3) *Automatic*: In these attacks, all the phases are automated (recruitment, exploitation & infection, attack), thus there is no need for communication between attacker and botnet. The start time, type, duration and victim of the attack are preprogrammed in the attack code. This category is the one which offers the minimal exposure for the attacker, since he is only involved in issuing the command that starts the attack.

In both Automatic and Semi-automatic attacks, the recruitment of agent machines is achieved through automatic scanning strategies (Subsection III-E) and propagation techniques (Subsection III-F). Notably, some DDoS attacks can use a mixed approach: for instance, the recruitment and the attack could be automated while the exploitation & infection and the communication could be performed manually.

### E. Scanning Strategy

During the recruitment phase, the attacker finds as many vulnerable machines as possible with a network scanning. Based on the scanning strategy, it is possible to classify DDoS attacks into five classes [1], [3]: *Random Scanning*, *Hitlist Scanning*, *Signpost* (or *Topological*) *Scanning*, *Permutation Scanning*, *Local Subnet Scanning*.

1) *Random Scanning*: With this scanning strategy, each compromised host uses a different seed to probe random addresses in the IP address space. As an example, Mirai utilizes a pure Random Scanning approach, randomly looking for any kind of IoT equipped with default login credentials.

2) *Hitlist Scanning*: With this scanning strategy, the scanning machine has an external list of possible victims to probe. Once the attacker detects and infects a new vulnerable machine, it forwards a portion of the initial hitlist, in order to have a high propagation speed and no collisions during the scanning.

3) *Signpost Scanning*: In DDoS attacks with Signpost Scanning, some pieces of information on the compromised machines are used to find new targets. As an example, e-mail worms could exploit information from address books of infected machines, a Web-server based worm could spread by infecting each vulnerable client that access to the server Web page, and so on.

4) *Permutation Scanning*: With this strategy, there is first a brief Hitlist Scanning from which a small initial population of agents is added to the botnet. Subsequently, all the compromised hosts share a common pseudo-random permutation of the IP address space and each IP address is mapped to an index in this permutation. A machine infected during the initial phase begins scanning through the permutation by using the index computed from its IP address as a starting point. Whenever it finds a machine that has already been infected, it chooses a new random starting point.

5) *Local Subnet Scanning*: The Local Subnet Scanning can be added to each of the previously described strategies, to include a scan for targets located on the same subnet of the compromised host. This technique allows a single copy of the scanning program to compromise many vulnerable machines behind a firewall.

### F. Propagation Mechanism

After the recruitment and the exploitation, the agent machine is infected with the attack code and, based on the mechanism chosen in this phase, it is possible to classify DDoS attacks into three different categories [1], [3]: *Central Source Propagation*, *Back-chaining Propagation* and *Autonomous Propagation*.

1) *Central Source Propagation*: With this propagation approach, the attack code is stored on a central server (or a set of servers) and downloaded through a file transfer mechanism (e.g. wget or tftp) as soon as a new agent is compromised.

2) *Back-chaining Propagation*: Back-chaining enables the machine that exploited the system to also inoculate the attack code. The infected machine then becomes the source of the

next propagation step. This propagation mechanism is more durable than the Central Source one because it does not have a single point of failure.

3) *Autonomous Propagation*: With this approach there are no extra files downloaded, but the attack instructions are directly injected into the target host during the same exploit phase, reducing the possibility that the attack is discovered [18].

### G. Impact on the Victim

Depending on the impact that DDoS attacks have on the victim, it is possible to classify them into two different categories [3], [5]: *Disruptive* and *Degrading*.

1) *Disruptive*: This type of attacks try to completely deny the victim services to its legitimate users. Nowadays, the majority of attacks belong to this class. Based on the *Possibility of Dynamic Recovery* during or after a disruptive DDoS attack, it is possible to further divide them in *Dynamically Recoverable*, when a victim can automatically restore its services as soon as the attack stops, and *Dynamically Non-Recoverable*, when the victim needs human intervention, such as a reboot or even a reconfiguration [3].

2) *Degrading*: This type of attacks aim at consuming some portion of the victim resources without causing a total service disruption, in order to remain undetected for an extended amount of time. Nevertheless, the damage inflicted to the victim could be huge: as an example, an attack that affects 30% of the victim resources could lead to a DoS for some customers during high load periods and the average performance of the service would be worse than expected.

### H. Attack Rate

The DDoS attack requires each agent to send a stream of packets to the victim. The Attack Rate generated by the botnet makes possible to classify DDoS attacks into two different categories [1], [3]–[6], [19]: *Constant Rate*, *Variable Rate*.

1) *Constant Rate*: The botnet produces attack packets at a fixed rate, usually at the highest rate possible. The output burst is so powerful that the target resources are filled up very quickly, hence the effects of the attack are quite instant on the victim.

2) *Variable Rate*: The attack rate of agent machines varies, in order to avoid or delay the detection. According to the *Rate Change Mechanism*, variable rate DDoS attacks can be further divided [19] into *Increasing rate*, where the attack rate is gradually and constantly increased through time, and *Fluctuating rate* where the attack is sporadically relaxed, in order to reduce detection chances [1], [3], [5].

### I. Persistence of Agent Set

This classification is based on the set of agents active at any time of a DDoS attack. Based on the persistence of the botnet, it is possible to distinguish two different categories [3]: *Constant Agent Set* and *Variable Agent Set*.

1) *Constant Agent Set*: All agents into the botnet act in the same way, taken into consideration resource constraints: they all receive the same set of commands and they are all engaged simultaneously during the attack.

2) *Variable Agent Set*: The available agents are divided into several groups and the attacker engages only one group of agents at a given time. An agent could belong to more than one group and each group could be engaged again after a period of inactivity. As a matter of fact, this entails that the botnet is internally partitioned.

#### J. Source Address Validity

Source address spoofing plays a critical role in most of DDoS attacks, because it hinders the prosecution of the attacker. Based on the Source Address Validity, it is possible to classify DDoS attacks into [3]: *Spoofed Source Address* and *Valid Source Address*.

1) *Spoofed Source Address*: This is the most common type of DDoS attack, where source addresses are spoofed without any kind of constraint. Moreover, the *spoofing technique*, that defines how the attacker chooses the spoofed source address, makes possible to further divide this DDoS attacks [3] in:

- *Random Spoofed Source Address*, in which source addresses are completely random 32-bit numbers [20], [21];
- *Subnet Spoofed Source Address*, in which source addresses are chosen within the agent machine subnet;
- *On Route Spoofed Source Address*, in which the address is picked from a machine which is on the route (or in a subnet) between the agent machine and the victim.

Based on the *Address Routability*, spoofed source address DDoS attacks can be further divided in *Routable Source Address* attacks, which spoof routable source addresses by taking over the IP address of another machine, and *Non-Routable Source Address* that spoof non-routable source addresses, which could belong to a reserved set of addresses (such as private IP addresses) or be part of an assigned but unused address space of a network.

2) *Valid Source Address*: These type of attacks usually require interactive exchanges between botnet and victim, hence a valid source address is needed.

#### K. Attack Traffic Distribution

The locations used as source of attack packets can be utilized to classify DDoS attacks into two *Attack Traffic Distribution* categories [4], [12]: *Isotropic* and *Non-isotropic*.

1) *Isotropic*: In Isotropic DDoS attacks, the attacker tries to distribute as much as possible uniformly the origin of its malicious packets.

2) *Non-isotropic*: In Non-isotropic DDoS attacks, the traffic origin is more aggregated in specific parts of the Internet than in others. It means that the victim receives malicious packets from one or more directions which are partially or totally aggregated and not uniformly distributed in the whole Internet.

#### L. Resources Involved

Based on the amount of Resources Involved in a DDoS attack, it is possible to classify it into two categories [22]: *Symmetric* and *Asymmetric*.

1) *Symmetric*: In this case, the resources involved are of the same type and scale as those denied to the victim. For instance, in a Network Flooding Attack the attacker uses the same amount of network bandwidth that the victim is deprived of.

2) *Asymmetric*: In this case, the resources required by the attacker are different from the resources neglected to the victim, in terms of type and scale (e.g., DNS Amplification Attack).

#### M. Victim Type

DDoS attacks can be classified according to the Victim Type into four classes [3]: *Application*, *Host*, *Network* and *Infrastructure*.

1) *Application*: In attacks of this class, one or more features of a specific application on the victim host are targeted, with the aim of preventing legitimate clients to use the application and possibly clogging up host resources.

2) *Host*: In this class of attacks, the victim machine is completely knocked out by disabling or overloading its communication mechanisms (e.g., network interface or network link). A peculiarity of this type of attacks is that all attack packets have the destination address of the target host.

3) *Network*: In this case, the incoming bandwidth of a target network is consumed with attack packets whose destination address can be taken from its network address space.

4) *Infrastructure*: In attacks of this class, the target is any distributed service that is extremely relevant for either the global Internet or a sub-network operations. The peculiarity of these attacks is the simultaneity by which multiple instances of the target service are attacked.

### IV. IOT MALWARES WITH DDoS CAPABILITIES

Nowadays, one of the most popular way to deliver such DDoS attacks is to target IoT devices. The choice is easily explained by the high availability of such devices which, as if it was not enough, are poorly protected by manufacturers and poorly maintained by owners. Therefore, in order to understand what problems we are facing and possibly find a general solution, a thorough analysis of the present situation is absolutely mandatory. We want to stress out that this specific topic is inherently an extremely unstable one, with a considerable number of offspring malwares that borrow lines of code from deeply divergent families of malwares. Moreover, source codes have been disclosed only for a portion of the existing malwares and the largest part of these information comes from complex reverse engineering jobs which makes the whole situation even worse, if possible. In this section we focus only on the DDoS capable IoT malwares, which entails that we neglect on purpose some other IoT malwares that have different goals, such as cryptocurrencies mining.

TABLE I  
IOT MALWARE DDoS CAPABILITIES

Malware				DDoS	
Name	Year	Source Code	Agents CPU	Architecture Model	Feasible Attacks
Linux.Hydra	2008	Open Source	MIPS	IRC-Based	SYN Flood, UDP Flood
Psybot	2009	Reverse Eng.	MIPS	IRC-Based	SYN Flood, UDP Flood, ICMP Flood
Chuck Norris	2010	Reverse Eng.	MIPS	IRC-Based	SYN Flood, UDP Flood, ACK Flood
Tsunami, Kaiten	2010	Reverse Eng.	MIPS	IRC-Based	SYN Flood, UDP Flood, ACK-PUSH Flood, HTTP Layer 7 Flood, TCP XMAS
Aidra, LightAidra, Zendran	2012	Open Source	MIPS, MIPSEL, ARM, PPC, SuperH	IRC-Based	SYN Flood, ACK Flood
Spike, Dofloo, MrBlack, Wrkatk, Sotdas, AES.DdoS	2014	Reverse Eng.	MIPS, ARM	Agent-Handler	SYN Flood, UDP Flood, ICMP Flood, DNS Query Flood, HTTP Layer 7 Flood
BASHLITE, Lizkebab, Torlus, Gafgyt	2014	Open Source	MIPS, MIPSEL, ARM, PPC, SuperH, SPARC	Agent-Handler	SYN Flood, UDP Flood, ACK Flood
Elknot, BillGates Botnet	2015	Reverse Eng.	MIPS, ARM	Agent-Handler	SYN Flood, UDP Flood, ICMP Flood, DNS Query Flood, DNS Amplification, HTTP Layer 7 Flood, Other TCP Floods
XOR.DdoS	2015	Reverse Eng.	MIPS, ARM, PPC, SuperH	Agent-Handler	SYN Flood, ACK Flood, DNS Query Flood, DNS Amplification, Other TCP Floods
LUABOT	2016	Reverse Eng.	ARM	Agent-Handler	HTTP Layer 7 Flood
Remaiten, KTN-RM	2016	Reverse Eng.	ARM, MIPS, PPC, SuperH	IRC-Based	SYN Flood, UDP Flood, ACK Flood, HTTP Layer 7 Flood
NewAidra, Linux.IRCTelnet	2016	Reverse Eng.	MIPS, ARM, PPC	IRC-Based	SYN Flood, ACK Flood, ACK-PUSH Flood, TCP XMAS, Other TCP Floods
Mirai	2016	Open Source	MIPS, MIPSEL, ARM, PPC, SuperH, SPARC	Agent-Handler	SYN Flood, UDP Flood, ACK Flood, VSE Query Flood, DNS Water Torture, GRE IP Flood, GRE ETH Flood, HTTP Layer 7 Flood

#### A. Linux.Hydra

Progenitor of all the IoT malwares, Linux.Hydra appeared in 2008 as an open source project that specifically aimed to routing devices based on MIPS architecture. The exploitation phase relies on a dictionary attack or, in case that the target device is a D-Link router, on a specific and well-known authentication vulnerability [23]. Once that the device has been infected, it becomes part of an IRC-Based network able to perform only a basic SYN Flood attack. The malware documentation reports that this malware also enables the attacker to strike a UDP Flood attack, but online available sources do not exhibit such capability [24]. All in all, even if it is quite simple, this malware laid the groundwork for all the successive MIPS-aiming malwares.

#### B. Psybot

Pretty much similar to Linux.Hydra, this malware appeared on the wild in the early 2009. Compared to its predecessor, Psybot is able to perform also UDP and ICMP Flood attacks [23]. It targets the same MIPS architecture (therefore, essentially network appliances) and, even though a direct comparison cannot be performed since the sources have not been disclosed, the two malwares show so many common points that it is safe to assume that Psybot is a Linux.Hydra offspring.

#### C. Chuck Norris

As soon as the Psybot botnet was taken down by its creator, probably due to a growing interest towards his operations, another competitor came out in 2010. Called Chuck Norris, from a string found into the reverse engineered headers, this malware has a lot of common points with Psybot, at a point

that it is probably its direct evolution [23]: the available attacks are the same, apart from the lacking of ICMP Flood which is replaced by the capability of carrying out an ACK Flood.

#### D. Tsunami/Kaiten

Last and strongest offspring of Linux.Hydra, Tsunami is a fusion of Kaiten-Tsunami DDoS tool and Chuck Norris. In particular, this malware shares with the latter many traits, such as the same encryption key and some CNC IP addresses. Tsunami enables the botnet zombies to carry not only traditional SYN Flood, UDP Flood and ACK-PUSH Flood attacks, but also some more sophisticated ones like HTTP Layer 7 Flood and TCP XMAS attacks. Interestingly, in 2016 this malware was sneaked on purpose into the Linux Mint Official ISO [25], jeopardising a huge quantity of freshly installed OSes.

#### E. Aidra/LightAidra/Zendran

Born around 2012, these three malwares exhibit slight variations of the same source code, small enough to let us group them under the same family. Compared to the aforementioned families, the complexity of these malwares is higher: they are able to compile on a number of different architectures such as MIPS, ARM and PPC, even though the infection method relies upon a simple authentication guessing [26]. The resulting botnet architecture is, once again, IRC-based and the type of deliverable attacks is still restricted to basic attacks like SYN Flood and ACK Flood.

#### F. Spike/Dofloo/MrBlack/Wrkatk/Sotdas/AES.DdoS

After the Linux.Hydra family subsided, a new bunch of malwares appeared in different times around 2014 [27]. Many

different malwares (such as Spike, Dofloo, etc.) belong to this family but they are so similar that it is hard to tell one from another. What is clear is that, conversely from all the previous families, the resulting botnet architecture is an Agent-Handler based one. Moreover, a mechanism of persistence has been developed by tampering with the */etc/rc.local* file, aiming to survive a device reboot. Another interesting characteristic is the so-called *SendInfo* thread that tries to derive the computing power of the infected host device [28], thus enabling the CNC server to tune the intensity of DDoS jobs that each bot should perform.

#### G. BASHLITE/Lizkebab/Torlus/Gafgyt

Another popular malware on the wild in 2014, BASHLITE shares similar characteristics with the Spike malware family. Particularly, the communication protocol is a lightweight version of IRC, but it has been so heavily modified that the resulting botnet architecture is totally non-dependant on IRC servers, therefore this botnet can be considered an Agent-Handler and not an IRC-Based one [29]. The variety of architectures vulnerable to this malware is impressive, as even SPARC devices can be infected. The DDoS attacks are basilar, nothing more than traditional SYN, UDP and ACK Flood attacks.

#### H. Elknot/BillGates Botnet

This 2015 malware has been mostly used by the chinese DDoS'ers, to such a point that the whole family has been dubbed China ELF [30]. Developed to target for the most part SOHO devices, the vulnerable architectures are MIPS and ARM; the possible DDoS attacks are quite a number, included HTTP Layer 7 Flood and some other TCP Flood attacks. Considering that all the available information are derived from reverse engineering techniques and, in addition, copious mutations of this malware has been created, in this case it is particularly hard to sketch out detailed characteristics.

#### I. XOR.DDoS

In 2015, during the tide wave of malwares that exploited the Shellshock vulnerability, XOR.DDoS started to silently infect many IoT devices all around the world, even though it did not rely upon the aforementioned vulnerability [31]. Probably another product of the chinese DDoS community, this malware is capable of various attacks like SYN Flood, UDP Flood, DNS Flood and more complex TCP Flood ones. As reported by Akamai [32], in October 2015 this botnet alone has been able to hit one of their customers with a DNS Flood of 30 million queries per second, combined with a SYN Flood attack of 140 Gbps.

#### J. LUABOT

Spotted in 2016, LUABOT is the first ever malware written in LUA programming language. In particular, the DDoS instruction script is detached from the main routines and this modular characteristic, highly simplified by the choice of LUA, in the first stages prevented researchers from understanding its real purpose [33]. So far, the only payload file that has

been identified suggests an HTTP Layer 7 Flood attack, but we don't exclude that some other kind of payload scripts are available for this malware to be run. Much more interestingly, this malware includes a V7 embedded JavaScript engine to bypass DDoS protections offered by some enterprises, such as Cloudflare and Sucuri [34].

#### K. Remaiten/KTN-RM

Appeared in 2016 alongside the much more famous Mirai, Remaiten merges the main characteristics of two different malwares, namely Tsunami and BASHLITE. In particular, the DDoS attacks are mostly derived from the former malware, whereas the telnet scanning capabilities are borrowed by the latter one [35]; unlike BASHLITE, Remaiten botnet architecture is IRC-Based. Most of the embedded architectures are vulnerable to Remaiten, which is unsurprising, since that nowadays it is a common characteristic for all the IoT malwares to be able to compile on different architectures.

#### L. NewAidra/Linux.IRCTelnet

NewAidra, also known as Linux.IRCTelnet, is somehow a nasty combination between Aidra root code, Kaiten IRC-based protocol, BASHLITE scanning/injection and Mirai dictionary attack [36]. All the embedded devices based on standard architectures can be infected by this malware and the variety of attacks is large: starting from the standard attacks, the attacker can also choose TCP XMAS and TCP Flood attacks (as an example, URG Flood attack). At the present moment, NewAidra is the strongest Mirai competitor in its worldwide IoT infection crusade.

#### M. Mirai

Mirai is one of the most predominant malware of the last years. It has been used to perpetrate some of the largest DDoS attacks ever known, included the abuse of the French internet service and hosting provider OVH on 22nd September 2016 [37], [38], the attack to KrebsOnSecurity blog on 30th September 2016 [37], [39], and the takedown of Dyn DNS services on 21st October 2016 [37], [40], [41].

The Mirai worm is designed to infect and control IoT devices (such as home routers, DVRs, CCTV cameras, etc., mainly manufactured by XiongMai Technology) using a dictionary attack based on 62 entries. Once exploited, the devices are reported to a control server in order to be used as part of a large-scale botnet [42]. Afterwards, the botnet can be used to perpetrate several types of DDoS attacks exploiting a wide range of protocols (such as GRE, TCP, UDP, DNS and HTTP).

## V. DISCUSSION

By further analysing Table I we can highlight some interesting data. First of all, source codes have been disclosed only for few malwares and most of them have been analyzed through reverse engineering techniques, which entails that part of the available data, such as the relationship between the different families of malwares, is based on incomplete and limited information.

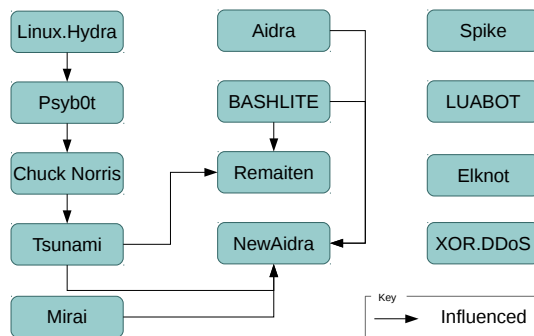

Fig. 3. IoT DDoS Capable Malwares - Correlations

Talking about relationships, Figure 3 shows how the different families are supposedly related to each other. Linux.Hydra was the first IoT DDoS capable malware and its source code evolved through the years into 3 different malwares. It seemed that Tsunami would have been Linux.Hydra very last evolution, but part of its code has also been used to develop chunks of Remaiten and even NewAidra, which is one of the most recently appeared malwares. Also, Figure 3 shows that the older malwares were mostly unrelated to each other, whereas in the last years we are witnessing a melting pot of characteristics borrowed from different families, which results into an increased complexity of detection and classification.

Nowadays we can clearly sense the growing in popularity of IoT malwares that exhibit DDoS capabilities. Figure 4 shows the yearly progression of such malwares, as reported in Table I, and clearly confirms this perception. As a matter of fact, it highlights that 4 new families were born in 2016 alone, which is troubling since the previous record was of only 2 new malwares per year (namely in 2010, 2014 and 2015) and before 2008 this category of malwares did not even exist.

Another thing that clearly stands out, is that the oldest malwares were designed to target specific devices that used MIPS processors, whereas the newest ones are able to target a much broader variety of devices and architectures, such as ARM and PPC.

Moreover, looking at the offensive capabilities we can easily see how the most recent malwares are able to hit the targets with much more attacks than the past. As an example, Linux.Hydra was only able to carry out SYN Flood attacks, but Mirai has been armed with refined attacks like GRE IP Flood, GRE ETH Flood and even the so-called DNS Water Torture. Furthermore, almost all the performable DDoS attacks are ascribable into the Flood attacks category, explainable with the enormous quantity of vulnerable IoT devices, which can be easily enslaved with such malwares. As a matter of fact, the Flood attacks require basic programming skills, few lines of code (which is relevant with embedded devices) and very little coordination between the bots.

Last thing, malicious coders take different approaches when it comes to choose the resulting malware botnet architecture. Some malwares build an IRC-based architecture and some

Fig. 4. IoT DDoS Capable Malwares – Year progression, as shown in Table I

others build an Agent-Handler one, therefore we currently cannot highlight a global favourite approach.

## VI. CONCLUSION

The IoT earthquake shook the market and flooded it with a huge amount of poorly secured devices, that were turned by malicious attackers in a potential army, ready to be engaged in highly disruptive activities, mainly DDoS attacks.

Motivated by the increasing number of DDoS attacks that negatively characterize the IoT revolution and by the lack of adequate literature on these attacks in the IoT context, in this paper we have provided an analysis of IoT malwares exposing DDoS capabilities. As a matter of fact, to the best of our knowledge previous surveys about DDoS attacks are dated before the IoT revolution. The analysis is based on an up-to-date comprehensive taxonomy of DDoS attacks based on previous scientific literature and the latest performed attacks to IoT devices. We compared and analyzed the families of malware that characterized the recent years of the IoT-DDoS landscape. The aim of the analysis is to provide a first reference to the scientific community in order to understand all the latest types of DDoS attacks targeting the IoT domain. We believe this study represents a key step in order to raise the awareness of the research community and tackle this security emergency.

# 1<sup>st</sup> Workshop on Internet of Things—Enablers, Challenges and Applications

**T**HE Internet of Things is a technology which is rapidly emerging the world. IoT applications include: smart city initiatives, wearable devices aimed to real-time health monitoring, smart homes and buildings, smart vehicles, environment monitoring, intelligent border protection, logistics support. The Internet of Things is a paradigm that assumes a pervasive presence in the environment of many smart things, including sensors, actuators, embedded systems and other similar devices. Widespread connectivity, getting cheaper smart devices and a great demand for data, testify to that the IoT will continue to grow by leaps and bounds. The business models of various industries are being redesigned on basis of the IoT paradigm. But the successful deployment of the IoT is conditioned by the progress in solving many problems. These issues are as the following:

- The integration of heterogeneous sensors and systems with different technologies taking account environmental constraints, and data confidentiality levels;
- Big challenges on information management for the applications of IoT in different fields (trustworthiness, provenance, privacy);
- Security challenges related to co-existence and interconnection of many IoT networks;
- Challenges related to reliability and dependability, especially when the IoT becomes the mission critical component;
- Zero-configuration or other convenient approaches to simplify the deployment and configuration of IoT and self-healing of IoT networks;
- Knowledge discovery, especially semantic and syntactical discovering of the information from data provided by IoT;

The IoT conference is seeking original, high quality research papers related to such topics. The conference will also solicit papers about current implementation efforts, research results, as well as position statements from industry and academia regarding applications of IoT. The focus areas will be, but not limited to, the challenges on networking and information management, security and ensuring privacy, logistics, situation awareness, and medical care.

## TOPICS

The IoT conference is seeking original, high quality research papers related to following topics:

- Future communication technologies (Future Internet; Wireless Sensor Networks; Web-services, 5G, 4G, LTE, LTE-Advanced; WLAN, WPAN; Small cell Networks...) for IoT,

- Intelligent Internet Communication,
- IoT Standards,
- Networking Technologies for IoT,
- Protocols and Algorithms for IoT,
- Self-Organization and Self-Healing of IoT Networks,
- Trust, Identity Management and Object Recognition,
- Object Naming, Security and Privacy in the IoT Environment,
- Security Issues of IoT,
- Integration of Heterogeneous Networks, Sensors and Systems,
- Context Modeling, Reasoning and Context-aware Computing,
- Fault-Tolerant Networking for Content Dissemination,
- Architecture Design, Interoperability and Technologies,
- Data or Power Management for IoT,
- Fog—Cloud Interactions and Enabling Protocols,
- Reliability and Dependability of mission critical IoT,
- Unmanned-Aerial-Vehicles (UAV) Platforms, Swarms and Networking,
- Data Analytics for IoT,
- Artificial Intelligence and IoT,
- Applications of IoT (Healthcare, Military, Logistics, Supply Chains, Agriculture, ...),
- E-commerce and IoT.

The conference will also solicit papers about current implementation efforts, research results, as well as position statements from industry and academia regarding applications of IoT. Focus areas will be, but not limited to above mentioned topics.

**Abstract**—Internet of Things (IoT) has gained substantial attention recently and plays a significant role in multiple real-world application deployments. A wide spectrum of such applications strongly depend on data fusion capabilities in the cloud from diverse information sources. In fact, various information sources often provide conflicting and contradictory for the same object, and thus it is important to fuse and resolve any possible information conflict before taking crucial decisions. For this reason, the primary aim of this paper is to provide a new evidential conflict resolution method that is able to automatically solve the problem of contradictory information provided by different sources in IoT applications. This method is based on the belief functions theory which is a powerful mathematical theory that can represent and manipulate various types of information imperfection. The performance of the proposed method was evaluated through simulation experiments. The results from these simulations demonstrated that our method outperforms the state-of-art methods in terms of effectiveness.

## I. INTRODUCTION

IN RECENT years, the Internet of Things (IoT) has received considerable attention among academic researchers as well as industrial managers. The principal reason behind this consideration is the capabilities that IoT promises to offer. Indeed, IoT technology promises to revolutionize the way people live, work and interact with each other, by providing new opportunities to create a smarter world where all the abundant physical smart objects surrounding us can connect to the Internet and collaborate with one another so as to accomplish a common task with limited human intervention [1].

The greatest strength of the IoT paradigm is indisputably the high impact it has on people's everyday life. Its application covers various domains ranging from transportation, retail, healthcare, and defense to smart environments such as homes and cities [1]. All these applications rely on information pieces collected from many sensors of multiple types and reliability levels. These sensors collect, generate, and preserve a variety of information with diverse representations, scales, and quality. Bringing all the information pieces together opens opportunities to measure, understand and infer a robust and complete description of an environment or process of interest, and further makes it possible to provide intelligent services.

Data fusion plays a central part of IoT [2]. It combines information pieces collected from multiple sensors to achieve improved accuracy, enhanced precision, increased availability

and more effective decision support than could be achieved by the use of a single sensor. Unfortunately, there are several issues involved in a sensory network that make the data fusion a difficult task. The majority of these issues arises from the quality of the information pieces to be fused and to the reliability degrees of the sensors providing them. In fact, information pieces produced by sensors are frequently dirty, which is mainly due to sensor failure, degradation or to its inherent limitation. Therefore, mechanisms to clean sensor information and improves the quality of decision-making are mandatory in IoT applications.

One way to overcome this problem is to eliminate the probable information conflict before the fusion procedure by considering the source reliability level. Consequently, all the information pieces to be merged should be corrected according to the reliability degree of the sources providing them. However, in many IoT applications, the information about the reliability of the sources is unavailable. In such situation, one should design an effective unsupervised method that is able to solve any probable information conflict and estimate the source reliability factors without having any training datasets. For this reason, we propose in this paper an unsupervised evidential conflict resolution method (U-ECRM) that overcome this problem. This method is based on the belief functions theory which has the merits of representing and handling various types of information imperfections.

The rest of this paper is structured as follows: Section 2 introduces the belief functions theory. Section 3 formulate the conflict resolution problem in IoT applications. Section 4 presents the main idea behind the proposed U-ECRM and details the proposed inference algorithm. The performances of the proposed method obtained from a synthetic dataset simulations are presented and discussed in Section 5. Finally, Section 6 concludes the paper.

## II. BASICS OF BELIEF FUNCTIONS THEORY

In the Belief Functions Theory (BFT)[3], the Frame of Discernment (FoD)  $\Theta = \{H_1, H_2, \dots, H_N\}$  is a set of  $N$  mutually exclusive and exhaustive hypotheses. The power set of  $\Theta$ , denoted by  $2^\Theta$ , contains all possible unions of the elements in  $\Theta$  including  $\Theta$  itself as well as the empty set.

The mass function (*MF*) expresses the degree of belief committed to a subset  $A \in 2^\Theta$  justified by the available information. The *MF* is defined as a mapping  $m : 2^\Theta \rightarrow [0, 1]$  satisfying the following properties:

$$m_{1 \oplus 2}(A) = \begin{cases} \frac{\sum_{\substack{B, C \in 2^\Theta \\ B \cap C = A}} m_1(B) * m_2(C)}{1 - \sum_{\substack{B, C \in 2^\Theta \\ B \cap C = \emptyset}} m_1(B) * m_2(C)} & A \in 2^\Theta, A \neq \emptyset \\ 0 & A = \emptyset \end{cases} \quad (1)$$

It is possible to have multiple *MF* on the same domain  $\Theta$  that correspond to different experts' opinions. Dempster's Rule of combination [3] can aggregate these *mf*. This rule is defined as follows:

$$m_{1 \oplus 2}(A) = \begin{cases} \frac{\sum_{B \cap C = A} m_1(B) * m_2(C)}{1 - \sum_{B \cap C = \emptyset} m_1(B) * m_2(C)} & \forall A \subseteq \Theta, A \neq \emptyset \\ 0 & \text{if } A \neq \emptyset \end{cases} \quad (2)$$

In BFT, a decision can be made by choosing the single hypothesis with the maximum pignistic probability [4] which is constructed from the *MF*. It is defined as follows:

$$BetP(A) = \sum_{B \subseteq \Theta, A \cap B \neq \emptyset} \frac{|A \cap B|}{|B|} m(B) \quad (3)$$

In the framework of BFT, a distance measure computes the dissimilarity between two pieces of evidence. Jousselme distance [5] has been widely used in this purpose. It is defined as follows:

$$d(m_1, m_2) = \sqrt{\frac{1}{2} (m_1 - m_2)^t \underline{D} (m_1 - m_2)} \quad (4)$$

$$\underline{D} = \begin{cases} 1 & \text{if } A = B \\ \frac{|A \cap B|}{|A \cup B|} & \forall A, B \in 2^\Theta \end{cases}$$

### III. PROBLEM FORMULATION

Let us consider a set of  $M$  objects (variable)  $O = \{o_1, o_1, \dots, o_M\}$  where each variable  $o_j \in O$  can takes its unique true value from the exhaustive and mutually exclusive FoD  $\Omega_j = \{H_{1,j}, H_{2,j}, H_{3,j}, \dots, H_{K_j,j}\}$ . That is one and only one hypothesis  $\hat{H}_j$  among the set of possible hypotheses  $\Omega_j$  is the actual value of object  $o_j$ . Besides, we also consider the close world assumption, where the complete knowledge about the definition domain of each object  $o_j$  is known by everyone in the fusion system. Thus, the available information about the actual value of  $o_j$  is represented by a correct value mass function *CV-MF*  $m_j^\Omega$  defined over the FoD  $\Omega_j$ .

To determine the correct values of the objects  $o_j \in O$ , one can exploit the power of data fusion techniques by aggregating multiple pieces of information collected from several sources. To do so, let us now consider a set  $S = \{s_1, s_2, s_3, \dots, s_N\}$  of  $N$  cognitively independent sources, where each source  $s_i$  provides pieces of information describing its knowledge about the actual value of each object  $o_j$ . These pieces of

information are encoded in the form of *MFs*  $m_{i,j}^\Omega$  defined over the FoD  $\Omega_j$ . The usage of BFT to model and manipulate the provided pieces of information allows a better exploration of all available information [3].

In addition to its expressiveness power, the BFT offers a promising tool to combine several pieces of evidence obtained from multiple sources. The principal aim of using the combination operator, such as Dempster's combination rule, is to reduce the epistemic uncertainty by acquiring and then merging several credible, yet possibly incomplete, evidence pieces delivered by various cognitively independent and equally reliable sources. Accordingly, this important operation can help the fusion system to determine the correct value among the set of all possible values, and thus leading the decision maker to make the best possible decision for a given task.

Unfortunately, sources are seldom of the same quality, and some of them frequently deliver wrong, biased and contradictory pieces of information for the same real-world object. As a consequence, combining these incorrect information pieces with the correct ones using Dempster's combination rule generally produces counter-intuitive results, which in turn can lead the fusion system to make misleading critical decisions. One possible solution to overcome this problem is to incorporate the reliability level of each source into the fusion task. In this way, the system can correct the quality of the provided information pieces according to their sources reliability level prior to combination and further usages. One of the most robust and effective ways to model the reliability level of the sources is to use our proposed Evidential Source Reliability Mass Function *ESR-MF*. In fact, unlike the traditional source reliability models, the *ESR-MF* exploits the power of BFT to model several possible types of the qualitative behavior of a given source. As a consequence, this model allows a more general modelization of the source attitude, and thus it can, along with the evidential correction mechanism, enhance the performance of the fusion system. In this regard, we suppose, in this paper, that the reliability level of each source  $s_i$  is encoded as an *ESR-MF*  $m_i^\Theta$  defined over the FoD  $\Theta = \{T, D, R\}$ , where the meaning of  $T$  is that  $s_i$  has a trustworthy qualitative behavior,  $D$  means that  $s_i$  is defective and  $R$  represents the state where  $s_i$  is considered to have a random qualitative behavior.

Let  $m_i^\Theta$  represents the *ESR-MF* of  $s_i$ . This *MF* can be defined as a mapping function  $m_i^\Theta : 2^\Theta \rightarrow [0, 1]$ , such that:

$$\begin{cases} m_i^\Theta(A) \in [0, 1], & \forall A \in 2^\Theta \\ m_i^\Theta(\emptyset) = 0 \\ m_i^\Theta(T) + m_i^\Theta(D) + m_i^\Theta(R) + m_i^\Theta(T, D, R) = 1 \end{cases} \quad (5)$$

The support mass assigned to each subset of the FoD  $\Theta_i$  have the following meaning:  $m_i^\Theta(T)$  represents the support degree that  $s_i$  is trustworthy.  $m_i^\Theta(D)$  represents the support degree that  $s_i$  is defective.  $m_i^\Theta(R)$  represents the support degree that  $s_i$  has a random behavior.  $m_i^\Theta(T, D, R)$  encodes the percentage of uncertainty about the behavior of  $s_i$ .

It is important to note that one of the possible ways to estimate the value of the *ESR-MF* is to focus the evaluation on the past contributions of the source. This can be achieved by evaluating the set of historical information pieces provided by the source with the actual values contained in the training dataset. In this way, it is possible to ascertain the historical behavior of the source, which in turn can be exploited to estimate its future behavior. This later can be used to correct the source's newly provided information pieces, and thus avoiding information conflict problems with the other sources. However, in many situations the *ESR-MF* of the sources are unknown a priori, and often training datasets are also unavailable. Therefore, the crucial problem that needs to be addressed is how to obtain the correct value of each object and to estimate the sources reliability level when there is no prior training dataset.

#### IV. THE PROPOSED UNSUPERVISED EVIDENTIAL METHOD

Due to the fact that the considered problem does not contain any prior knowledge other than the information pieces that is delivered by a set of sources, a robust method that is able to resolve the probable information conflict between the diverse sources without any supervision needs to be developed, where both the *ESR-MFs* and the *CV-MFs* can only be estimated based on the provided pieces of information. To do so, the *ESR-MF* estimation and *CV-MF* determination steps are tightly related through the following two principles:

- 1) First, the sources that often deliver correct information pieces will be assigned higher trustworthiness degrees, the sources that mainly provide incorrect pieces of information will be regarded as defective and the ones that give a combination of correct and incorrect information pieces will be considered as random. At the same time, the estimated qualitative behavior of sources that supply more relevant information pieces will be considered as more certain than the ones that provide fewer pertinent information pieces.
- 2) Second, the information piece that is supported by trustworthy sources will be regarded as correct. Conversely, the information piece that is mostly supported by defective sources will be considered as wrong, and its complement is regarded as correct. On opposition to the two previous cases, the information pieces given by random or uncertain sources will be ignored and their support will not be taken into consideration.

This idea presents a chicken-and-egg dilemma. An unsupervised evidential conflict resolution method (U-ECRM) can solve this task by operating iteratively to simultaneously estimate the *ESR-MFs* and to determine the *CV-MFs* by following the above principles.

Following the previously principle, our proposed method is designed to jointly estimate source reliability and to determine the correct values. The flowchart of the inference algorithm is depicted in Figure 1. The basic core of the U-ECRM is an iterative algorithm, which starts with an initial setting of some parameters and then iteratively conducts the source weight

update and truth update steps until a stopping condition is satisfied. Finally, a decision making step on the correct values of the considered objects is performed.

##### A. Parameters initialization

For the iterative methods, some parameters must be initialized in order to start the algorithms. In our U-ECRM, the *CV-MFs* are chosen to be the set of parameter to be initialized. Various techniques can be used to choose the initial value of these parameters. However, since the iterative methods are generally sensitive to arbitrary initializations, we prefer to use one of the majority opinion combination rules to infer the first guess of each *CV-MF*. For instance, in the current setting, each set of the provided information pieces about a particular object is combined by Murphy combination rule [6] in order to get a first value for the correct. This rule first applies a simple arithmetic averaging method, then the obtained averaged *MF* is combined with itself  $N-1$  times by Dempster's combination rule.

##### B. Evidential source reliability mass function estimation

To estimate the *ESR-MF*  $m_i^\Theta$  of each  $s_i$ , two series of input parameter are needed: the provided *MF*  $m_{i,j}^\Omega$  about the actual value of each object  $o_j$ , and the objects' previously computed *CV-MFs*  $m_{j \in \{1,2,\dots,M\}}^{\Omega,*}$ . Since these two series of parameters are available in this step of computation, the *ESR-MFs*  $m_{i \in \{1,2,\dots,N\}}^\Theta$  can be computed. For each source, we start by evaluating the correctness degree of each of the *MFs* that is provided by this source with respect to the computed *CV-MFs* of the considered objects. This evaluation step yields a set of evidence correctness mass functions *EC-MFs*  $m_{i,j}^\Psi$ , which represent how correct and relevant the source's information pieces are. The *EC-MF*  $m_{i,j}^\Psi$  is defined over the FoD  $\Psi_{i,j} = \{C, \bar{C}\}$  where  $C$  represents the hypothesis that the provided information  $m_{i,j}^\Omega$  is correct, whereas  $\bar{C}$  represents the hypothesis that the provided information  $m_{i,j}^\Omega$  is incorrect.

Given  $m_{i,j}^\Omega$ , the *EC-MF*  $m_{i,j}^\Psi$  can be computed by comparing  $m_{i,j}^\Omega$  with the *CV-MF*  $m_{j}^{\Omega,*}$ . This comparison can be made by equation 6.

$$\begin{cases} m_{i,j}^\Psi(C) = \sum_{B \in 2^\Omega} m_j^\Omega(B) \left( \sum_{B \cap A = B} f(|A|) m_{i,j}^\Omega(A) \right) \\ m_{i,j}^\Psi(\bar{C}) = \sum_{B \in 2^\Omega} m_j^\Omega(B) \left( \sum_{B \cap A = \emptyset} m_{i,j}^\Omega(A) \right) \\ m_{i,j}^\Psi(C, \bar{C}) = 1 - (m_{i,j}^\Psi(C) + m_{i,j}^\Psi(\bar{C})) \end{cases} \quad (6)$$

where  $f$  is a function which distributes the imprecision of  $s_i$  between the support degree that the given evidence is correct  $m_{i,j}^\Psi(C)$  and the support degree that the provided information is irrelevant  $m_{i,j}^\Psi(C, \bar{C})$ . This function can be defined as follows:

$$f(|A|) = \frac{|\Omega_j| - |A|}{|\Omega_j| - 1} \quad (7)$$

Figure 1. Flowchart of the unsupervised evidential conflict resolution method.

Once the  $EC-MF_d$  of all objects are obtained, the total true positive  $TP_i$  and the total false negative  $FN_i$  of  $s_i$  are calculated by means of equation 8 and equation 9 respectively.

$$TP_i = \sum_{j=1}^M m_{i,j}^{\Psi}(C) \quad (8)$$

$$FN_i = \sum_{j=1}^M m_{i,j}^{\Psi}(\bar{C}) \quad (9)$$

After computing the  $TP_i$  and  $FN_i$  of  $s_i$ , they are used along with an application-specific user-specified cautious parameter  $C_{cautious}$  to estimate the qualitative behavior of the source by using equation 10 or equation 11 depending on the difference between  $TP_i$  and  $FN_i$ .

- **Case 1:**  $TP_i \geq FN_i$ :

$$\begin{cases} m_i^{\Theta}(T) &= \frac{TP_i - FN_i}{TP_i + FN_i + C_{cautious}} \\ m_i^{\Theta}(D) &= 0 \\ m_i^{\Theta}(R) &= \frac{2FN_i}{TP_i + FN_i + C_{cautious}} \\ m_i^{\Theta}(T, D, R) &= \frac{C_{cautious}}{TP_i + FN_i + C_{cautious}} \end{cases} \quad (10)$$

- **Case 2:**  $TP_i \leq FN_i$ :

$$\begin{cases} m_i^{\Theta}(T) &= 0 \\ m_i^{\Theta}(D) &= \frac{FN_i - TP_i}{TP_i + FN_i + C_{cautious}} \\ m_i^{\Theta}(R) &= \frac{2TP_i}{TP_i + FN_i + C_{cautious}} \\ m_i^{\Theta}(T, D, R) &= \frac{C_{cautious}}{TP_i + FN_i + C_{cautious}} \end{cases} \quad (11)$$

### C. Correct value mass function determination

The  $CV-MF$  determination procedure aims at computing the set of all  $CV-MFs$   $m_{j \in \{1,2,\dots,M\}}^{\Omega,*}$  given that the set of all sources' provided  $MFs$   $m_{i \in \{1,2,\dots,N\}}^{\Omega}$  and the estimated  $ESR-MFs$   $m_{i \in \{1,2,\dots,N\}}^{\Theta}$  of all sources  $s_{i \in \{1,2,\dots,N\}}$  are available. For a given object  $o_j$ , this procedure begins by correcting the provided  $MFs$   $m_{i \in \{1,2,\dots,N\},j}^{\Omega}$  according to their appropriate sources'  $ESR-MFs$   $m_{i \in \{1,2,\dots,N\}}^{\Theta}$  by means of the evidential correction mechanism. This mechanism can take advantages of the information contained in the  $ESR-MF$  to correct the provided information pieces before further exploitation. It can be formally defined in equation 12.

Immediately after correcting all the provided information pieces, these obtained corrected  $MFs$   $m_{i \in \{1,2,\dots,N\},j}^{\Omega,*}$  can be aggregated by Dempster's rule to produce the combined  $CV-MF$   $m_j^{\Omega,*}$ . Note that the correction step and the aggregation step must be applied to all objects  $o_j \in O$ . Once done,

the set of all  $CV-MFs$   $m_{j \in \{1,2,\dots,M\}}^{\Omega,*}$  is returned as the output of this procedure, and can be used to either re-estimate the  $ESR-MFs$  or make decision about the correct values.

### D. Correct values decision making

The main purpose of the U-ECRM is to resolve the probable evidence conflict between the sources by estimating and then incorporating the  $ESR-MFs$  into the fusion task. In the current problem, these decisions can be made from the obtained  $CV-MFs$   $m_{j \in \{1,2,\dots,M\}}^{\Omega,*}$ . To make reasonable decisions in the U-ECRM, the pignistic transformation  $BetP_j$  of each  $CV-MF$   $m_j^{\Omega,*}$  is firstly constructed. Then, the decision can be made based on selecting the hypothesis  $\hat{H}_j$  with the largest pignistic probability.

### E. Stopping condition

The iterative process in the proposed U-ECRM is carried out until the stopping criterion is satisfied. The stopping condition is defined with regard to the computed  $CV-MFs$   $m_{j \in \{1,2,\dots,M\}}^{\Omega,*}$ . In each iteration, we first compute the Josselme distance between the computed  $CV-MF$  of the current iteration and the computed  $CV-MF$  of the previous iteration of each  $o_j$ . If the mean of all computed Josselme distances of all objects is less than a small positive number  $\varepsilon$ , then the convergence criterion is satisfied.

## V. EXPERIMENTAL EVALUATION

The performance evaluation of our U-ECRM is tested and compared with the baseline methods (majority voting, TruthFinder [7], 2-Estimate [8]) on samples of synthetic datasets generated by Waguih et al. synthetic datasets generator [9].

To evaluate the Precision rate of the proposed method, we chose the following configuration. We first defined the scale parameters by setting the number of objects to 1,000, and the number of possible values for each object to 4. We also chose the uniform distribution for the distribution of the distinct values per object. In addition, we configured the source coverage to follow the exponential distributions. More importantly, we selected 80-pessimistic distributions for the ground truth distribution. The main reason behind choosing these distributions for the generated synthetic dataset is their close similarity to real-world scenarios.

Based on the above setting, we generate 20 synthetic datasets for each experiment of a specific number of sources.

$$\begin{cases} m_{i,j}^{\Omega*}(A) = m_i^{\Theta}(T)m_{i,j}^{\Omega}(A) + m_i^{\Theta}(D)m_{i,j}^{\Omega}(\bar{A}) & \forall A \in 2^{\Omega}/\Omega \\ m_{i,j}^{\Omega*}(\Omega) = m_{i,j}^{\Omega}(\Omega) + [m_i^{\Theta}(R) + m_i^{\Theta}(T, D, R)] \sum_{A \in 2^{\Omega}/\Omega} m_{i,j}^{\Omega}(A) \end{cases} \quad (12)$$

Figure 2. The precision of the conflict resolution methods on synthetic datasets with varying in the number of sources.

To reduce the randomness of the dataset generation process, the evaluation metric of each conflict resolution method is computed as the average of these 20 generated datasets.

Figure 2 is a bar chart that illustrates the precision rate of the considered conflict resolution methods on the generated synthetic datasets. It can be seen from this bar chart that the proposed U-ECRM overcomes the other methods in terms of precision rate. It can also be observed that adding more sources to the fusion task increases the precision rate of our proposed method and hence it improves the performance of the fusion task. This is a good property since the number of sources in real-world applications is generally large. However, this behavior is not observed with the other methods where their performance tends to degrade after the number of sources exceeds 100. This is to be expected because the distribution of the ground truth is 80-pessimistic. In other words, when the number of sources increases, the number of unreliable sources becomes higher and hence the influence of these sources will decrease the performance of the methods. On the other hand, the proposed U-ECRM benefits from this situation since it can identify the defective sources, and then it exploits this information to improve the performance of the fusion task.

## VI. CONCLUSION

In this paper, we focused on the problem of resolving the information conflict between different sources in the case where the reliability factors of the sources are unknown because no training dataset is available to assess their values. To do so, we proposed in this paper an unsupervised evidential method that is able to simultaneously estimate the evidential source reliability mass functions and determining the correct value mass functions in the case where no training dataset

is available. This method proceeds iteratively over the whole datasets, and thus it guarantees a general consensus between all the sources over the entire available information pieces. In this way, several data fusion problems in multiple IoT applications can be solved. The primary simulation experiments have shown that the proposed evidential method outperforms the state-of-art methods in terms of effectiveness.

**Abstract**—During the last decade, several Internet of Things (IoT) applications has been developed to facilitate machine-to-human and machine-to-machine communication with the physical world by integrating both digital and physical entities through the internet. However, multiple important challenges need to be addressed in order to take the full advantage of these applications. One of the most important of these challenges concerns the management of IoT data, practically the data generated in dynamic and volatile environments and then provided in the form of streaming datasets. To enable reliable IoT applications in such scenario, it is crucial to develop methods that are able to automatically resolve any possible data conflict between diverse information sources in the case where the data is coming in a streaming fashion. In this paper, an incremental evidential conflict resolution method (I-ECRM) that is able to overcome this problem is introduced. The efficiency and effectiveness of the proposed method have been tested and evaluated through extensive experiments on synthetic datasets. The obtained results have shown that our method achieves a nice performance over different tradeoffs dimensions.

## I. INTRODUCTION

ACTIVE research, industry and standardization efforts in the field of next-generation networking are pushing towards a smart connected world where everyday objects will be dotted with the ability to sense, act and exchange information about their surroundings [1, 2]. Combined with today's Internet infrastructure, these objects can make a huge difference in our way of life. Thus, the number of expected applications is only bounded by imagination with applications on smart grid, smart cities, smart homes, smart health, industrial automation, and connected cars to name a few [3].

This new trend is commonly referred to as the future Internet architecture or simply the Internet of Things (IoT) [3]. This vision is starting to gain widespread adoption in today's world by building upon advances in a multitude of fields including micro-electromechanical systems, advances in wired and wireless communication technologies, networking, machine learning and big data. Many challenges are however being tackled and/or need to be addressed in order to unleash the full potential of the IoT applications. One of the most fundamental of these challenges is related to the quality of the generated data by the information sources (also known as things). In fact, due to the variety of the reliability level of the information sources, different sources can provide different

contradictory information about the same real-world object, and thus a conflict between the sources' provided information may occur. In this situation, the collected information pieces about the same real world object need to be corrected according to their corresponding source reliability level and then fused in order to reduce uncertainty and obtain a more coherent, integrated information.

In general, the value of sources reliability degrees can be either obtained from external sources such as human experts, learned by using training datasets or constructed as a function of general agreement and corroboration between various sources. In this paper, we consider the case when no training dataset is available to assess the quality of the information sources. Thus, it is quite challenging to ascertain the reliability of each information source from the massive amounts of unlabeled data without knowing whether their provided information pieces are correct or wrong. Therefore, one of the main questions exposed in this paper is how to develop an efficient and effective unsupervised method that can both learn the sources reliability degree and determine the credibility degree of each provided information pieces without relying on manual user interaction, master data, or training dataset.

With the great evolution of computers technology, low-cost wireless sensor devices, Web technologies, and their recent multiple applications provide access to new types of data, which were not taken into account by the traditional processing applications. Two particularly interesting features of such data sets include their large volume and high velocity [4]. In several IoT applications, the amount of everyday generated data has grown exponentially during the last few years. This means that it is impossible to store and manipulate all that data since even a large scale algorithms exceed the processing capacity of the current single computing systems. Furthermore, the batch unsupervised data processing methods cannot handle its complex structure and size, fulfill very strict constraints as even simple computational operations are too costly. On the other hand, this could be seen as an opportunity to try to design and develop new methods that are able to deal with this new types of data complexity.

The above-mentioned requirements and challenges are particularly noticeable in emerging online data-intensive IoT

applications, on which data are being continuously generated at a high speed and/or large volume in a streaming format [5]. Sensor networks, weather forecast, traffic management, stock price prediction, or social media information analysis are just a few representatives of such applications where multiple data sources, such as sensors, human crowd, as well as web services, working in dynamic environments generate high rate data stream. Compared to static environments, streaming data sets arrive at a great speed and their processing algorithms have to meet tight computational requirements including limited memory usage, short processing time, and an online scan of incoming sets. Thus, the batch unsupervised evidential conflict resolution method cannot be used in such a scenario, as this technique is based on cost-effective iterative updates of the sources reliability degrees and information credibility values, which requires the totality of the data for the processing. Therefore, it is vital to develop efficient and effective techniques for data conflict resolution in the data streams scenario.

In this paper, we tackle this challenging scenario of conflict resolution problem. This scenario concerns the situation where the collected information pieces from the different sources arrive in a streaming fashion, i.e. the sources' provided information pieces are continuously collected by the fusion system in sequential chunks over a long period of time. In the light of this challenge, we propose an I-ECRM. This incremental method is able to resolve any probable conflict among the information sources and it can update the estimated evidential source reliability mass functions simultaneously in the case where the collected information is arriving in a streaming way.

The proposed method is based on the belief functions theory [6, 7]. This mathematical theory has been recently recognized to be one of the most effective tools to encode and manage information imperfection that is abundant in IoT applications [8]. This is due to its remarkable ability to represent and manipulate various types of imperfection (incomplete, imprecise, uncertain, or a combination of them). In particular, the belief function theory has an appealing tool that is able to combine multiple imperfect information pieces, and thus aiming at reducing uncertainty and obtaining more coherent, integrated information.

The rest of this paper is organized as follows. First, we briefly introduce the basic notions of the belief functions theory. After that, we motivate in Section 3 the need for a new incremental method for the evidential conflict resolution problem in the context of data streams. We then formalize the problem in Section 4. In Section 5, we introduce our I-ECRM. Next, we provide in Section 6 preliminary simulation results about the effectiveness and efficiency of the proposed incremental method via experimental evaluation over synthetic datasets. Finally, we conclude the paper Section 7.

## II. BELIEF FUNCTIONS THEORY

The belief functions theory, also known as Dempster Shafer theory or evidence theory, is considered as one of the most widespread mathematical frameworks for data fusion. It was

first introduced by Dempster in the 1960s [6] and later developed and improved by Shafer in the 1970s [7]. Some more recent advances in this theory were introduced later in the Transferable Belief Model (TBM) proposed by Smets [9]. The belief functions theory is also considered as a generalization of probability theory [10]. It provides an attractive, powerful and efficient mathematical framework to encode and aggregate a wide spectrum of imperfect information.

### A. Basic notations

In the framework of belief functions, a problem domain is represented by a finite non empty set  $\Theta = \{H_1, H_2, \dots, H_N\}$  of  $N$  mutually exclusive and exhaustive hypotheses (events) representing the possible solutions of the considered task that we attend to determine its real value  $H$ .  $2^\Theta$  represents the power set composed of all the possible subsets of  $\Theta$ . The basic belief assignment (*bba*), also known as mass function, is a function  $m$  mapping from  $2^\Theta$  to  $[0, 1]$  and verifies the following conditions:

$$\begin{cases} m(\emptyset) = 0 \\ m(A) \geq 0 \\ \sum_{A \in 2^\Theta} m(A) = 1 \end{cases}, \forall A \in 2^\Theta \quad (1)$$

$m(A)$  is the support degree that is assigned exactly to a proposition  $A$  and to no smaller subset. The mass functions  $m$  assigned to all the subsets of  $\Theta$  are summed to unity and there is no belief left to the empty set. A mass function assigned exactly to  $\Theta$  is referred to as the degree of global ignorance, denoted by  $m(\Theta)$ , and a mass function assigned exactly to a smaller subset of  $\Theta$  except for any singleton proposition or  $\Theta$  is referred to as the degree of local ignorance. If there is no local or global ignorance, a mass function will reduce to a classical probability function.

Besides the mass function, there are two other important functions to encode pieces of evidence: the belief function  $Bel$  and the plausibility function  $Pl$  [7]. These functions represent differently the same piece of information as the mass function. They are especially used to facilitate the manipulation and reasoning within the framework of belief functions. They are formally defined as follows:

$$\begin{cases} Bel : 2^\Theta \rightarrow [0, 1] \\ A \mapsto \sum_{\substack{B \in 2^\Theta \\ B \subseteq A}} m(B) \end{cases} \quad (2)$$

$$\begin{cases} Pl : 2^\Theta \rightarrow [0, 1] \\ A \mapsto \sum_{\substack{B \in 2^\Theta \\ A \cap B \neq \emptyset}} m(B) \end{cases} \quad (3)$$

$Bel(A)$  represents all masses assigned exactly to  $A$  and its smaller subsets, and  $Pl(A)$  represents all possible masses that could be assigned to  $A$  and its smaller subsets. Note that  $Bel(A)$  and  $Pl(A)$  can be interpreted as the lower and upper bounds of the real probability  $P(A)$ .

### B. Discounting operation

In several real-world situations, the information sources are not considered equally fully reliable. In this case, it is reasonable to discount each unreliable source  $s$  by a reliability factor  $\alpha \in [0, 1]$ . Following the classical discounting method [7], a new discounted mass function  $m^\alpha$  is obtained from the initial mass function  $m$  provided by the partially reliable source  $s$  as follows:

$$\begin{cases} m^\alpha(A) = \alpha \times m(A) \\ m^\alpha(\Theta) = (1 - \alpha) + \alpha \times m(\Theta) \end{cases} \quad \text{for } A \neq \Theta \quad (4)$$

The discounting operation is mostly applied to model a situation where a source  $s$  delivers a mass function  $m$ , and the reliability of  $s$  is quantified by  $\alpha$ . If the information source  $s$  is totally reliable (i.e.  $\alpha = 1$ ), then  $m$  is left unchanged and it is considered as an acceptable piece of evidence. On the other hand, if the source  $s$  is completely unreliable, the mass function  $m$  is converted into the vacuous mass function (i.e.  $m^\alpha(\Theta) = 1$ ), and thus this piece of evidence cannot be taken into consideration. In practice, the discounting operation can be used efficiently if one has an accurate estimation of the reliability value of the considered information source.

### C. Combination of mass functions

The kernel of belief functions theory is Dempster's rule of combination that was originally adopted as the sole . this rule is the normalized conjunctive operation which aims to aggregate various mass functions from multiple independent information sources defined within the same frame of discernment. Given two mass functions  $m_1$  and  $m_2$  derived from two independent information sources  $s_1$  and  $s_2$ , the combined mass function by Dempster's rule, denoted by  $m_{1 \oplus 2}(A) = m_1(A) \oplus m_2(A)$ , is defined by the following equation:

$$m_{1 \oplus 2}(A) = \begin{cases} \frac{\sum_{\substack{B, C \in 2^\Theta \\ B \cap C = A}} m_1(B) * m_2(C)}{1 - \sum_{\substack{B, C \in 2^\Theta \\ B \cap C = \emptyset}} m_1(B) * m_2(C)} & A \in 2^\Theta, A \neq \emptyset \\ 0 & A = \emptyset \end{cases} \quad (5)$$

where the denominator represents the conflict coefficient, reflecting the degree of conflict between the two mass functions  $m_1$  and  $m_2$ .

It is worth noting that this rule is widely used by the belief functions' community. This is due to its interesting mathematical properties. Indeed, Dempster's rule of combination is inherently commutative and associative, meaning that it can be used to aggregate several pieces of information in any order without changing the final results. This fact makes Dempster's rule very attractive from an engineering implementation perspective. In addition to these two properties, Dempster's rule is Non-idempotent i.e. the combination of two similar independent mass functions gives generally another more precise combined mass function. This is due to the fact that aggregating these two independent mass function may increase the total amount of information. Moreover, the vacuous mass

function, that support the total ignorance, can be easily proved to be the neutral element for Dempster's rule for any mass function  $m$  defined over a frame of discernment  $\Theta$ . This property is reasonable since the total ignorant evidence should not affect the fusion outcome since it doesn't provide any useful information that can be valuable to make a difference between the components of the power set  $2^\Theta$ .

### D. Decision making

In addition to the combination operation, one of the main goal of using the belief functions theory is to make preeminent decisions by selecting the hypothesis that best fits the solution of the fusion problem under consideration. Therefore, the ultimate step in this framework is to make a decision about the studied task based on the reasoning results.

In order to make a reasonable decision, it is usually preferable to use a well-defined probability function. Probabilistic transformation is a great tool to map mass functions to probabilities. A classical transformation is the pignistic transformation [9], defined formally as follows:

$$BetP(A) = \sum_{B \subseteq \Theta, A \cap B \neq \emptyset} \frac{|A \cap B|}{|B|} m(B) \quad (6)$$

where  $|B|$  is the number of elements in subset  $B$ .  $BetP$  transfers uniformly the positive mass of each nonspecific element onto the singletons involved in that element according to the cardinal number of the proposition. Once the pignistic probability  $BetP$  is computed, the decision can be made based on selecting the hypothesis  $\hat{H}_j$  with the largest pignistic probability.

## III. DATA STREAM FUSION IN IOT

A streaming datasets can be considered as a set of potentially unlimited, ordered sequence of information pieces that are continuously coming at a fast speed, in such a way that it is impossible to permanently store and keep the entire information in memory or an external data repository [11]. In general, data streams have the following important properties:

- Data streams are sequences of information pieces, ordered by arrival time or another ordered property which can be, for instance, the generation time. This fact makes information pieces in data streams arrive for processing over time instead of being available a priori.
- Since data streams are produced continually and have unlimited or at least unknown length. Thus, their volume is considered as extremely huge.
- The arriving rate of data streams is very high with respect to the processing power of the fusion system.
- The qualitative behavior of the sources providing streaming datasets are susceptibility to change, and hence the quality of the provided information pieces may change over time.

Due to the above properties, processing methods that deal with streaming dataset should differ from the batch methods that need to process the whole complete dataset at once.

Table I  
DIFFERENCES BETWEEN BATCH AND STREAM DATA PROCESSING  
METHODS [12].

	Batch	Stream
Number of passes	Multiple	Single
Processing time	Unlimited	Restricted
Memory usage	Unlimited	Restricted
Type of result	Accurate	Approximate
Distributed	No	Yes

The main dissimilarities include the sequential nature of the arriving information pieces, immense volumes, processing speed constraints, and the fact that the information pieces in the streaming dataset can generally be accessed only one time compared with the batch methods, where multiple access to the complete static dataset is possible. A summary of the differences between batch and stream data processing is presented in Table I.

In [13], the Unsupervised Evidential Conflict Resolution Method (U-ECRM) was developed to resolve the evidential conflict among the diverse sources by simultaneously estimating the evidential source reliability mass functions and determining the correct value of each considered objects. Unfortunately, this method cannot be directly applied to data streams due to the fact that this iterative method was specially designed to deal with static datasets. This fact makes the unsupervised evidential conflict resolution method do multiple passes through the entire dataset in order to resolve the conflict. Thus, this batch evidential method is impractical in the case where the dataset is in the form of a continuous flow of data streams. More importantly, the behavior of the information source can change over time. Thus, this evolving behavior needs to be captured and the evidential source reliability values have to be adjusted according to these changes. Furthermore, the method needs to take into account the problem of resource allocation when dealing with unbounded streaming datasets, which is mainly due to the massive volume and rapid speed of data streams. Accordingly, how to achieve greatest results under different resource constraints becomes a challenging task. The principal goal of this task is to decrease the resource allocation as compared to the batch iterative method and maximize the effectiveness of the method's outputs.

As a consequence, the applications that need to process data streams require a novel method that can do intelligent data processing and real-time analysis of the massive quantity of the generated streaming datasets in reasonable processing time and restricted memory space.

#### IV. PROBLEM FORMULATION

Suppose we have a set of  $N$  sources  $S = \{s_1, s_2, s_3, \dots, s_N\}$  where the reliability level of each information source  $s_i$  is encoded as an evidential source reliability mass function  $m_i^\Theta$  defined over the frame of discernment  $\Theta = \{T, D, R\}$ . Here  $T$  means that the source

is trustworthy,  $D$  means that the source is defective and  $R$  means that the source is Random.

Each information source  $s_i$  provides information pieces in the form of mass functions  $m_{i,j}^{\Omega, T=t}$ . These pieces of information are continuously delivered in a streaming way i.e. the information pieces arrive in a sequential sets of information  $D = \{D^{T=0}, D^{T=1}, \dots, D^{T=t}, \dots\}$ , where each set  $D^{T=t}$  contains a number of the sources' delivered information pieces  $D^{T=t} = \{m_{i \in \{1,2,\dots,N\}, j \in \{1,2,\dots,M^t\}}^{\Omega, T=t}\}$  about the actual values of a specific set of objects  $O^{T=t} = \{o_1^t, o_2^t, o_3^t, \dots, o_{M^t}^t\}$  where each variable  $o_j^t \in O^t$  can takes its unique true value  $\hat{H}_j^t$  from the exhaustive and mutually exclusive frame of discernment  $\Omega_j^t = \{H_{1,j}^t, H_{2,j}^t, H_{3,j}^t, \dots, H_{K,j}^t\}$ . It is worth noting that different sets of objects in different time  $t$  can contain different objects. In other words, the two objects  $o_1^{t-1}$  and  $o_1^t$  may not represent the same object. This meaning can be the same as if we consider the same object  $o_1$  but its correct value change over time. For instance, if we suppose that the object  $o_1$  represents the weather prediction of a specific city, the actual value of this object is different and independent from one day to another.

Due to several reasons, the information pieces that are provided by different sources about the same object can be conflicting. As a consequence, the main objective in this paper is to find a robust solution to this problem. This can be done by designing a method that is able to resolve the probable conflict between the information sources by determining the correct value of each object  $o_j^t$  in a specific time  $t$ . Moreover, this method should resolve the conflict and determine the correct value of each object with a single scan of the streaming dataset, short processing time, and use a limited memory space. Furthermore, the method should capture any changes in the behavior of the information sources, and thus adjusting the evidential source reliability mass function of each source according to its new state.

To achieve this objective, we adjust, in this paper, our proposed U-ECRM [13] so that the evidential source reliability mass functions and the correct values determination can be learned incrementally. This incremental method can also be used in the case of datasets with a gigantic volume that can only permit one single sequential pass through the whole datasets.

In fact, incremental methods have been used by several researcher to deal with computational problems that need to process streaming datasets [11, 14]. This kind of methods aims at analyzing and processing the newly arriving information pieces sequentially in such a way that the obtained results are as accurate, or approximately as accurate, as a traditional batch method that uses the entire dataset at once. A well-developed incremental method that is able to deal with data streaming scenarios should have the following important practical merits [15]

- **Use an incremental data access:** The method should process chunks of information pieces at a time, rather

than require the entire set of information pieces at the beginning of the processing.

- **Consider a single pass nature:** The method needs to handle and to process the newly arrived information pieces at once in the arriving order. This is due to the fact that the incoming information pieces cannot be kept permanently in memory, and thus the method should make only one pass through the available dataset.
- **Proceed in real time fashion:** the method should treat each information piece that belongs to the streaming datasets in real time fashion i.e. the newly arrived information pieces should be processed in an approximately short time once they are arrived. This processing time should be shorter than or at least equal to the data stream incoming rate, otherwise some important information pieces may be lost without treating and analyzing them.
- **Use bounded storage space:** since the streaming datasets is considered as an unlimited set of information pieces that are continuously arriving, it is impossible to store the entire streaming datasets in memory. As a consequence, the incremental method that deals with data streams should exploit a limited memory space to store a summary of the predicted model as well as the recently arrived information pieces.
- **Be ready to predict at any time:** the method should produce the best possible result at any point of time regardless the number of the past information pieces that are used to predict the model's parameters. Particularly, the results obtained from the incremental method should be as accurate as possible compared with the results achieved by the traditional batch methods that use the entire dataset up to a specific time  $t$ .

An incremental method with the above-stated capabilities can effectively process and deal with large streaming dataset without the need of re-executing the method from scratch after the arrival of a new set of information pieces. Such incremental methods can be built by scaling up traditional batch methods. This can be achieved by modifying the batch methods and tailored them to fit the data stream setting. In the next section, we introduce our proposed I-ECRM that is designed specifically to handle data streams or a static dataset with a massive volume.

## V. THE PROPOSED INCREMENTAL EVIDENTIAL METHOD

The key idea behind the proposed I-ECRM is to determine the correct value  $\hat{H}_j^t$  of each considered object  $o_j^t$  in the time-stamp  $t$  based on the evidential source reliability mass functions  $m_i^{\Theta, t-1}$  that are learned from the past interactions of the sources. Once done, the evidential source reliability mass functions  $m_i^{\Theta, t}$  at time  $t$  should be updated according to the newly determined correct values without the need to re-execute the method on the complete dataset from scratch every time a new chunk of the streaming dataset is collected by the fusion system. Applying this idea in the U-ECRM [13], we modify the evidential source reliability mass functions update

and the correct value mass functions determination steps to conduct I-ECRM.

Figure 1 presents the main concepts and the key idea in the architecture of the proposed I-ECRM. Specifically, a set of information sources continuously generate and provide chunks of streaming datasets to the fusion system. For each new arrived chunk of the streaming datasets at the time-stamp  $T = t$ , the incremental method first uses the evidential source reliability mass functions  $m_{i \in \{1, 2, \dots, N\}}^{\Theta, T=t-1}$  learned from the previously processed chunks of information to correct the sources' provided information pieces. After that, the incremental method combines the sources' corrected information pieces by using Dempster's combination rule in order to obtain the correct value mass function  $m_j^{\Omega, T=t}$  of each object  $o_j^t$ . Once done, the evidential source reliability mass functions  $m_{i \in \{1, 2, \dots, N\}}^{\Theta, T=t}$  can be updated based on the difference between the computed correct value mass functions  $m_{j \in \{1, 2, \dots, M^t\}}^{\Omega, T=t}$  and the sources' provided information pieces  $m_{i \in \{1, 2, \dots, N\}, j \in \{1, 2, \dots, M^t\}}^{\Theta, T=t}$ .

The detailed description of the I-ECRM is summarized in Algorithm 1. This algorithm starts with an initialization step where it first uses Murphy aggregation method [16] to combine and fuse the information pieces of the first chunk  $D^{T=0}$  of the streaming dataset. This can be done by computing the pignistic probability  $BetP_j^{T=0}$  for each object  $o_j^{T=0}$  and then selecting the hypothesis  $\hat{H}_j^{T=0}$  that has the maximum pignistic probability.

$$\hat{H}_j^{T=0} = \arg \max_{H_{l,j}^{T=0} \in \Omega_j^{T=0}} (BetP_j^{T=0}(H_{l,j}^{T=0})) \quad (7)$$

Next, the initial evidential source reliability mass function  $m_i^{\Theta, T=0}$  of each source can be estimated. To do so, the algorithm begins by evaluating the correctness degree of each of the mass functions that is provided by this source with regard to available information about the correct values. This evaluation step produces a set of evidence correctness mass functions  $m_{i,j}^{\Psi, T=0}$ , which encode how correct and relevant the source's information pieces are. The evidence correctness mass function  $m_{i,j}^{\Psi, T=0}$  is defined over the frame of discernment  $\Psi_{i,j} = \{C, \bar{C}\}$  where  $C$  encodes the hypothesis that the provided information  $m_{i,j}^{\Omega, T=0}$  is correct, whereas  $\bar{C}$  represents the hypothesis that the provided information  $m_{i,j}^{\Omega}$  is incorrect. In order to compute  $m_{i,j}^{\Psi, T=0}$ , we use equation 8.

$$\begin{cases} m_{i,j}^{\Psi, T=0}(C) = \sum_{B \in 2^{\Omega, T=0}} m_j^{\Omega, T=0}(B) \left( \sum_{B \cap A = B} f(|A|) m_{i,j}^{\Omega, T=0}(A) \right) \\ m_{i,j}^{\Psi, T=0}(\bar{C}) = \sum_{B \in 2^{\Omega, T=0}} m_j^{\Omega, T=0}(B) \left( \sum_{B \cap A = \emptyset} m_{i,j}^{\Omega, T=0}(A) \right) \\ m_{i,j}^{\Psi, T=0}(C, \bar{C}) = 1 - (m_{i,j}^{\Psi, T=0}(C) + m_{i,j}^{\Psi, T=0}(\bar{C})) \end{cases} \quad (8)$$

where  $f$  is a function which distributes the imprecision of the source  $s_i$  between the support degree that the given evidence is correct  $m_{i,j}^{\Psi, T=0}(C)$  and the support degree that

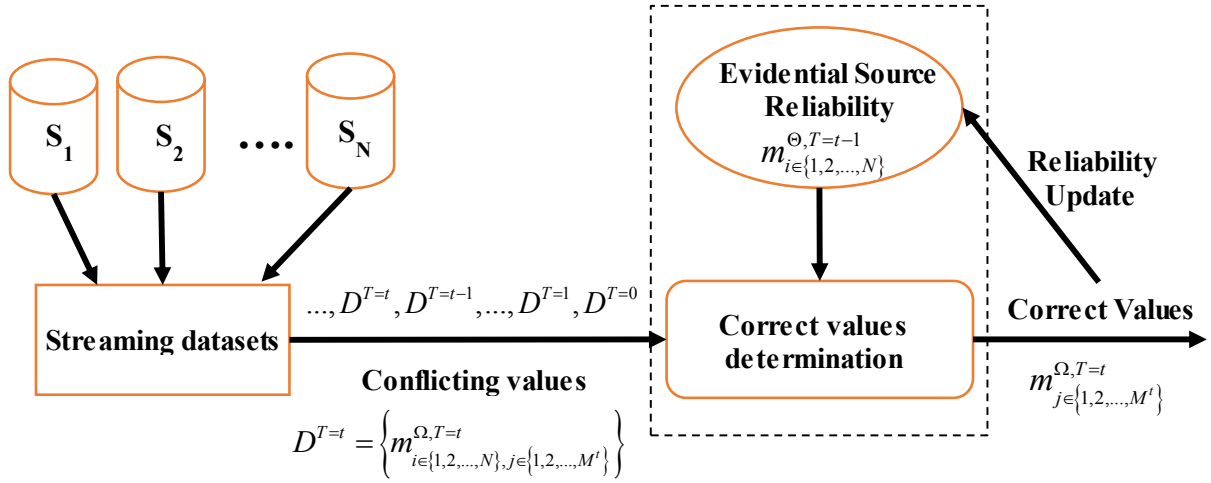

Figure 1. Conceptual view of the incremental evidential conflict resolution method for streaming datasets.

the provided information is irrelevant  $m_{i,j}^{\Psi, T=0}(C, \bar{C})$ . This function can be defined as follows:

$$f(|A|) = \frac{|\Omega_j| - |A|}{|\Omega_j| - 1} \quad (9)$$

Function  $f$  is, in reality, based on the uniform distribution of the correct identification of wrong hypotheses. In fact, one can reason about the wrong hypothesis that was correctly mentioned. Indeed, if source  $s_i$  supports proposition  $A$  i.e. the actual value  $\hat{H}_{i,j}$  belongs to subset  $A$ , this can also mean that source  $s_i$  claims that the complement set of  $A$  does not contain the correct value. In other words, the piece of evidence provided by source  $s_i$  was (in somehow) correct concerning the identification of some wrong hypotheses. Therefore, one can give a proportion of  $m_{i,j}^{\Omega, T=0}(A)$  to the mass function supporting the correctness of the provided information i.e.  $m_{i,j}^{\Psi, T=0}(C)$ . Whereas the rest of the proportion should be allocated to proposition  $\{C, \bar{C}\}$ , where the meaning is that the provided piece of evidence is irrelevant and does not contain any useful information.

After obtaining the evidence correctness mass functions of all objects, the total true positive  $TP_i^{T=0}$  and the total false negative  $FN_i^{T=0}$  of the source  $s_i$  are calculated by means of equation 10 and equation 11 respectively.

$$TP_i^{T=0} = \sum_{j=1}^M m_{i,j}^{\Psi, T=0}(C) \quad (10)$$

$$FN_i^{T=0} = \sum_{j=1}^M m_{i,j}^{\Psi, T=0}(\bar{C}) \quad (11)$$

After that, the algorithm uses the  $TP_i^{T=0}$  and  $FN_i^{T=0}$  along with an application-specific user-specified cautious parameter  $C_{cautious}$  to estimate the reliability of the source by using

equation 12 or equation 13 depending on the difference between  $TP_i^{T=0}$  and  $FN_i^{T=0}$ .

- **Case 1:**  $TP_i^{T=0} \geq FN_i^{T=0}$ :

$$\begin{cases} m_i^{\Theta, T=0}(T) &= \frac{TP_i^{T=0} - FN_i^{T=0}}{TP_i^{T=0} + FN_i^{T=0} + C_{cautious}} \\ m_i^{\Theta, T=0}(D) &= 0 \\ m_i^{\Theta, T=0}(R) &= \frac{2FN_i^{T=0}}{TP_i^{T=0} + FN_i^{T=0} + C_{cautious}} \\ m_i^{\Theta, T=0}(T, D, R) &= \frac{C_{cautious}}{TP_i^{T=0} + FN_i^{T=0} + C_{cautious}} \end{cases} \quad (12)$$

- **Case 2:**  $TP_i^{T=0} \leq FN_i^{T=0}$ :

$$\begin{cases} m_i^{\Theta, T=0}(T) &= 0 \\ m_i^{\Theta, T=0}(D) &= \frac{FN_i^{T=0} - TP_i^{T=0}}{TP_i^{T=0} + FN_i^{T=0} + C_{cautious}} \\ m_i^{\Theta, T=0}(R) &= \frac{2TP_i^{T=0}}{TP_i^{T=0} + FN_i^{T=0} + C_{cautious}} \\ m_i^{\Theta, T=0}(T, D, R) &= \frac{C_{cautious}}{TP_i^{T=0} + FN_i^{T=0} + C_{cautious}} \end{cases} \quad (13)$$

At this point, the incremental method is ready to incrementally process the newly arriving streaming chunks. For each newly arrived chunk  $D^{T=t}$  of the streaming dataset at time  $t$ , the algorithm uses the previously learned evidential source reliability mass functions  $m_{i \in \{1,2,\dots,N\}}^{\Theta, T=t-1}$  to compute the correct values mass function  $m_j^{\Omega, T=t}$  for each object  $o_j$  of the chunk  $D^{T=t}$ . For each object  $o_j^{T=t}$ , the algorithm starts by correcting the provided mass functions  $m_{i \in \{1,2,\dots,N\}, j}^{\Omega, T=t}$  according to their appropriate sources' evidential source reliability mass functions  $m_{i \in \{1,2,\dots,N\}}^{\Theta, T=t-1}$  by means of the evidential correction mechanism. This mechanism can be formally defined in equation 14.

Once correcting all the provided information pieces about the actual value of the considered object  $o_j$ , these corrected mass functions  $m_{i \in \{1,2,\dots,N\}, j}^{\Omega, T=t}$  can be aggregated by Dempster's combination rule so as to produce the combined correct

$$\begin{cases} m_{i,j}^{\Omega*,T=t}(A) = m_i^{\Theta,T=t-1}(T)m_{i,j}^{\Omega,T=t}(A) + m_i^{\Theta,T=t-1}(D)m_{i,j}^{\Omega,T=t}(\bar{A}) \\ m_{i,j}^{\Omega*,T=t}(\Omega) = m_{i,j}^{\Omega,T=t}(\Omega) + \left[ m_i^{\Theta,T=t-1}(R) + m_i^{\Theta,T=t-1}(T, D, R) \right] \sum_{A \in 2^{\Omega}/\Omega} m_{i,j}^{\Omega,T=t}(A) \end{cases} \quad \forall A \in 2^{\Omega,T=t}/\Omega \quad (14)$$

value mass function  $m_{i,j}^{\Omega*,T=t}$ . Immediately after that, the algorithm selects the correct values  $\hat{H}_{j \in \{1,2,\dots,M^t\}}^{T=t}$  by choosing the hypothesis  $\hat{H}_j^{T=t}$  that has the maximum pignistic probability.

$$\hat{H}_j^{T=t} = \arg \max_{H_{l,j}^{T=t} \in \Omega_j^{T=t}} (\text{Bet} P_j^{T=t}(H_{l,j}^{T=t})) \quad (15)$$

After that, the values of the evidential source reliability mass functions can be updated according to the estimated correct values  $\hat{H}_{j \in \{1,2,\dots,M^t\}}^{T=t}$  of the current chunk  $D^{T=t}$ . To do so, the algorithm begins by computing the true positive value  $TP_i^{\Delta t}$  and the false negative value  $FN_i^{\Delta t}$  of each source over the current streaming chunk  $D^{T=t}$ . These two important values can be obtained by means of equation 16 and equation 17 respectively.

$$TP_i^{\Delta t} = \sum_{j=1}^M m_{i,j}^{\Psi,\Delta t}(C) \quad (16)$$

$$FN_i^{\Delta t} = \sum_{j=1}^M m_{i,j}^{\Psi,\Delta t}(\bar{C}) \quad (17)$$

where  $m_{i,j}^{\Psi,\Delta t}$  is the evidence correctness mass function of each provided information piece  $m_{i,j}^{\Omega,T=t}$  with regard to the obtained correct value  $\hat{H}_j^{T=t}$ .

In order to control the effect of possible changing behaviors of the information sources, the I-ECRM uses a decay parameter  $\lambda \in [0, 1]$  that determines the impact of historical interaction on the current evidential source reliability mass function  $m_i^{\Theta,T=t}$ . Intuitively, the recent interactions of the sources  $m_{i \in \{1,2,\dots,N\}, j \in \{1,2,\dots,M^t\}}^{\Omega,T=t}$  should play a more important role in the estimation of  $m_i^{\Theta,T=t}$  than the historical interaction when  $T < t$ . In other words, the key idea of the use of the decay parameter is to scale the past information about the behaviors of the sources by a constant factor  $\lambda$ , i.e. each time a new chunk of the streaming dataset is arrived, the past learned total true positive values  $TP_{i \in \{1,2,\dots,N\}}^{T=t-1}$  and the total false negative values  $FN_{i \in \{1,2,\dots,N\}}^{T=t-1}$  are scaled down by the factor  $\lambda$ . Qualitatively, this means that the smaller the decay parameter  $\lambda$  is, the less impact from historical interactions in the estimation of the current evidential reliability values and hence it will make the model respond quickly to any behavioral changes. As a result, the newly computed  $TP_{i \in \{1,2,\dots,N\}}^{T=t}$  and  $FN_{i \in \{1,2,\dots,N\}}^{T=t}$  can be obtained as follows:

$$\begin{cases} TP_{i \in \{1,2,\dots,N\}}^{T=t} = \lambda \cdot TP_{i \in \{1,2,\dots,N\}}^{T=t-1} + TP_{i \in \{1,2,\dots,N\}}^{\Delta t} \\ FN_{i \in \{1,2,\dots,N\}}^{T=t} = \lambda \cdot FN_{i \in \{1,2,\dots,N\}}^{T=t-1} + FN_{i \in \{1,2,\dots,N\}}^{\Delta t} \end{cases} \quad (18)$$

Once the  $TP_i^{T=t}$  and  $FN_i^{T=t}$  are computed, the method can estimate the  $m_i^{\Theta,T=t}$  by means of equation 19 or

equation 20 depending on the difference between the values of  $TP_i^{T=t}$  and  $FN_i^{T=t}$ . These newly estimated evidential source reliability mass function  $m_{i \in \{1,2,\dots,N\}}^{\Theta,T=t}$  can be further used to resolve the conflict of the newly arriving chunk  $D^{T=t+1}$  at time  $T = t + 1$ .

- **Case 1:**  $TP_i^{T=t} \geq FN_i^{T=t}$ :

$$\begin{cases} m_i^{\Theta,T=t}(T) &= \frac{TP_i^{T=t} - FN_i^{T=t}}{TP_i^{T=t} + FN_i^{T=t} + C_{cautious}} \\ m_i^{\Theta,T=t}(D) &= 0 \\ m_i^{\Theta,T=t}(R) &= \frac{2FN_i^{T=t}}{TP_i^{T=t} + FN_i^{T=t} + C_{cautious}} \\ m_i^{\Theta,T=t}(T, D, R) &= \frac{C_{cautious}}{TP_i^{T=t} + FN_i^{T=t} + C_{cautious}} \end{cases} \quad (19)$$

- **Case 2:**  $TP_i^{T=t} \leq FN_i^{T=t}$ :

$$\begin{cases} m_i^{\Theta,T=t}(T) &= 0 \\ m_i^{\Theta,T=t}(D) &= \frac{FN_i^{T=t} - TP_i^{T=t}}{TP_i^{T=t} + FN_i^{T=t} + C_{cautious}} \\ m_i^{\Theta,T=t}(R) &= \frac{2TP_i^{T=t}}{TP_i^{T=t} + FN_i^{T=t} + C_{cautious}} \\ m_i^{\Theta,T=t}(T, D, R) &= \frac{C_{cautious}}{TP_i^{T=t} + FN_i^{T=t} + C_{cautious}} \end{cases} \quad (20)$$

We now show how the I-ECRM can effectively address the computational requirements of processing and dealing with data streams introduced in Section 6.2. First, the I-ECRM makes a single scan (one-pass) through the streaming datasets since it is obvious that the proposed incremental method process the provided information pieces only once. Second, the I-ECRM uses a limited memory space to process the whole data streams because it only exploits a size of memory space equivalent to the size of the evidential source reliability mass functions as well as only one chunk of the provided information pieces at any time  $t$  in the stream. Third, the I-ECRM processes the streaming datasets in short time since the algorithm computes and then reports the objects' correct values online, which is in effect much shorter than the computation time of the batch unsupervised evidential conflict resolution method. Finally, the proposed incremental method can capture and handle any changes in the behavior of the sources. This is ensured by the decay parameter which allows the fusion system to gradually forget about the sources' old interactions and mainly focus focus on the current interactions.

## VI. EXPERIMENTAL EVALUATION

In this section, we report and analyze the initial experimental results of the proposed I-ECRM on some instances of synthetic datasets. The obtained experimental results demonstrate that our proposed incremental evidential method can achieve a good efficiency-effectiveness trade-off. We first introduce the overall experiment settings in subsection VI-A, and then we present and discuss the experimental results in subsection VI-B.

---

**Algorithm 1:** Incremental Evidential Conflict Resolution Method I-ECRM
 

---

**Input :** Streaming dataset  $\{D^{T=0}, D^{T=1}, \dots, D^{T=t}, \dots\}$   
 where:  $D^{T=t} = \{m_{i \in \{1,2,\dots,N\}, j \in \{1,2,\dots,M^t\}}^{\Omega, T=t}\}$ .  
 A cautious parameter  $C_{cautious}$ .  
 A decay parameter  $\lambda$ .

**Output:** The set of all  $\hat{H}_{j \in \{1,2,\dots,M^t\}}^{T=t}$  representing the correct values of objects  $o_{j \in \{1,2,\dots,M^t\}}^{T=t}$ .

### A. Experimental setting

1) *Datasets:* In order to show the benefit of the I-ECRM over the unsupervised conflict resolution method, we use the synthetic dataset generator developed by Waguih et al. [17] to produce some instances of synthetic datasets. This dataset generator was developed in order to generate and simulate a wide range of real-world situations where the behaviors of the information sources can be controlled and configured in terms of a set of parameters such as coverage, reliability level, conflicting information, to name a few.

2) *Methods in comparison:* We evaluate the performance of the I-ECRM with regard to the batch unsupervised evidential conflict resolution method (U-ECRM) and the native voting method where the correct value is the one which is supported by the majority of the sources.

3) *Evaluation metric:* we use the following metrics to evaluate the performance of the proposed methods:

**Precision rate:** We use the precision rate to evaluate the effectiveness of the proposed methods. A highest precision rate implies a better and a more effective method.

**CPU time:** We use the CPU time to evaluate the time efficiency of the proposed evidential conflict resolution method. A shorter CPU time implies a faster and a more efficient method.

**Space usage:** We use the memory space occupation of the proposed methods to evaluate the space efficiency. A smaller memory space occupation implies a more space efficient method.

4) *Environment:* To ensure the implementation of our method, we have developed our incremental evidential conflict resolution Matlab R2010a. We have further conducted our experiments on PC 8GB RAM, Intel(R) core (TM) i2CPU 2.30GHz, and windows 10 installed.

### B. Experimental results

We begin by setting the scale parameters of our considered scenario as follows: we set the number of sources to 60, and the number of possible values for each object to 4. We also select the uniform distribution for the distribution of the distinct values per object. In addition, we configure the source coverage to follow the exponential distributions. Furthermore, we select 80-pessimistic distributions for the ground truth distribution. As for the number of objects, we change this parameter from 1,000 to 10,000 objects with increments of 1000 objects. The key idea behind varying this parameter is to evaluate the effect of changing the number of object in the effectiveness and the efficiency of the proposed conflict resolution methods.

Based on the above setting, we generate 20 synthetic datasets for each experiment of a specific number of sources. In order to reduce the randomness of the dataset generation process, the evaluation metrics of each considered conflict resolution method is computed as the average of these 20 generated datasets included in the dataset of the same number of objects.

To simulate the scenario of streaming dataset, we consider that every time  $t$  a chunk containing the information pieces

Figure 2. The evaluation of the precision of the considered method with regard to the number of objects.

about 50 objects are arriving to the fusion system. In this case, we should process each time 50 objects by the considered conflict resolution methods.

We first start by comparing the effectiveness of the I-ECRM with regard to the batch unsupervised evidential conflict resolution method and the trivial voting method. Then, we provide the time and space efficiency analysis of the considered methods.

*Effectiveness results:* Figure 2 plots the precision of the considered conflict resolution methods on the synthetic dataset. As can be seen in Figure 2, the precision of the considered methods quickly increase in the beginning when more objects are involved. However, these precision values become on average approximately constant after the number of objects is greater than 1000. Also, it can be observed that the unsupervised evidential conflict resolution method is the most effective method, followed by the I-ECRM. This latter method performs only slightly worse than the former one. In the opposite, the voting method is the less effective method. This is due to the fact that this trivial method does not consider the reliability of the source while determining the correct value of each object.

*Time efficiency results:* Figure 3 plots the CPU time of the considered conflict resolution methods on the considered synthetic dataset. The results obtained from Figure 3 show that the voting method is the most time efficient, followed by the I-ECRM. When processing 10,000 objects, the voting and incremental methods take around 0.7 seconds and 5.5 seconds respectively. The unsupervised evidential conflict resolution method is the less time efficient as it needs to make several iterations over the entire datasets. Its CPU time increases quickly as more objects are involved, which exceeds 1,000 seconds when processing 6000 objects. Accordingly, the unsupervised evidential conflict resolution method is not appropriate for processing and analyzing streaming datasets or datasets with massive volumes.

It is worth mentioning that when new chunks of information

Figure 3. The evaluation of the processing CPU time efficiency of the considered conflict resolution methods with regard to the number of objects.

pieces arrive over time, the voting and I-ECRM need only to process these new coming chunks. Therefore, Their CPU time relies only on the size of the chunk to be processed. On the other hand, the supervised evidential conflict resolution method needs to process the entire dataset each time a new chunk arrives. Thus, its CPU time depends on the size whole dataset.

*Space efficiency results:* Figure 4 plots the memory space used by the considered conflict resolution methods to process the synthetic dataset. As can be seen from Figure 4, the voting method has the lowest memory consumption, as it is a method that processes each time only one object and its corresponding provided information pieces. Thus the voting method is considered as the most space efficient. The second most space efficient method is the I-ECRM. This incremental method cache only the newly arrived chunk of information pieces each time. Moreover, it needs to cache additional information concerning the evidential source reliability mass functions (the model parameters). Finally, the worst space efficient method is the supervised evidential conflict resolution method which is the most space consuming. This is due to the fact that this method needs to cache the complete streaming dataset in memory (the old as well as the newly arrived streaming chunks).

## VII. CONCLUSION

In this paper, we addressed the challenging problem of resolving information conflict in the case where the sources' provided information pieces are continuously arriving at the fusion system in the form of streaming datasets. This problem is very important because recent years have witnessed a huge range of online IoT applications that need to process data streams. To deal with this problem, we proposed and developed an incremental evidential conflict resolution method that is able to resolve the evidential conflict among sources by jointly and incrementally estimating the evidential source

Figure 4. The evaluation of the processing memory space efficiency of the considered conflict resolution methods with regards to the number of the objects.

reliability mass function of each information source and discovering the correct value of each object among the set of all possible values. This incremental method works under the constraints of a single scan of the streaming data, real-time processing fashion, and a limited memory space usage. The proposed method was empirically evaluated by using synthetic datasets in order to verify its efficiency and effectiveness. The obtained results show that the proposed incremental evidential method has a nice efficiency-effectiveness trade-off.

**Abstract**—Triage on the battlefield is a very challenging task. Life of the wounded soldiers depends on the efficiency of this process and there is still lack of supporting solutions. This paper presents a new approach for using Internet of Military Things in combat triage. We propose an ontological approach to evaluate soldiers' health state and information framework which allows first responders and commanders to query the sensor network for needed information. Some simulation experiments were conducted, which results show that the proposed method can be applied in highly distributed and heterogeneous environment of the smart devices on the battlefield.

## I. INTRODUCTION

**T**RIAGE of casualties is important part of the modern military operations. It is a proven method of providing medical care in situations where available resources are not sufficient. It is also a process which gives commanders information about troops ability to accomplish the mission. In this paper we propose a method for supporting combat triage process using devices connected into Internet of Military Things. Its goal is to monitor and provide information about soldiers health status for commanders and medical support like field medics. An important feature of this method is that it is information-centric, so user can define information need and the role of the smart devices is to fulfil this need. All processing of the raw data is done in distributed environment of the sensors network. Using this method triage process can be conducted with different types of sensors which monitor different vital signs of soldiers, and user does not need to be an medical expert to analyse readings.

## II. COMBAT TRIAGE

In a healthcare *triage* is a process of categorizing criticality of patient's condition [1]. The person responsible for triage performs a brief, focused assessment and assigns the patient a triage acuity level, which is a proxy measure of how long an individual patient can safely wait for a medical screening examination and treatment [2]. Such process is conducted especially when the demand for medical care overwhelms the available resources. In such cases first responders perform triage of casualties to ensure that they receive treatment in ordered way, depending on their health status.

Civilian and combat triage has a lot in common. Both of them refer to crisis situations and use similar methods. For instance, in the USA, The National Association of Emergency Medical Technician's (NAEMT) adopts a military Tactical Combat Casualty Care (TCCC) course to train civilian Emergency Medical Services (EMS) [3]. However there are some factors which make differences between civilian and combat triage. According to TCCC [4], those are:

- Hostile fire,
- Darkness,
- Environmental extremes,
- Different wounding epidemiology,
- Limited equipment,
- Need for tactical maneuver,
- Long delays to hospital care,
- Different medic training and experience.

All those factors cause that the combat triage, in many cases, is more challenging than civilian one. Especially first responders, medics and patients themselves are under constant threat. It is also worth pointing out that during combat operations, the patient is only part of the mission, where in civilian setting patient is the mission. That is why the combat triage has, in fact, three goals [4]:

- 1) Treat the casualty.
- 2) Prevent further casualties.
- 3) Complete the mission.

NATO's AJP-4.10(A) standard [5] defines situation in which triage should be conducted as a Mass Casualty (MASCAL) situation in which an excessive disparity exists between the casualty load and the medical capacities locally available for its management. In such situation principle of treatment may, mainly at the onset of the medical response, change from one based on the individual needs of each patient to one based on the greatest good for the greatest number. That is why NATO standard defines following triage priorities:

- 1) *Immediate Treatment* (Group T1). To consist of those requiring emergency care and life-saving surgery. These procedures should not be time-consuming and should concern only those patients with high chances of survival.
- 2) *Delayed Treatment* (Group T2). To consist of those in

need of surgery, but whose general condition permits delay in surgical treatment without unduly endangering life.

- 3) *Minimal Treatment* (Group T3). To consist of those with relatively minor injuries who can effectively care for themselves or who can be helped by untrained personnel.
- 4) *Expectant Treatment* (Group T4). This group comprises of patients who have received serious and often multiple injuries, and whose treatment would be time-consuming and complicated, with a low chance of survival. If fully treated they make heavy demands on medical manpower and supplies. Until the MASCAL situation is under control, they will receive appropriate supportive treatment. The extent of treatment will depend on available supplies and manpower and may involve the use of large doses of narcotic analgesics. For these patients every effort should be devoted to their comfort, and the possibility of survival with even alarming injuries.

Triage and especially its combat version is a very challenging task, where proper diagnosis and classification of patients are crucial. All decisions must be taken within a very short time and with maximum certainty. Triage is also a continuous process, which means that even when all casualties are prioritized, they need to be monitored constantly, because they state may change. All these challenges cause that there is a great need for triage support.

#### A. Information framework

In the presented method a user, which might be commander or field medic or any other person involved in triage process, can define information need which should be fulfilled by the smart sensors. Depending on the situation on the battlefield, number of commanded soldiers, combat intensity and mission goals such need might be different. That is why we propose flexible approach in which responses of the system are not predefined, but rather network of devices works as a kind of information search engine, however restricted to the triage domain.

To describe an information need we use the infon theory proposed by Keith Devlin [6]. Infons are *items* of information. In its basic form it can be understood as a fact that some objects  $a_1, \dots, a_n$  are in some relation  $R$ . It is formally defined as follows:

$$\sigma = \ll R, a_1, \dots, a_n, i \gg \quad (1)$$

where  $R$  is an  $n$ -place relation and  $a_1, \dots, a_n$  are objects appropriate for  $R$ . Element  $i$  is called *infor polarity* and takes value 1 if objects  $a_1, \dots, a_n$  are in fact in relation  $R$  and 0 otherwise. Infor description can be extended by adding elements which describe spatial  $l$  and temporal  $t$  location:

$$\sigma = \ll R, a_1, \dots, a_n, l, t, i \gg \quad (2)$$

Having that it is possible to indicate that given objects are in relation  $R$  at location  $l$  and/or time  $t$ .

Infons are atomic items of information which are used to build more complex sentences called *situations* [7]. According

to the Devlin's theory, situations are natural source of information about the world. Only in particular situation one can state that given infon is factual. To denote that some infon  $\sigma$  is an item of information that is true of situation  $sit$  the following notion is used:

$$sit \models \sigma \quad (3)$$

It should be read as " $sit$  supports  $\sigma$ ". Situation  $sit$  in this case is not a part of the real world. We call it an abstract situation which is a mathematical construct. Of course there is an intuitive sense in which to every real situation corresponds an abstract one. Abstract situation in such context is a set of infons:

$$\{\sigma \mid sit \models \sigma\} \quad (4)$$

The construct of abstract situation gives a framework to describe situations in a formal manner on a desired level of complexity. For every real situation it possible to define more or less sophisticated description using infons. Situations may be "static", which means that they involve one spatial and temporal location (or a number of contemporary spatial locations) or they may be "dynamic" which means that they are spread over a time sequence of locations.

As long as abstract situation is just a mathematical construct, some restrictions should be imposed. The most important is the *coherence*. An abstract situation  $sit$  is said to be *coherent* if it satisfies the following three conditions:

- 1) for no  $R, a_1, \dots, a_n$  is the case that:

$$sit \models \ll R, a_1, \dots, a_n, 1 \gg$$

$$sit \models \ll R, a_1, \dots, a_n, 0 \gg;$$

- 2) if for some  $a, b$  it is the case that:

$$sit \models \ll same, a, b, 1 \gg$$

then  $a = b$ ;

- 3) for no  $a$  is it a case that:

$$sit \models \ll same, a, a, 0 \gg.$$

From this point we can say that the need for information can be formally described by an abstract situation using presented notation of infons. To make such description as flexible as possible it is important to introduce parameters into infons. Each infon can be parametrized using one of the basic types:

- *TIM* : the type of temporal location;
- *LOC* : the type of a spatial location;
- *IND* : the type of an individual;
- *REL* : the type of an relation;
- *POL* : the type of polarity (i. e. the 'truth values' 0 and 1).

Those types of parameters correspond to the cognitive abilities of the smart devices which allow them to individualize uniformities of the world at the basic level. For each object  $x$  there is at least one type such that  $x$  is of that type. For example, if  $t$  is temporal location, then  $t$  is of type *TIM*. Having that it is possible to construct more generic infons like:

$$\sigma = \ll atPosition, \dot{p}, l, 1 \gg \quad (5)$$

which 'says' that some individual  $\dot{p} : IND$  is at some position  $l$ . Naturally there is need for some mechanism, which assigns values for parameters. From mathematical point of view such role play *anchors*. Formally an anchor for set  $A$  of parameters is a function defined on  $A$  which assigns to each parameter  $T_n$  in  $A$  an object of type  $T$ . For previously presented infon we can write:

$$\sigma = \ll atPosition, f(\dot{p}), l, 1 \gg \quad (6)$$

where  $f(\dot{p})$  return an individual which, in fact, is at position  $l$ . In presented method the devices connected into IoT act like anchors, so their responsibility is to populate parametric infons with data relevant to the situation which they observe. In other words, they need to answer whether given abstract situation is actual or not. Abstract situation  $sit$  is considered actual if:

- $sit$  is coherent situation,
- whenever  $sit \models \ll R, a_1, \dots, a_n, 1 \gg$  then in the real world it is really the case that  $a_1, \dots, a_n$  stand in relation  $R$ ,
- whenever  $sit \models \ll R, a_1, \dots, a_n, 0 \gg$  then  $a_1, \dots, a_n$  really do not stand in the relation  $R$ .

By using presented framework it is possible to build different information needs. Some examples, in terms of triage, are shown below:

- 1) Is *Soldier1* in condition *immediate*?
  - *Information need*:  
 $sit' \models \ll immediate, Soldier1, \dot{x} \gg$
  - *Response*:  
 $sit \models \ll immediate, Soldier1, 1 \gg$
- 2) What is the state of *Soldier1*?
  - *Information need*:  
 $sit' \models \ll \dot{r}, Soldier1, 1 \gg$
  - *Response*:  
 $sit \models \ll delayed, Soldier1, 1 \gg$
- 3) Which soldiers are in state *minimal treatment*?
  - *Information need*:  
 $sit' \models \ll minimal, \dot{h}, 1 \gg$
  - *Response*:  
 $sit \models \ll minimal, Soldier1, 1 \gg$   
 $\wedge \ll minimal, Soldier2, 1 \gg$   
 $\wedge \ll minimal, Soldier5, 1 \gg$

Important in this approach is that, the user does not need to know what kind of sensors are used for soldiers health state monitoring. Devices are responsible for analysing the need, identifying which object/properties are important and answering the question. It means that devices must have some cognitive capabilities and understand (at least in terms of given domain) what they observe. We propose an ontology as a method for handling device's knowledge.

#### B. IoT triage ontology

In order to perform classification with the system we have designed a problem solving ontology which represents some of the domain concepts of sensor and medical domains. The

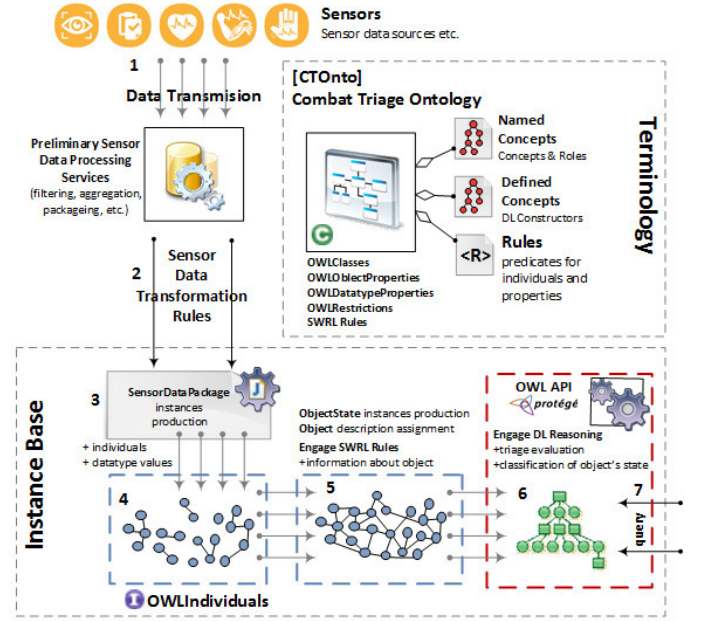

Fig. 1. Sensor Data processing path deliver seven stage combat triage evaluation proces classifying given battlespace object

utilization of ontology model forms terminology and model constraints on which a triage knowledge base is formulated. In presented system, the knowledge base utilizes Description Logic and First Order logic [8] reasoning techniques delivered by the Pellet reasoner [9]. Knowledge base supported by the reasoning mechanisms deliver model consistency check of instance base (data) ensuring valid relations between data instances, performing classification tasks for instance data and executing rules to infer new facts in the knowledge base. These tasks have been used as tools solving the problem of classifying health state of an individual based on the sensor data measuring stimuli. Implemented in otology concept definitions as well as rules perform data classification tasks evaluating sensor data introduced within the system. The evaluation process takes preliminary data package and confronts the data with "evaluation rules" which analyse specific characteristics of data (discrete or continuous in nature), in order to aggregate and produce information about the inspected (monitored) object. In order to perform the analysis rules contain evaluation or decision predicates. The predicates determine if calculated characteristic contains useful information in context of evaluated object and the environment, e.g. photoplethysmography sensor data containing photoplethysmogram can be processed to evaluate heart rate, which depending on the object's age, physiological stamina can determine, the stress level, exhaustion and health state. The ontology in that matter offers a set of rules which interpret sensor data (inertial, biomedical) in order to evaluate object's characteristics in context of current health state. The Combat Triage Ontology delivers means to produce more than one predicate based on one instance of SensorDataPackage, which can help to evaluate sensor

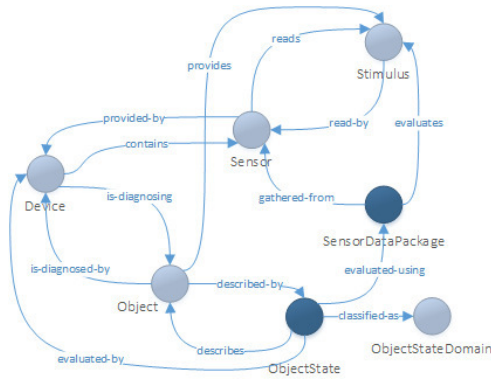

Fig. 2. Main concepts and relations in Combat Triage Ontology formulating basic terminology for diagnosing Object state based on the sensor data analysis

data in context of a health state but also other monitored object's characteristics. The next stage of processing is aimed at evaluating the ObjectState based on the series of associated SensorDataPackages. ObjectState concept holds several DL constructors, which assign to each and every ObjectState the ObjectStateDomain value. The ObjectStateDomain is a nominal concept (enumeration) which holds evaluation statuses for any monitored object. The evaluation status can be understood as an outcome of evaluation process produced by the reasoning mechanism. The classification mechanism in the knowledge base is iteratively performing sensor data analysis after which instances of ObjectState are evaluated and linked with adequate ObjectStateDomain value. The ObjectStateDomain concept provides detailed taxonomy leading towards HumanStateDomain, TriageHumanStateDomain and further specialized according to AJP-4.10.A standard (AJP-4.10A-TriageHumanStateDomain), S.M.A.R.T. (S.M.A.R.T-TriageHumanStateDomain). Depending on the Object type and aim of object's state evaluation the reasoner is able to evaluate particular ObjectState with status taken from the AJP-4.10A combat triage standard. Having such result the reasoner is able to evaluate instances of SensorDataPackages, engage a set of rules which produce information about given monitored Object, confront sensor information with the context in which the Object is found with respect to the environment (e.g. combat mission, medical treatment, etc.).

The knowledge base utilizes also built-in semantic mapping between enumerated values. This feature is useful for mapping purposes, in which well-defined concept or an instance has a corresponding entity - synonym or entity of very similar semantics. In case of Combat Triage Ontology semantic mapping has been used to map various triage standards and approaches between each other. Using owl axiom owl:sameAs (for individuals) and owl:equivalentTo (for concepts) we have been able to map AJP-4.10.A triage statuses with the S.M.A.R.T. methodology statuses and more found in crisis management methodologies.

To ensure efficiency of classification, a decision was made to restrain the concept list. This ensures model readability

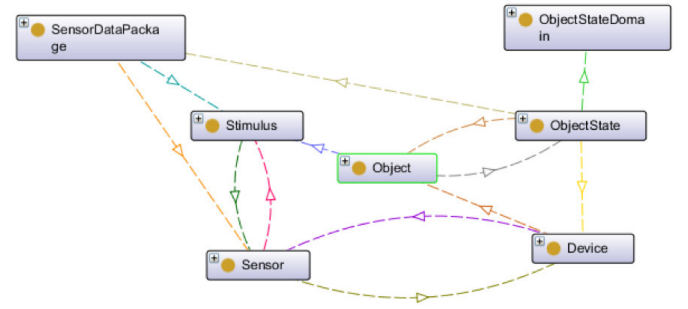

Fig. 3. Combat Triage Ontology core concepts and object properties formulating available associations between instance data

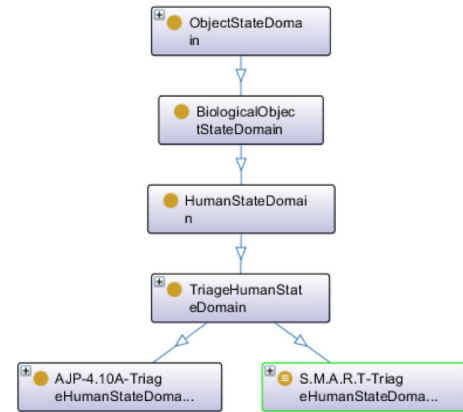

Fig. 4. Combat Triage Ontology core concepts and object properties formulating available associations between instance data

and supports future modularisation. The ontology has been developed using OWL 2.0 RL [10] merging OWL and SWRL language capabilities. Final form of the ontology has been developed using SHOIN(D) Description Logic dialect [11], which demonstrates complexity of ontology definitions, containing over 20 SWRL rules, 50 concepts, 20 object properties and over 20 datatype properties. One of the important characteristics of the ontology is that it contains over 29 defined concepts implementing both value and cardinality restrictions, moreover the model has been modularised consisting of three parts: base terminology, defined concepts terminology and instance base. Such construction supports further extensions of terminology but most of all separates meta model from data instances and prepares the knowledge base to be fed with data from the real sensor system or simulation software.

### III. SIMULATION EXPERIMENTS

#### A. SenseSim simulator

To verify presented approach we used *SenseSim* simulator [12]. It is capable of simulating smart sensors or devices both connected in WSN and IoT. It focuses less on technical aspects of wireless communications, so its communication model is idealistic and does not cover all low level issues [13]. That is

because SenseSim is designed to simulate sensors network as an autonomous, self organizing system, which is embedded in the environment, where many different phenomena may occur. It focuses on the interaction of smart devices with the external world by the process of perception. One of the key feature of the simulator is that it allows flexibly define sensors attached to the device. This is possible thanks to usage of formal model of perception [14]. It bases on a construct of observers. An *observer* is a six-tuple:

$$\langle (X, \chi), (Y, \nu), E, S, \pi, \eta \rangle \quad (7)$$

which satisfy the following conditions:

- 1)  $(X, \chi)$  and  $(Y, \nu)$  are measurable spaces;  $E \in \chi$  and  $S \in \nu$ .
- 2) Map  $\pi : X \rightarrow Y$  is a measurable surjective function with  $\pi(E) = S$ .
- 3) Let  $(E, \varepsilon)$  and  $(S, \varsigma)$  denote the measurable spaces on  $E$  and  $S$  respectively induced from those of  $X$  and  $Y$ . Then  $\eta$  is a statistic kernel on  $S \times \varepsilon$  such that, for each point  $s \in S$ ,  $\eta(s)$  is a probability measure supported in  $\pi^{-1}\{s\} \cap E$ .

When  $O$  observes it does not interact with the object of perception itself. Space  $X$  is a mathematical construct and is called *configuration space*. It represents all properties of relevance to  $O$ . Space  $Y$  is a formal representation of premises about events which occur in  $X$ . Based on those premises the observer can conclude what happen in the external world. Set  $E$  is called a *distinguished configuration* and represents events of interest of an observer. Set  $S$  is called *distinguished premises* and holds the premises about event  $E$ . Transformation between spaces  $X$  and  $Y$  is realized by function  $\pi$ , called *perspective*. Let us suppose that some point  $x \in X$  represents the property of relevance to  $O$ . Then  $O$ , in consequence of interaction with the outside world, does not see  $x$  but its representation  $y = \pi(x)$ , where  $y \in Y$ . If  $x$  is in  $E$  then  $y$  is in  $S$ . However all that  $O$  receives is  $y$ , not  $x$ . In other words, the observer must decide whether event  $E$  really occurred, basing on premises  $S$ . Function  $\pi$  is surjection, so  $O$  does not really know which point  $x \in E$  corresponds to given point  $y \in S$ . That is why with observer's definition comes conclusion kernel  $\eta$ . It provides, for each point in  $S$ , the probability distribution supported on  $E$ .  $\eta$  gives the final result of the observer - the probability that for given premises  $S$  event  $E$  occurred in the real world.

For instance consider an electronic thermometer (which can be one of the sensors used in a triage process). One of the most common are resistance thermometers, for example PT100 [15]. In this case the space  $X$  is a temperature of an object in the external (for the observer) „world”. The role of thermometer is to „guess” as accurately as possible what is its value. It is know, physical fact that resistance of some materials may change according to temperature and that is why resistance thermometers consist of some resistor, for instance platinum. So, what thermometer really knows is the current resistance, which is considered as an element of space  $Y$ .

Basing on this knowledge thermometer concludes what is the value of temperature in the external world. For example PT100 thermometer has a built in table which maps resistance into temperature. In fact it is an implementation of the conclusion kernel  $\eta$ .

Another example of observer can be infrared camera. In this case the space  $X$  is a three dimensional scene (in the infrared light spectrum). The space  $Y$ , on the other hand, is two dimensional space which represents the projection of the 3D scene onto digital image sensor. The  $\pi$  function describes how this projection is done. For instance it can be standard perspective projection which angle is determined by the focal length of the sensor's lens. At this point the observer has some premises (space  $Y$ ) about the external world (space  $X$ ). Let us assume that considered observer is designed to distinguish objects like human thermal image. In this case its *distinguished configuration*  $E$  is this part of the 3D scene with a human. Accordingly its *distinguished premise*  $S$  is 2D projection of the scene. All the observer knows about the external world is its premise so it uses the *conclusion kernel*  $\eta$  to decide if there is really a human. In this case  $\eta$  is more complicated than in previous example and should consists of a pattern recognition methods.

Implementation of the Theory of Perception in SenseSim simulator gives great flexibility in designing sensors which are used in experiments. It allows us to model wide variety of observers, both real and futuristic, which can provide perceptual capabilities for the simulated devices.

SenseSim has quite idealistic model of communication [12], however the network model allows to define heterogenous wireless networks, with fixed or ad-hoc topology as well as different communication interfaces. Network of devices ( $DN$ ) is modeled as an Bounded Independence Graph [16]:

$$DN(t) = \langle DEV, E^{DN}(t), \Upsilon^{DN}(t) \rangle \quad (8)$$

Where:

- $DEV$  - a set of devices,
- $\Upsilon^{DN}(t)$  - set of independent devices:  $\Upsilon^{DN}(t) = \{\{dev_u, dev_v\} : dev_u, dev_v \in DEV; dev_u \neq dev_v\}$
- $E^{DN}(t)$  - a set of edges at time  $t$ , which is defined as:

$$\begin{aligned} E^{DN}(t) = \{ \{dev_x, dev_y\} : dev_x, dev_y \in DEV; \\ dev_x \in N_{dev_y}^{DN}(t); dev_y \in N_{dev_x}^{DN}(t); \\ dev_x \neq dev_y; \\ \{dev_x, dev_y\} \notin \Upsilon^{DN}(t) \} \end{aligned} \quad (9)$$

Where  $N_{dev_x}^{DN}$  and  $N_{dev_y}^{DN}$  are sets of neighbors of device  $dev_x$  and  $dev_y$  respectively.

Neighbor for a device  $dev_x$  is other device which fulfills the following conditions:

- 1) Let  $Com^{dev_x} \subset COM$  be a set of communication interfaces installed on device  $dev_x$  and  $Com^{dev_y} \subset COM$  be a set of communication interfaces installed on device

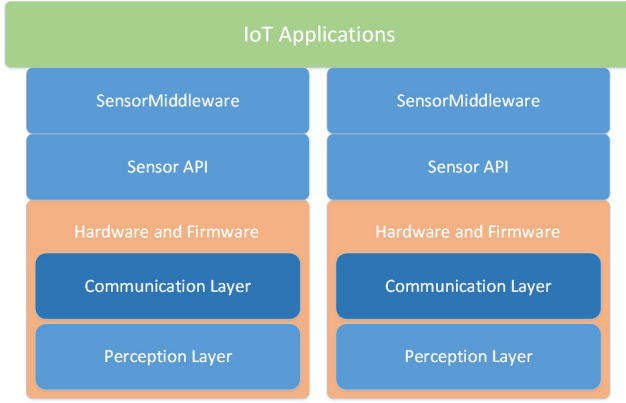

Fig. 5. Sensor's architecture

$dev_y$  then:

$$\exists_{com^{dev_x} \in Com^{dev_y}} \exists_{com^{dev_y} \in Com^{dev_x}} c_{com^{dev_x} com^{dev_y}} = 1; \quad (10)$$

$c_{com^{dev_x} com^{dev_y}}$  is an element of  $CMI$  matrix, defined as

$$CMI = [c_{ik}]_{|COM| \times |COM|}. \quad (11)$$

Where:

- $c_{ik} \in \{0, 1\}$  - defines interoperability of  $i$ -th and  $k$ -th communication interface. If  $c_{ik} = 1$  it means that  $Com_i$  and  $Com_k$  can cooperate with each other. In the opposite case they cannot.
- 2) Let  $l_{dev_x}^G(t) = \langle lat_x, lon_x, elv_x \rangle$  be a spatial (geographic) location of device  $dev_x$  at time  $t$  and  $l_{dev_y}^G(t) = \langle lat_y, lon_y, elv_y \rangle$  be a spatial (geographic) location of device  $dev_y$  at time  $t$ . Then:

$$d^G(l_{dev_x}^G(t), l_{dev_y}^G(t)) \leq \min(r(t)_{com^{dev_x}}, r(t)_{com^{dev_y}}) \quad (12)$$

Where:

- $r(t)_{com^{dev_x}}$  - radio range of the communication interface of the device  $dev_x$  which fulfills first condition.
- $r(t)_{com^{dev_y}}$  - radio range of the communication interface of the device  $dev_y$  which fulfills first condition.
- $d^G(l_{dev_x}^G(t), l_{dev_y}^G(t))$  - geographical distance between devices  $dev_x$  and  $dev_y$

SenseSim has idealistic communication model, because it is focused mainly on cognitive and behavioral aspects of the IoT devices. The simulated devices have multilayer architecture with three main layers (see Figure 5), which is currently standard approach [17] [18]:

- Hardware & Firmware,
- Sensor API,
- Sensor Middleware.

The first one consists of two other layers: Perception Layer, which is responsible for managing perceptual capabilities, and

Communication Layer, which is responsible for communication issues. The first layer, in the context of simulation, is artificial. On the top of the Hardware, the Sensor API is built. It is an interface which allows to manage the device's hardware from the outside. Our approach to the device's architecture is compliant with IEEE P2413 standard, which specify the Properties layer (in our case the Perception layer), the Information Exchange layer (in our case the Communication Layer) and the Function/Method layer (in our case decomposed into Sensor API and Sensor Middleware layers) [19]. From the point of view of the presented method the most important layer of this architecture is the middleware. To support the triage process we implemented the middleware capable of handling ontologies (especially the triage domain ontology) and infer among them. That makes each device an cognitive agent, which can monitor soldier vital signs using its sensors and understand the measured data. Each of the devices can also receive information need defined in infon logic, interpret it and give as precise as possible response.

Presented method was verified in simulation environment. The main goal of the experiments was to check if the method is suitable for distributed, heterogeneous sensor network system.

## B. Simulation results

Figure 6 shows initial state of the scenario simulated in *SenseSim*. The network has 15 devices which connect to each other using wireless channel. It is assumed that each device has the same communication capabilities and all messages are sent in peer-to-peer manner. Topology of the network is not strict and may change in time due to devices movement. Devices can communicate with each other as long as they stay within radio range. In this scenario maximum range is 200 m and bandwidth of the link is maximum 5 kbps. Devices use flooding routing algorithm for distributing messages. Flooding is not efficient algorithm, it generates a lot of network traffic and may cause redundant messages. On the other hand it gives high probability of message delivery, especially when network topology may change and devices have little or even no knowledge about it.

In this scenario it is assumed that each soldier has one personalised device with connected sensors. For simplicity one device has one of the following sensors attached:

- ECG sensor,
- Pulse oximeter sensor,
- Blood pressure sensor,
- Temperature sensor.

Devices can be interpreted as soldiers' personal computers like in future soldier systems i.e.: FIST [20], IdZ [21], TYTAN [22].

During scenario different information needs were sent into the network from device number 10, which can be considered as a team leader. Figure 7 shows example of information need processing. Device 10 sends at time 19,9 into the network question about the state of the Soldier\_3:

$$\llcorner? : ObjectState, Soldier\_3, 1 \gg \quad (13)$$

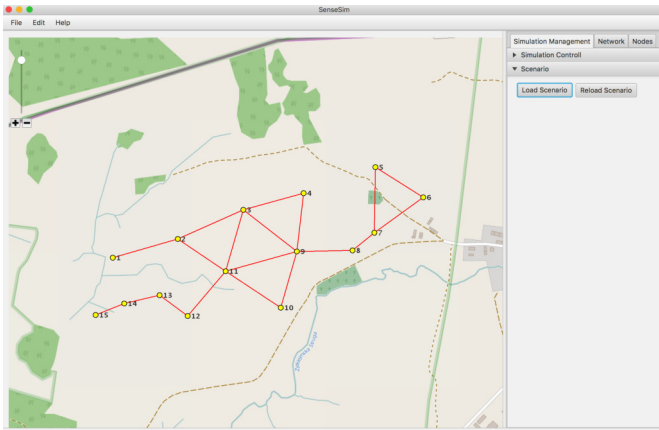

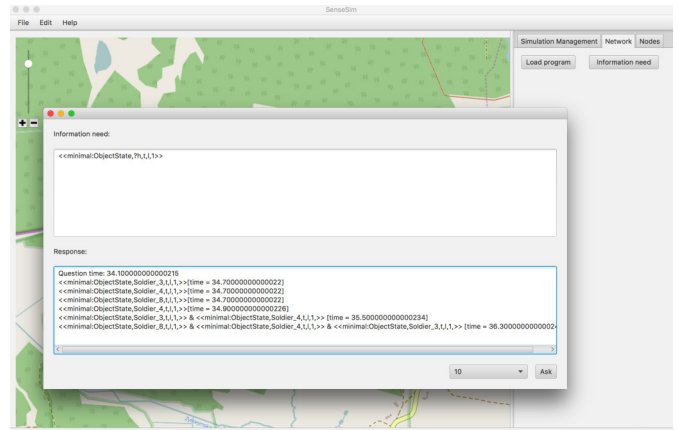

Fig. 6. Simulated network in *SenseSim*

Fig. 8. Example of question about soldiers who are in state minimal

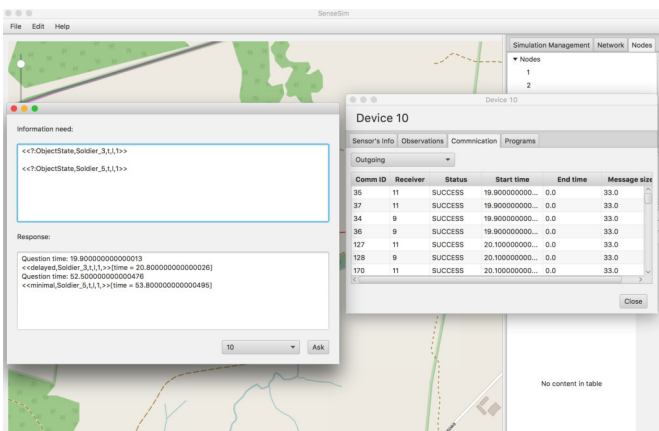

Fig. 7. Example of the question about the state of one soldier

Information need is distributed between devices using flooding algorithm. The role of each middleware is to interpret the need and check if the device can answer it. In this case only the middleware of the device number 3 can fulfil the need (because this device monitors Soldier\_3). Basing on ontology reasoning it comes to conclusion that the Soldier\_3 is in state *delayed*. After that device 3 sends response for the need:

$$\ll \text{delayed}, \text{Soldier}_3, 1 \gg . \quad (14)$$

It is received at time 20,8 by the asking device 10.

Figure 8 shows example of different need processing. In this case the network was asked to define which soldiers are in state *minimal treatment*. Information need was sent at time 34,1 and had the following form:

$$\ll \text{minimal} : \text{ObjectState}, ?h, 1 \gg \quad (15)$$

This question requires action from every device in the network, because each have to verify the state of monitored soldier and decide if he is in state *minimal treatment* or not. That is why fulfilling such need is a more complicated process than shown in earlier example. Response for the need circles

in the network and each device adds a part to it. Because of the flooding algorithm, the asking device also receives parts of the answer and at time 36,3 receives full answer:

$$\begin{aligned} &\ll \text{minimal}, \text{Soldier}_8, 1 \gg \\ &\& \ll \text{minimal}, \text{Soldier}_4, 1 \gg \\ &\& \ll \text{minimal}, \text{Soldier}_3, 1 \gg \end{aligned} \quad (16)$$

In every simulated scenario devices were able to answer the information need basing on its own knowledge about monitored objects (soldiers).

#### IV. CONCLUSION

In this paper a novel approach to supporting combat triage was presented. Currently developed solutions focus on supporting triage by providing ontology based expert systems [23] [24] or by providing dedicated triage sensors [25] [26]. The first approach gives first responder great support, but still requires a lot of resources and attention to monitor wounded continuously. The second approach is more automatic, but also less flexible. It requires that every wounded has the same sensor for health monitoring. If they are not available, manual work is needed. Our approach is more flexible. It does not need any additional infrastructure than sensors network. Also we do not close our method to particular sensors. In fact any sensor adequate for triage process can be used by our approach. Moreover we do not limit sensors only to wearable devices. Soldier's state may be evaluated also by nearby sensors, for instance those installed in vehicle. From the perspective of end user it is transparent.

Thanks to ontology reasoning and presented information framework, an expert knowledge is not required from first responders to carry out the triage process properly. Some vital signs registered by sensors, like ECG, may be hard to interpret without medical background, but there are methods for automatic processing and extracting valuable information. Moreover using IoT devices for triage, makes this process to become continuous with minimal manual effort.

**Abstract**—This article describes the use of the comparison method MM to protect the Internet user from the effects of DNS Injection attacks. A description of the basic concepts of this area of the computer network and the dangers of DNS Injection attacks is presented. The description of the MM method used in the literature is concluded. In the paper the concept of using above-mentioned method to protect Internet user from the effects of DNS Injection attacks and the initial design of the DNS server software including the diagnostic component are presented.

## I. INTRODUCTION

Domain Name System (DNS) is one of the most commonly used service over the Internet. It allows, among others, to connect to a web site using its mnemonic name (usually easier to remember) instead of its IP address. Converting a domain name to an IP address is done by a DNS server that, in most cases, is a separate host in the network. The DNS user does not have direct control over the server, which involves the risk of obtaining an incorrect name mapping from the server. Unfortunately, practice shows that there is a lack of universal way by which the user can make sure that the responses received from the DNS servers are reliable. Correct DNS performance is critical to the smooth operation and security of the Internet. The lack of entries in the DNS server records database may cause the network resources to be inaccessible, while erroneous entries may redirect network traffic to the incorrect location specified (and controlled) by the attacker [3].

This article focuses on protecting the Internet user from the effects of DNS Injection attacks – which relies on modification of the entries in the DNS server mapping tables [9]. Any Internet user who will be able to send false updates to the DNS server or detect and be able to exploit the vulnerabilities in the server software could be an attacker. Unlike traditional security systems (like firewalls, IDS/IPS), the proposed method is to detect the effects of an attack (not to protect against it).

## II. RELATED WORK

The proposed approach of protecting the Internet user against the effects of DNS Injection attacks attempts to use a comparative method known as the MM<sup>1</sup> method [6], [7]. In the literature there are works that use this method most often to diagnose a network of processors (with different logical structure). A. Arciuch in [1] presented the technical aspects of diagnosing a network of microprocessors with a mild type of degradation using the MM method, R. Kulesza and Z. Zieliński in [4] used this method to determine diagnostic insight of network of processors. A. Sengupta and A. T. Dabura in [8] proposed usage of the MM method in a self-diagnosing multiprocessor system, and G.Y. Chang, G.H. Chen and G.J. Chang in [2] used the MM<sup>\*2</sup> model to develop a sequential diagnosis of the processor network.

In this work it was decided to use a different approach and use the comparison method to diagnose DNS servers.

## III. PROPOSAL

This section is based on [4] and [5]. The MM method uses comparative graph as a way to represent the logical structure of nodes with the corresponding set of comparative tests. This concept (along with examples) is explained later in this article. In the area of the problem (mutual testing of DNS servers) an elementary comparative test will be sending by a comparator a DNS query to resolve a domain name to both nodes of a comparative pair. Then the comparator verifies that the obtained results - IP addresses - are identical. These type of checks will be performed periodically, every  $k^3$  queries, ensuring continuous DNS servers reliability without overloading the network.

A *fit* comparator will give the opinion that a comparative pair is fit (the result of comparative test will be equal to 0) if the results of the DNS query are identical. The different

<sup>1</sup>The name of the method comes from the names of the creators: M. Malek and J. Maeng.

<sup>2</sup>The MM\* model is characterized by the use of diagnostic structures consisting of all possible comparative tests, while the MM model uses a minimal number of comparative tests to detect  $t$  damaged network nodes.

<sup>3</sup> $k$  is an arbitrary value.

results of the DNS query will result in an opinion that the comparison pair is *unfit* (the result of the comparative test will be equal to 1), with at least one node from the comparative pair is compromised (it is not indicated which one). The opinion expressed by a suitable comparator is consistent with reality. An unfit comparator gives an opinion that is random and assumes a value of 0 or 1.

#### A. Significant features of the MM type comparative structure

Consider an exemplary logical structure of a network described by a connected common graph  $G=(E, U)$ . An example graph is shown in Fig. 1.

Fig 1. Sample graph representing the logical structure of network

The logical structure  $G$  corresponds to the set of all comparative tests denoted by  $\Psi(G)$ , and the single comparative test is denoted by  $\psi \in \Psi'$ ,  $\Psi' \subseteq \Psi(G)$ . For comparison test  $\psi$  exists a set of comparators labeled  $K(\psi)$  and a set of comparative pairs labeled  $P(\psi)$ . The set of nodes involved in the comparative test  $\psi$  is labeled  $E(\psi)$ . A single comparative test is shown in Fig. 2.

Fig 2. Illustration of single comparative test

In a comparative test the comparator  $e_k \in E(G)$  orders the comparative pair  $e_i, e_j \in E(G)$  the same task and checks if the results are identical.

The comparative test is denoted by  $(e_k; e_i, e_j)$ . The result of the comparative test  $d((e_k; e_i, e_j))$  is equal to:

$$d((e_k; e_i, e_j)) = \begin{cases} 0 & \text{for } [n(e_k)=0 \wedge r(e_i|e_k)=r(e_j|e_k)] & \text{case a)} \\ 1 & \text{for } [n(e_k) \wedge r(e_i|e_k) \neq r(e_j|e_k)] & \text{case b)} \\ x \in [0,1] & \text{for } n(e_k)=1 & \text{case c)} \end{cases} \quad (1)$$

where  $n(e_k)$  is functional reliability of node  $e_k$  and  $r(e_j|e_k)$  is the result of a task ordered by node  $e_k$  and executed by node  $e$ .

In the area of the problem in *case c)*, unlike the classic MM model, the unfitness of the DNS server that is the comparator has no impact on the outcome of the test it performs. During the comparison, the comparator verifies the mutual compatibility of the results obtained from the nodes

of the comparative pair. These results are not matched with the entries of the DNS server records database, so even if it had been compromised (as a result of a DNS Injection attack), name mappings in its database would not affect the accuracy of the opinion. The interpretation of diagnosis results is presented in Table I.

TABLE I.  
THE DIAGNOSIS RESULTS INTERPRETATION IN PROPOSED METHOD

$n(e_k)$	$n(e_i)$	$n(e_j)$	$d((e_k; e_i, e_j))$
x	0	0	0
	0	1	1
	1	0	1
	1	1	1

**Definition 1.** [10] The computer network described by the structure  $G$  is defined as *single-step  $t$ -diagnosable* by a set of comparative tests  $\Psi' \subseteq \Psi(G)$ , if each pair of sets  $E'$  and  $E''$  of unfit nodes such that  $|E'| \leq t$  and  $|E''| \leq t$  is distinguishable by at least one comparative test  $\psi \in \Psi'$ .

**Definition 2.** [10] *Comparative graph* of computer network described by the structure  $G$  for a set of comparative tests  $\Psi' \subseteq \Psi(G)$ , is called such ordinary graph  $\hat{G}(G, \Psi') = (E(G), U(G, \Psi'))$  with labeled edges that  $[(e', e'') \in U(G, \Psi')] \leftrightarrow [\exists \psi \in \Psi' : P(\psi) = \{e', e''\}]$ , where the label of the  $(e', e'')$  edge is  $K(\psi)$ .

**Property 1.** [4], [6] The necessary condition for graph  $G$  to be  $t$ -diagnosable by the set of comparative tests  $\Psi' \subseteq \Psi(G)$  is to fulfill the dependence:

$$(|E(G)| \geq \max\{t+3, 2 \cdot t+1\}) \wedge (\forall_{e \in E(G)} : \mu(e) \geq t) \quad (2)$$

where  $\mu(e)$  denotes the input degree of the node  $e$ .

**Property 2.** [6] The structure is  $t$ -diagnosable by the comparative tests  $\Psi' \subseteq \Psi(G)$  if and only if for every pair of subsets of nodes  $E_1, E_2 \subseteq E(G)$  such that  $E_1 \neq E_2$  and  $|E_1| = |E_2| = t$  one of the following conditions is true:

$$\begin{aligned} \text{a) } & \exists_{\psi' \in \Psi'(G)} : \left[ \left( [K(\psi'), K(\psi'')] \cap [E_1 \cup E_2] = \emptyset \right) \wedge \right. \\ & \left. \wedge \left( [P(\psi') \cap [E_1 \setminus E_2]] = 1 \right) \vee \left( [P(\psi'') \cap [E_2 \setminus E_1]] = 1 \right) \right] \end{aligned} \quad (3)$$

$$\text{b) } \exists_{\psi' \in \Psi'(G)} : \left[ [P(\psi') \cap [E_1 \setminus E_2]] = 2 \right] \wedge \left[ [P(\psi') \cap [E_1 \cup E_2]] = \emptyset \right] \quad (4)$$

$$\text{c) } \exists_{\psi' \in \Psi'(G)} : \left[ [P(\psi') \cap [E_2 \setminus E_1]] = 2 \right] \wedge \left[ [P(\psi') \cap [E_1 \cup E_2]] = \emptyset \right] \quad (5)$$

#### B. Method of identifying unfit servers

The results of the comparative tests conducted in one diagnostic session will create so-called *the global syndrome*. Each server has in its resources reference values determining the reliability of servers participating in performed diagnostic session using the indicated diagnostic structure. These reference values are different for each diagnostic structure and are defined as *the pattern of syndromes*. The example of the pattern of syndromes for diagnostic structure presented later in Fig. 5. is presented in Table II. Single

value (row in example Table II) is often defined as *pattern syndrome*<sup>4</sup>.

TABLE II.  
THE EXAMPLE OF THE PATTERN OF SYNDROMES

$i$					1	2	3	4	5	6	7	8
$K(\psi_i)$					1	1	2	2	3	3	4	4
$P(\psi_i)$					2	2	3	3	4	4	1	1
					4	3	1	4	2	1	3	2
$e$	1	2	3	4	$d(\psi_i)$							
$n(e)$												
0	0	0	0	0	0	0	0	0	0	0	0	0
0	0	0	1	1	1	0	0	1	1	1	0	0
0	0	1	0	0	0	1	1	1	0	0	1	0
0	1	0	0	0	1	1	0	0	1	0	0	1
1	0	0	0	0	0	0	1	0	0	1	1	1

Each server after building the global syndrome will attempt to match it to one of the pattern syndromes. After a positive match, it will be possible to indicate the reliability status of the tested DNS servers.

### C. Requirements for the developed method

An unauthorized change of even one record in the DNS server records database creates a threat to users which are communicating with the node whose entry was modified. Such conclusion can be derived on the basis of the analysis of the impact of attacks described, among others in [9].

It is required that the method will be able to detect a specified number of compromised DNS servers in the network environment (defined as  $t$ ). The mechanism of action consists in mutual testing of DNS servers by sending the response to the DNS query. The number of required comparisons depends on the number of unfit nodes to be detected. The collected responses will be evaluated, which will allow to determine which of them are invalid and indirectly to make it possible to indicate the unfit DNS servers.

The article focuses on the prevention and protection of the user against the considered type of attacks. The results of the comparisons that are sent to the client computer will allow him to use only those DNS servers that have been identified as fit. It is assumed that the developed method will be able to detect DNS servers successfully exploited by DNS Injection.

The diagnostic software that would use the developed method would extend the DNS server architecture. Working in the background, it would regularly examine the suitability of DNS servers while informing the DNS client about the results of the tests. The preliminary scheme of the DNS server diagnostics software is shown in Fig. 3. It is assumed that the software will carry out two main tasks:

- sending DNS queries for indicated domain and receiving replies,
- group replies and base on them conclude the reliability of DNS servers participating in the test.

The initial class scheme of the DNS server after adding the diagnostic module is shown in Fig. 4.

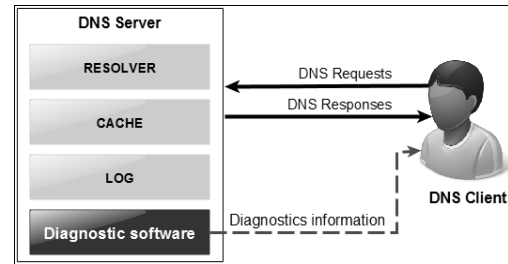

Fig 3. Architecture diagram of the DNS servers diagnostics software

Fig 4. Initial Class scheme of the DNS servers diagnostics software

### D. Description of the developed method

The proposal of protecting the Internet user, developed within this article, is supposed to fulfill the requirements mentioned in sections B. and C.. In addition, the following assumptions must be met.

1. The comparative test consists of three DNS servers: one being a comparator (denoted as  $K(\psi)$ ), the other being a comparative pair (denoted as  $P(\psi)$ ).
2. Comparing the response pairs from the DNS servers to the DNS query sent by the comparator will be understood as a *test*.

The logical structure of the network of tested nodes can be described by connected common graph  $G=(E, U)$ . The developed method of protecting the Internet user is based on the  $t$ -diagnosable (by comparison set  $\Psi' \subseteq \Psi(G)$ ) comparative graph  $\hat{G}(G, \Psi')$  which fulfills the necessary and sufficient conditions for the MM method (dependencies (2)-(5) presented in section A.). These dependencies guarantee a suitable comparative graph as a diagnostic structure. Except for the number of nodes participating in the comparison and the appropriate number of comparisons completed (which is forced by the Property 1 described in section A.), mentioned comparisons must involve the appropriate nodes to determine the fitness of the DNS servers (which is forced by the Property 2 described in section A.).

From the Definition 1 of the  $t$ -diagnosable MM structure it follows that if each of the nodes has  $t$  comparative tests with different nodes and is judged by different comparators, then

<sup>4</sup>The notions: *the global syndrome*, *pattern syndrome* and *the pattern of syndromes* are well defined in [4].

such structure is  $t$ -diagnosable. Thus, it is possible to propose a comparative graph for the graphical structure shown in Fig. 1, represented by the graph  $\hat{G}(G, \Psi')$  shown in Fig. 5.

Fig 5. Comparative graph  $\hat{G}(G, \Psi')$  corresponding to the optimal diagnostic structure  $(G, \Psi')$

The node in the graph  $\hat{G}(G, \Psi')$  corresponds to the DNS server. From the set of comparative tests  $\Psi'$  the individual comparative tests  $\psi_i$  ( $i \in \{1, 2, \dots, |\Psi'|\}$ ) are designated. The algorithm for diagnosing network of DNS servers (implemented by each server) is shown below in the pseudocode<sup>5</sup>.

```

for each  $\psi_i \in \Psi'$  do
  if  $server = K(\psi_i)$ 
    Send to  $P(\psi_i)$ : DNS query for host "xyz";
    Collect responses from  $P(\psi_i)$ ;
     $d(\psi_i) := \text{Result of comparison responses from } P(\psi_i)$ ;
  do
     $TMP\_Global\_Syndrome[\psi_i] := d(\psi_i)$ ;
    Send  $TMP\_Global\_Syndrome$  to all DNS servers in diagnostic structure;
  else Send to  $K(\psi_i)$ : Response to DNS query for host "xyz" from  $K(\psi_i)$ ;
end
Collect  $TMP\_Global\_Syndrome$  from all servers;
Build  $Global\_Syndrome$ ;
Decode  $Global\_Syndrome$  and identify which server is unfit;
Send  $List\_of\_unfit\_servers$  to client;

```

The DNS server which is the comparator in the  $i$  test (denoted by  $K(\psi_i)$ ) sends to the nodes of the comparative pair (denoted by  $P(\psi_i)$ ) the DNS query for the domain name for example: *wat.edu.pl*. Servers of the comparison pair answers with the IP address which they have stored in their records databases. Next the comparator compares the responses according to the dependence (1) and the result of the comparative test (denoted by  $d(\psi_i)$ ) is passed to each DNS server. All comparative tests form diagnostic structure are performed as described. Then, on the basis of the results of the tests, identification of unfit nodes takes place according to identification method described in section B.. The end user is informed which DNS servers were indicated as unfit - a so-called *black list of DNS servers* is created which are not used for resolving domain names. As a result, the user only uses the servers that are diagnosed as fit it means that those which can be trusted.

#### IV. SUMMARY

This article proposes a method of protecting the Internet user from the effects of DNS Injection attacks. The proposed

method uses the comparative tests - MM model. Based on the diagnostic structure described by comparative graph, comparative tests are carried out involving three nodes (DNS servers). One is a comparator and the other two are comparative pair. The results of the comparative tests are complemented by DNS servers and unfit nodes are indicated based on the mentioned results. The user is given a list (in for example DNS TXT record) of unfit (untrusted) servers that he or she should not use to resolve domain names. The developed solution can be customized for use in a DNS client environment who itself (as a reliable core) will compare the results from the DNS servers and determine which nodes are unfit.

A number of laboratory experiments were performed in order to confirm the effectiveness of the developed method. In a prepared computer network with suitable number of DNS servers correctness of the method was verified. Servers were "attacked" in random order, resulting the invalid responses to the DNS queries. Then, in such prepared lab environment, diagnostic software implementing proposed method was executed. The obtained results were comparable with the actual state of the laboratory network, which allows me to conclude about the practical application of the developed method. The obtained results provide the basis for developing a more accurate test environment and conducting a series of experiments for example including checking whether the network topology affects the diagnostic results.

# 6<sup>th</sup> International Conference on Wireless Sensor Networks

A FEW years ago, the applications of WSN were rather an interesting example than a powerful technology. Nowadays, this technology attracts still more and more scientific audience. Theoretical works from the past, where WSN principles were investigated, grew into attention-grabbing applications practically integrated by this time in a real life. It could be said, that countless application fields, from military to healthcare, are already covered by WSN. Together with this technology expansion, still new and new tasks and interesting problems are arising. Simultaneously, such application actions stimulate the progress of WSN theory that at the same time unlocks new application possibilities. The typical examples are developments within the “Internet-of-Things” field as well as advancements in eHealth domain with WBAN IEEE 802.15.6 standard progress.

## TOPICS

Original contributions, not currently under review to another journal or conference, are solicited in relevant areas including, but not limited to, the following:

Development of sensor nodes and networks

- Sensor Circuits and Sensor devices – HW
- Applications and Programming of Sensor Network – SW
- Architectures, Protocols and Algorithms of Sensor Network
- Modeling and Simulation of WSN behavior
- Operating systems

Problems dealt in the process of WSN development

- Distributed data processing
- Communication/Standardization of communication protocols
- Time synchronization of sensor network components
- Distribution and auto-localization of sensor network components
- WSN life-time/energy requirements/energy harvesting
- Reliability, Services, QoS and Fault Tolerance in Sensor Networks
- Security and Monitoring of Sensor Networks
- Legal and ethical aspects related to the integration of sensor networks

Applications of WSN

- Military
- Health-care
- Environment monitoring
- Transportation & Infrastructure
- Precision agriculture

- Industry application
- Security systems and Surveillance
- Home automation
- Entertainment – integration of WSN into the social networks
- Other interesting applications

□

**Abstract**—This paper aims to provide an image on the usability of low power, short distance standard communications technologies for specific applications, like messaging, in cooperative collision avoidance or emergency vehicles guidance. Specific measurements regarding communications interferences and density have been performed in representative road junctions in Bucharest and the results were used to determine modalities for employing this type of communications for such applications.

## I. INTRODUCTION

WIRELESS communications are the backbone of many applications in transports, ensuring proper data transfer between different equipment related to traffic management, travel information etc. Moreover, these days critical applications like collision warning systems and route guidance for emergency vehicles use wireless communications to send valuable information onboard selected vehicles. Most part of wireless communications that are being used are those for short & medium distance, Bluetooth (BT) and Wi-Fi appearing to be the most commonly used. The main issue is they share same frequency bands, which makes the communications interfere with each other. In the literature, many studies regarding this aspect can be found (like [1], [2], [3]), revealing interferences that occur in different scenarios. However, in proper conditions, Bluetooth and Wi-Fi are the cheapest solution for communication and, hence, the first choice.

One convenient feature is the capability of Bluetooth and Wi-Fi devices to send general data, regardless of their connection to an access point (AP) or another device. This data may be used to determine the density of communications in a specific area or on a specific route, and the radio frequency signal power. This information may be then used to determine the feasibility of a communication technique in specific points or areas in the city or outside of it.

□ This work has been funded by University Politehnica of Bucharest, through the “Excellence Research Grants” Program, UPB – GEX. Identifier: UPB-EXCELENȚĂ-2016 Research project title “VEHINET – Rețea cu conținut informațional adaptiv la condițiile mediului destinată deplasării inteligente a vehiculelor”, Contract number 45/26.09.2016 (acronym: VEHINET).

To search for solutions to a common use of BT and Wi-Fi without critical interferences, a series of measurements have been made in different sites and junctions in Bucharest city, scanning for Wi-Fi communications. The goal was to determine the possibility of implementing another wireless communication technology that would not be affected by these interferences.

## II. WIRELESS COMMUNICATIONS BASICS

BT and Wi-Fi devices use the same frequencies to communicate. Such links between the transmitter and the receiver of a specific technology might, therefore, be perturbed by another transmission from the other technology. Moreover, the time to transfer a specific length message may, in this case, increase significantly. This is of crucial importance especially for critical messaging in vehicular communication, if a communication point is located on a vehicle traveling with speed  $s$ , and the other communication point is either fixed or mobile, then the time the two devices may be in range for communicating is limited. Beside the classic Wi-Fi access points, or communicating devices, there is a set of other electromagnetic devices that may cause interference: microwave ovens, cables associated with satellite receivers, power lines, cordless telephones etc. From the 2.4 GHz and 5 GHz bands, the most crowded with communicating devices is the 2.4 GHz band. In [4], Baccour et al. notes that, from another point of view, interferences might be classified as internal (generated by communicating nodes belonging to the same appliance) or external (generated by sources from exterior). The authors wrote that “The primary outcome of interference is an increase in the packet loss rate, and it is in turn often followed by an increase in the network traffic due to retransmissions, as well as by a decrease in the performance and efficiency of the overall network”.

In a context of a low power communicating nodes, external interference may be caused by devices operating in the same frequency range (from other technology), but employing higher transmission powers and thus creating interferences.

The IEEE 802.15.1 (BT) standard specifies 79 channels, spaced 1 MHz, in the range 2402–2480 MHz, with center frequency  $F_c = 2402 + k$ , with  $0 \leq k \leq 78$ . Bluetooth uses the Frequency Hopping Spread Spectrum (FHSS) technology to combat interference and fading: it hops 1600 times per second, and therefore it remains at most 625  $\mu$ s in the same channel. Given that only 79 channels are available, on average, one channel is used approximately 20 times each second: this makes interference generated by Bluetooth devices uniformly distributed across the whole 2.4 GHz band.

The Wi-Fi standard uses 2 bands divided into channels: the 2.4 GHz band (2400–2483.5 MHz), for example, is divided into up to 14 2.2 Crowded Spectrum 27 channels, 2 each of which having a bandwidth of 22 MHz. The standard evolved significantly in the last decade (the first version was released in 1997), with data rates increasing from the original 2 Mbit/s to the 11 Mbit/s of 802.11b (1999), 54 Mbit/s of 802.11g (2003), up to the 150 Mbit/s of 802.11n (2009); and it is still undergoing changes, with the new high-throughput 802.11ac protocol currently under development. Several works in the literature investigate the impact of IEEE 802.11 communications on the reliability of IEEE 802.15.4 transmissions, and show that wireless sensor networks suffer from high packet loss rates in the presence of Wi-Fi interference.

In [5], Marina Petrova et al. performed a set of measurements to examine the interference of IEEE 802.11g/n on IEEE 802.15.4 devices. The authors concluded that in an environment with a middle or high IEEE 802.11n traffic load it is very difficult to guarantee the quality of the nearby operating IEEE 802.15.4 based communicating nodes. Also, even outside of the operating channel the IEEE 802.11n power is high enough to seriously interfere the IEEE 802.15.4 channels. Some authors also propose techniques to tolerate external interferences [6]. In [4] a taxonomy for external interference mitigation techniques is described (Fig. 1).

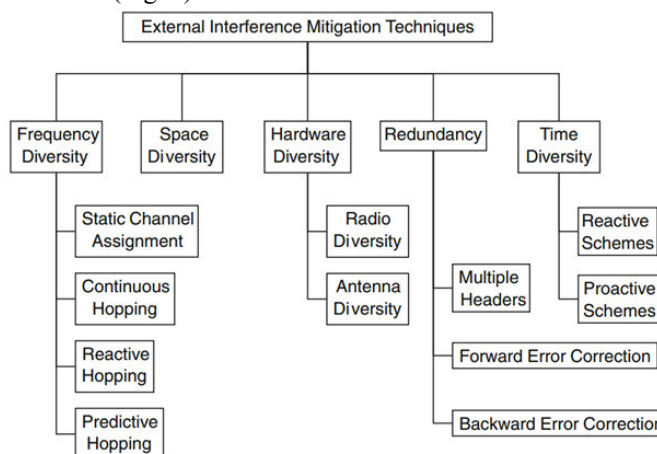

Fig. 1. A taxonomy proposed from literature study for external interference mitigation techniques (source: [4])

Shuaib et al. in [7] show that is necessary to distinguish between uplink and downlink when interference occurs. There are two kinds of devices for IEEE 802.11: access points and terminals. The packets transmission from terminal to access point is defined as “uplink”, while the reverse is denoted “downlink”. This idea might be useful in traffic information, with systems employing anonymous detection of vehicles, where only “listening” to traffic between passing BT and/or Wi-Fi nodes (vehicles equipped with such technologies) is used to collect information regarding traffic, speed, heading etc. Of course, special filtering and statistics is to be used for obtaining final information regarding traffic. However, in some situations there is no need for very accurate information regarding traffic flow or density (such examples may include: environmental protection techniques of traffic regulation, global information for traffic participants etc.).

Interference may also lead to unpredictable medium access contention times and high latencies, which are also important issues for vehicular communication of critical messages, where guaranteeing high packet delivery rates and limited delay bounds is necessary, and where unreliable connections cannot be tolerated. One reason for this is that vehicles and roadside communicating nodes are not in range for too long. Therefore, the applications in this case should take care of interferences, QoS, and allocate critical messages on less disturbed channels or communication media.

In [8], Hauer, J.H. et al. present the spectrum usage of the above two standards, showing that despite interference mitigation mechanisms like DSSS (Direct Sequence Spread-Spectrum) and “listen-before send” incorporated in both standards, it is well established that their mutual interference can result in notable deterioration of packet delivery performance.

The authors also noticed that in the urban environments transmission failures sometimes span over multiple consecutive 802.15.4 channels, are often correlated in time and substantial losses are typically accompanied by an increase in the noise floor. This suggests that external interference, in particular where there is the omnipresent WLAN and channels are overlapping (Fig. 2), can be a major cause for substantial packet loss in IEEE 802.15.4 vehicular area networks.

Fig. 2. IEEE 802.15.4 and 802.11 frequencies in the 2.4 GHz ISM band (source: [8])

From the above-mentioned tests, it may be concluded that Wi-Fi communications (which may be found in almost every point of an urban road network) produce noise with a negative influence on other wireless communications that might be implemented in the area with the purpose of supporting Intelligent Transport Systems. Therefore, it seems that a major step in introducing a new communication system (regardless of the solution), is to scan the environment for other communications that are already in place and are being impossible to control (e.g. Wi-Fi access points from companies located near the road junctions or bus stops). Such tests may offer an image of the RF environment and provide a proper support for the analysis that will conclude the best new communication technology that may be used for future applications.

### III. WI-FI COVERAGE – FIELD MEASUREMENTS

To have some knowledge about the Wi-Fi spectrum coverage that may be found in different junctions in dense urban area, a series of tests have been performed in several junctions in Bucharest city (the largest city in Romania). Highly congested junctions have been chosen near blocks of flats, or company buildings and communications density in these areas has been analysed. As Wi-Fi can send anonymous data that can be identified, Wi-Fi Analyzer application for mobile phones have been chosen, capable of detecting and providing information on Wi-Fi devices in the area. Both frequency bands (2.4 GHz and 5 GHz) have been scanned. However, the data obtained for the 5 GHz frequency band is for the moment considered irrelevant, as few communications of this type were detected. The information was obtained as graphs and lists, as presented in Fig. 3 and Fig. 4.

Fig. 4. Example of Wi-Fi data obtained as a detailed list

In the following, the data obtained in three road junctions, in four time intervals will be presented. It is considered relevant to take into account the total number of devices for each Wi-Fi channel, differentiated where possible in 20 MHz and 40 MHz wide channels, along with the density of Wi-Fi communications on each channel. Afterwards, the maximum signal power for each channel will be presented, as an average for the whole period when measurements took place. The lowest power of -100 was considered for the channels with no communication detected. For convenience, road junctions were named J1 – J4.

In Fig. 5 it is noted that the general theory that Wi-Fi channels 1, 6, and 11 are the most used ones [6], [9] is confirmed in real life measurements - this is because they are non-overlapping.

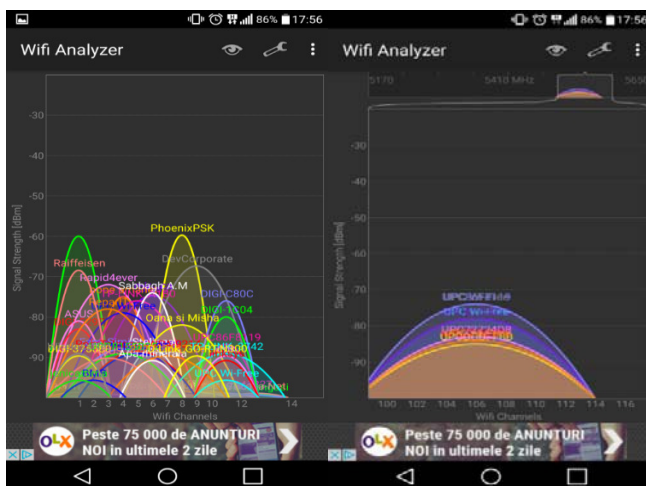

Fig. 3. Example of Wi-Fi data obtained for 2.4 GHz and 5GHz frequency bands

Fig. 5. Average number of devices for each Wi-Fi channel

Fig. 6. Average maximum power for each Wi-Fi channel

Fig. 6 presents a comparison for average maximum signal power detected for each channel in each road junction.

Maximum signal power for each junction is provided for each Wi-Fi channel, and the average for all 4 data sets is calculated and represented.

#### IV. CONCLUSION

From the tests performed it can be concluded that indeed, Wi-Fi channels 1, 6, and 11 are the most used. This fact has influence mainly on Bluetooth communications, that use three advertising channels overlapping Wi-Fi channels 1 and 6. Therefore, the implementation of new communications in the proximity of road areas must also consider the existing technologies, besides the application goal, in order to be able to provide a reliable data transfer. Dynamic channel allocation is recommendable for critical applications that do not accept message delaying. Therefore, the involved communication equipment and related protocol should be able to "listen" to all channels before deciding which is best suitable for a specific threshold accepted for the quality of service (message delaying and packet loss). Another solution for specific vehicular applications might be the installation of a roadside unit able to perform these operations (in a RF noisy environment), with the ability to collect information regarding the most crowded frequencies, then to compose a broadcast message recommending the best channels to communicating devices.

In the next period, field measurements will be performed to determine the density of Wi-Fi and BT communications over a determined sector of road (the average number of communicating nodes over a determined distance). Also, another goal is to determine the number of fixed communicating nodes over mobile ones' ratio. This information might be useful in conceiving new communication protocols, aware of the RF environment and more protective regarding message delaying in critical vehicular applications.

Also, it is in the authors' intention to perform Bluetooth and ZigBee data transfer tests in previously tested road junctions, to evaluate and quantify also the influence of Wi-Fi over other wireless data transfer technologies.
